siderable portion of the rectum is obliterated I believe the prognosis for the future life of the child is unfavorable. I do not think that life is worth living which is dependent upon constant dilatation of a congenital stricture of the rectum. It is quite different, however, in those cases where the orifice is closed by a thin layer of skin and mucous membrane. In such it is quite practicable to stitch the mucous membrane of the rectum to the skin and to have no after-trouble from the congenital deformity. In those rare forms of congenital malformation where it is necessary to open the intestine in the groin or in the back, after the method of Littré, or by the classical operation of lumbar colotomy, recovery is even less desirable.

Dr. Conant's very brilliant case has interested me greatly, and his method in the emergency seems to me a distinct contribution to the literature of the subject. At birth, few children have the strength to survive the combined operations of laparotomy and attempts at restoring the canal from below. We get by this method, nevertheless, a most excellent idea of the congenital condition, and we are enabled thereby to operate understandingly where otherwise we should be groping about in great obscurity. I have felt the uncertainty of establishing communication between the distended rectum and the anus even in simple cases. My method has been to put in an aspirating needle of considerable size until meconium escapes, then to dilate this opening, after enlarging with the straight, probe-pointed bistoury. Once having got the finger into the rectum, the subsequent manipulations are quite simple. Where the obstruction is up more than an inch or two, it seems to me impracticable and unwise to attempt a union of the mucous membrane with the skin. Yet if this is not done, we must anticipate a chronic stricture which will require constant dilatation. Two or three such cases in my experience have proved fatal, and as I could not have an autopsy I have been unable to tell exactly the cause of death. It has occurred to me that in some cases there may have been an extravasation of meconium, possibly through a diverticulum of peritoneum, where the needle had gone through the recto-vesical pouch, and there has been extravasation. It is impossible to say, however, that this has been the case. It is much more probable that the child died from the combined shock of the congenital condition and the surgical efforts to relieve it.

An unusual form of congenital malformation came under my observation this summer in a girl six or eight months of age, who was born with a communication between the vagina and the rectum. I examined the case very carefully, and had it under observation for some weeks. There was a dimple at the place where the anus should be. Just inside the ostium vaginae there was an opening about a quarter of an inch in diameter from which the faeces escaped from time to time. The case seemed a very simple one previous to the exploration, for it was very evident, apparently, that it consisted simply of a communication between the rectum and the vagina. After etherization and exploration I found that there was apparently no uterus, that the communication led into a blind pouch somewhere in the region of the margin of the pelvis on the left. On dilating the vaginal opening sufficiently to explore, I found that the rectum or the sigmoid flexure communicated with the vagina about opposite the opening of this cul-de-sac. The condition of things

¹ See page 287 of the Journal.

could be ascertained only approximately, but there seemed to be apparently a double bowel, the one toward the left ending in a blind pouch and the other toward the right being the ordinary sigmoid flexure. The opening was found to be near the fundus of the vagina, where the os uteri should be. No uterus could be felt, nor was there any sign of a cervix or os. The rectum was obliterated from the intero-rectal fold to the anus. It was obvious that nothing could be done to relieve this condition and that the child's vagina would always have to be a part of the rectum. After dilating the vaginal opening, the child was sent home, to remain under the observation of her physician with directions to keep the opening patent by occasional dilatation.

DR. C. W. TOWNSEND said he had seen several cases of imperforate rectum in the Clinic of the Boston Lying-in Hospital, and he had found seven cases in the records of the hospital out of 5,500 cases, a proportion of a little over one-tenth of one per cent. Another case is recorded among the out-patients. Five of these cases were operated on, all at the Massachusetts General Hospital, with one recovery; two died without operation, and one was still-born. Three of these cases were operated on on the second day, including the one that recovered; two were operated on on the third day. In one case the lower end of the gut was sutured to the blind rectal pouch and the partition between the two was then incised and dilated. In all the other cases including the one case that recovered the operation consisted simply in passing a trocar and dilating.

Dr. Townsend remembered especially a case operated on by Dr. Cabot in 1886. There was a normal anus with a blind anal pouch nearly an inch deep. The lower end of the gut above could be felt through the anal pouch, and a trocar was passed giving vent to meconium. The opening was then dilated, but no more meconium appeared, and the patient died in four days. The reasons for this were clearly shown at the autopsy made by Dr. Townsend. The inner end of the anal pouch was separated from the rest of the gut by a slight fibrous cord about an inch in length. The gut above being distended, pushed down on the anal pouch so that the trocar easily pierced it. As soon as some of the meconium was evacuated the gut returned to its normal position, an inch distant from the end of the anal pouch, on which alone was the force of dilatation expended, leaving the gut above unrelieved except by a trocar puncture through which meconium escaped into the surrounding tissues.

A ninth case occurred in the obstetrical department of the Boston Dispensary. Here, when the baby was nearly moribund, Dr. Reynolds did Littré's operation, but death soon occurred.

In speaking of a projecting fold or valve in the rectum, the reader called to mind a case seen by Dr. Townsend only after death on the third day. An out-patient of the Lying-in Hospital, where all the symptoms of imperforate rectum had been present, namely, non-passage of meconium, distension and tympanites, and vomiting; on making the autopsy nothing could be found in the way of intussusception or congenital occlusion of the bowels, but a distinct valve-like fold existed about two inches from the anus, which allowed easy passage of the finger up from below but which had apparently effectually blocked the passage of faeces from above.

The kindred subject of imperforate urethra he would like to mention here merely to say he had never seen a case and none are recorded in the books of the Boston Lying-in Hospital. The externees of the hospital frequently think they have such cases, and report that no urine has been passed for twenty-four hours since birth. Of course, the observation may be defective in many of these cases, but Dr. Townsend believes that it is not a very rare thing for infants to pass water unnoticed during birth and then not to empty their bladders for twenty-four hours. He had seen cases where the meatus of the male child appeared to be lacking, having his attention called by the anxious exerne, and found that the lips of the meatus were simply stuck together, not sufficiently so, however, to prevent micturition.

Dr. Townsend had within a few days seen a young woman of twenty-one years in the Massachusetts General Hospital Out-patient Clinic, where the rectum opened out, inside the posterior commissure of the vulva, an anomaly unrecognized by the owner thereof.

DR. M. H. RICHARDSON showed some

GALL-STONES,

and reported briefly a case in which they were removed from the common duct.

Recent Literature.

Denmark: Its Medical Organization, Hygiene, and Demography, pp. 473. Copenhagen, 1891.

At the Second International Congress of Hygiene, which was held at Brussels in 1876, a series of papers was presented in the French language, upon the same subject as the present volume. This new volume (published in English) treats more completely of the sanitary progress of that country during the past fifteen years. It was prepared by a large corps of editors, many of whom are officers of the Danish government, or of the city of Copenhagen, and submitted to the recent Congress of Hygiene at London.

The first sixty pages are devoted to the medical organization of the country, civil, military and naval; forensic medicine, medical education, dentistry, pharmacy, midwifery and veterinary practice, each is treated in a brief chapter.

The chief portion of the volume is devoted to public hygiene, and the principal topics treated in this section are, general sanitary measures, such as water-supply, house ventilation and heating, lighting, sewerage, disposal of the dead (a crematory was built in 1886, but this process of disposal was soon declared illegal by the government).

Other chapters relate to food inspection, house inspection, and the hygiene of schools, factories, prisons and hospitals, poor-laws, first aid in cases of accident or sickness, nursing, quarantine and the control of infectious diseases, public baths and the abuse of alcohol.

The section upon the dwellings of the working-classes shows that much attention has been paid to this subject. The Classen Trust Fund was created at the close of the war of 1864, to give homes to people from the provinces who had taken refuge in Copenhagen. It provides 380 small tenements, one-third having single rooms and kitchen, and two-thirds hav-

ing two rooms and kitchen. The rents are very low, and the returns hardly one per cent. per annum.

Several working-men's building societies are also in successful operation, furnishing homes of two to four rooms each, both in Copenhagen and in the smaller cities. The Danish Society for the aid of the crippled and deformed is a well-organized society, established by a philanthropic clergyman in 1872. It maintains a polyclinic and a manual training-school, in which many ingenious devices are introduced to aid paralytics, single-handed persons and others in pursuing industrial employments.

The last section of the book is devoted to statistical information, including the usual matters pertaining to registration, the census of the blind, deaf and dumb, insane and imbeciles. The population of the kingdom, including that of Iceland, Greenland, and the Danish West Indies is at present nearly identical in numbers with that of Massachusetts. The increase since 1840 has been about one per cent. annually. The death-rate (1880-90) was 18.7.

Surgical Anatomy for Students. By A. MARMADUKE SHEILD, M.B., Cantab., F.R.C.S., Senior Assistant Surgeon, Aural Surgeon, and Teacher of Operative Surgery, Charing Cross Hospital. New York: D. Appleton & Company. 1891.

This book is intended for students to use with the living model, and is the substance of a series of demonstrations delivered by the author to students in course of preparation for examinations. It does not pretend to be a complete work on surgical anatomy; but considers the various anatomical regions, such as the head and face, the neck, abdomen, etc. It is reliable, and is more readable than "Holden's Landmarks." Though the book is addressed to students, it can be read with benefit by all operating surgeons. The book is filled with practical suggestions in the application of anatomy to surgical work.

Practical Intestinal Surgery. By FRED B. ROBINSON, B.S., M.D., Professor of Anatomy and Clinical Surgery, Toledo Medical College, Toledo, O. In two volumes. The Physicians' Leisure Library, Detroit, Mich.: George S. Davis. 1891.

To any one engaged in abdominal surgery the experiments recorded in these two little volumes will be of interest. They are not written in an attractive style, but are faithful presentations of much interesting work.

Hospitals and Asylums of the World: Their Origin, History, Construction, Administration, Management and Legislation. With plans of the chief medical institutions accurately drawn to a uniform scale, in addition to those of all the hospitals of London in the Jubilee year of Queen Victoria's reign. By HENRY C. BURDETT. In four volumes and portfolio. Vols. I and II: Asylums—History and Administration. London: J. & A. Churchill. 1891.

The author of this handsome and elaborate work has been engaged for twenty-five years in the administration of hospitals and kindred institutions, and during the earlier part of that period gained practical experience in every department of the work by active participation, first as a paid official, and subsequently as governor and hospital-manager. During these years his interest in the subject of hospitals has been constantly growing.

For the purpose of visiting hospitals and kindred

institutions and comparing their merits and defects, he has travelled on the continent of Europe, in this country and in the British Colonies. He was here a short time ago, not for the first time, in the interest of a national pension fund for nurses. He is known in connection with the organization of pay hospitals for the well-to-do in London and other large cities. He is the author of a number of books on hospitals and subjects connected directly or indirectly with hospital administration.

He has spent nearly twelve years in the preparation of these volumes, four in number, the first two of which—the only ones as yet received by us—deal with asylms for the insane: their history, administration and construction. The third and fourth volumes will deal with hospitals for the sick and similar institutions established for the treatment of acute diseases and accidents. The supplementary portfolio will contain many hundred plans of the principal hospitals throughout the world.

A book of this sort, undertaken largely as a labor of love by an intelligent and experienced enthusiast who has devoted so many years of work to his task, cannot fail, notwithstanding the many difficulties the subject presents, to be of great value as a standard authority upon the subjects treated. The publication of the book has been somewhat delayed in order to obtain the figures of the last United States census in regard to the insane population of this country. These figures, however, were not available when the book was sent to press, and a longer delay was deemed unadvisable as the returns from other countries were losing thereby in accuracy.

The author expresses the belief that intercommunication and co-operation amongst all those engaged in the administration of asylums and hospitals, and in the treatment of the inmates of such establishments throughout the world, would result in immeasurable benefit to all concerned. He offers his book as a contribution to this desirable end.

The press-work is admirable, reflecting the liberality of the author and the care and taste of the publishers.

Stricture of the Rectum: A Study of One Hundred and Thirty-eight Cases. Second Edition, Enlarged; pp. 48; illustrated. By CHAS. B. KELSEY, M.D. New York. 1892.

This monograph opens with a complete classification of the possible forms of this disease, and seems to be satisfactory and complete. The symptoms of the affection are concisely reviewed. The next seven pages are devoted to "diagnosis" including "physical examination." The greater part of the brochure (35 pages) is devoted to "treatment," and the work, concludes with a tabulated list of the author's operations and results. He discusses in this connection the methods of dilatation, incision; partial destruction, (that is, electrolysis, raclege, cauterization, etc.) excision, extirpation. He describes his method of operating, that of Krasko, colotomy, and ends with a few remarks on general treatment.

The book is exceedingly interesting, is well written, and is a thoroughly modern work. The author quotes somewhat extensively from Cripps and Allingham; and, with the exception of the subject of colotomy, the description of operative technique is at times somewhat abbreviated. The results shown by his tabulated cases are excellent.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, MARCH 24, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 28 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

WORD-BLINDNESS.

FACTS are accumulating which prove the validity of the doctrine of partial memories connected with certain centres of the cerebrum. Each special sense is believed to register its own impressions as the condition of their being remembered, and the permanence of the memories depends on the integrity of the nervous substraction. Visual images have their seat in the occipito-angular region, auditory, in the first temporo-sphenoidal convolution. Doubtless, the memories associated with smell, taste and touch, have a similar localization in some part of the cortex.

Words, which are visual and audible signs, have a double registration, in the cortical centres, both of sight and hearing, and the recognition of an object depends on the calling into consciousness of its image in one or the other of those respective centres, that is, by the sight of the object, or by its written or spoken signs. Disease of the registering centre may destroy sets of memories connected therewith, and the written or spoken word fails to elicit recognition; we have what is called word-blindness or word-deafness.

Word-blindness is defined as the abolition more or less complete of the memory of figured signs. The subject is unable to read letters, syllables and words, the divers figured signs placed before his eyes, while he may be able perfectly to distinguish their form, outline, and general position.¹ "To read is to translate writing into words, to interpret an image. In word-blindness, this translation, this interpretation are impossible by the intermediation of the sight."

Kussmaul in 1877 was the first to describe word-blindness as a distinct entity. Wernicke had a few years before treated in a very lucid manner of word-deafness under the name of "sensorial aphasia." Guenean de Mussey in 1879, published in Galczowski's *Journal Ophthalmologique*, a remarkable paper on "asemiognosie optique" or "aphasic amblyopia," in

which he records a typical case of his own, and gives a clear description of the malady (reprinted in the fourth volume of his *Clinique Médicale*). The patient of Guenean de Mussey was able to read by retracing with an instrument or simply with the finger the letters which composed the words, "the muscular sense supplying the visual."

In 1881 Nadine Skwartzoff published a memoir in which fourteen cases — some typical and some incomplete — were published; while about the same time, Dejerine communicated to the *Société de Biologie*, of Paris, the first case which had been observed in France connected with a careful autopsy. Two cases followed by an autopsy were shortly afterward published by Chauillard and another. These were the only cases with autopsy which Charcot had before him, when in 1883, he delivered his lectures on aphasia, which form the substance of Bernard's book.

Of late years facts have been multiplying; the symptoms and pathological anatomy of sensorial aphasia are now tolerably well known. (See articles by Bastian, Ferrand, and M. Allen Starr, also Seguin's and Gray's valuable summaries in *Sajous's Annual*.) Dr. Starr, in *Brain*, July, 1890, analyzed fifty cases of sensory aphasia, in which Brocas's centre was not diseased, and found that in all, the lesion lay in the lower posterior third of the cerebrum. This writer says: "If the lesion be extensive enough to involve the cuneus, or deep enough to reach the visual tract to the cuneus as it passes beneath the angular gyrus and convexity of the occipital lobe, it will produce hemianopsia; if not, actual blindness may not accompany psychical blindness. In either case, it is found, that when things are not recognized, they cannot be named when seen." When limited in extent and strictly cortical, the lesion was found in five cases in the angular gyrus and in the inferior parietal lobule. It is here, therefore, that the visual memory pictures lie, according to this writer, and he states that in all the cases in this collection in which the lesion involved this area and in which reading was tested, there was word-blindness.²

The most recent contributions to our knowledge of the subject of psychical blindness have been made to the Paris Biological Society. At the session February 13, 1892, Dr. Charles Richet presented a dog which had been mutilated by ablation of the cortex of the *pli courbe* (angular gyrus); there was permanent abolition of the mental representation of objects. This dog, when placed in an apartment, distinguished the furniture and avoided hitting objects, but these objects awakened in him no idea, no image; as proof of this, if a rabbit were placed in the room, the dog passed to one side without paying any attention to the animal. In order that the rabbit should be recognized it was necessary that the recognition should take place by other senses than the sight, as olfaction. Thus, when the rabbit was placed under the dog's nose, the dog snapped at it. M. Richet claimed that the facts showed that in this animal, if visual perceptions persisted, the

¹ Bernard.

² Sajous's Annual, 1890.

mental representations which these perceptions awaken in the normal state were completely abolished.

At the session held January 16, 1892, an interesting case of word-blindness with agraphia, followed by an autopsy, was reported by Dr. P. Serieux. The patient was a woman, aged sixty-five years. Vision was intact, there was no hemianopsia, but the patient could not read either written or printed words. Writing under dictation, and after copy, were also as impossible as spontaneous writing. There was neither motor aphasia nor word-deafness. At the autopsy, a recent ventricular hemorrhage was found as the immediate cause of death, but the sole lesion to which could be referred the alexia and the agraphia, was an old focus of softening as large as a five-franc piece, occupying the whole of the inferior parietal lobule. The second and third frontal, the lobule of the insula, the Rolandie convolutions were intact. Serieux defines this as "a case of graphic visual amnesia, not to be confounded with agraphia from loss of the memory of the movements necessary for writing, an agraphia dependent on a lesion of the foot of the second frontal convolution."

At the same meeting, Dejerine remarked that the case of M. Serieux was just like an observation which he reported last year relative to a case of word-blindness with total agraphia due to a lesion exactly localized in the *pli courbe*. In both cases, the agraphia resulted from destruction of the optical images of letters, and the centre of these images, M. Dejerine believes to be the angular gyrus.

At the meeting of the *Société de Biologie*, February 27, 1892, the subject was continued, and Dejerine spoke "of the localization of word-blindness with integrity of the faculty of spontaneous writing and writing under dictation." The substance of his remarks was as follows: We are now able clinically to distinguish two forms of word-blindness. In the one, the word-blindness is accompanied with total agraphia. In the other, writing, spontaneous and under dictation, is conserved, while the act of copying is performed in a defective manner. The first of these forms has been designated by Wernicke under the name of cortical alexia, and the second under the name of sub-cortical alexia. The anatomical localization of the first of these forms is the angular gyrus of the left side, and the patients cannot read because their centre of the optical images of letters is destroyed.

The form of word-blindness in which spontaneous writing and writing under dictation are conserved, has not yet been anatomically localized. The clinical and psychological analysis of this form, however, tends to show that it is due, not to destruction of the optic centre of letters (*the pli courbe*), but to a lesion separating the *pli courbe* from the cortical centres of common visual memory (the occipital lobes).

Dejerine's patient was a man aged sixty-eight years, intelligent and cultivated. One day (in 1887) this man found that he no longer understood anything that he read. Dejerine, when consulted, noted the existence

of complete word-blindness with right lateral homonymous hemianopsia and hemiacromatopsia. There was also complete musical blindness, for the man, though a good musician, could not read a note of music. Spontaneous writing and writing under dictation were perfect, and as normal as in the physiological state; the act of copying, however, was very defective; the patient copied letters and words, but slowly and painfully, and on condition of having the copy incessantly before his eyes, as the outlines of the letters were all strange to him. Though afflicted with verbal and musical blindness, he could read figures and make calculations, both mentally and by writing. There was no word-deafness, no disturbance of speech, no hemiplegia, or hemianesthesia. It was quite easy in this patient to awaken in his interior vision the optical image of letters which he could no longer comprehend in the act of reading by making him trace in the air these letters with the finger.

These symptoms continued for four years, while this patient was under observation. The word-blindness did not improve. This man, who went out every day, could never read the name of the street, the signs on the shops, an advertisement, a journal, not even the letters which he himself wrote, and which were corrected by others. He continued to transact his business, till December 31, 1891, when he was attacked suddenly, and without hemiplegia, with "pronounced paraphasia and total agraphia." He had no "shock," or loss of consciousness, and preserved his comprehension of spoken language till his death, which took place suddenly January 10, 1892.

At the autopsy, two lesions were found in the left hemisphere, one old, the other recent. The recent lesion consisted in a patch of red softening occupying the inferior parietal lobule and the angular gyrus. The old lesions — yellow patches of atrophy — occupied the point of the occipital lobe, the base of the cuneus, the lingual and fusiform lobules. All these parts were diminished in volume, yellow, hard, and the optic radiations of Gratiolet appeared, under Flechsig's section, extremely atrophied. The right hemisphere was intact.

It will be seen that this is one of the most typical examples of word-blindness yet published. The old lesions affected only the posterior regions of the left hemisphere, in the cortical optic zone. These lesions explain the hemianopsia and hemiacromatopsia noted during life, and to understand the word-blindness, we must admit that the fibres connecting the centres of optical memory of the two hemispheres with the angular gyrus were altered. This man could not read because the continuity between the central terminations of the optic nerve and the angular gyrus, centre of the optical images of letters, was interrupted. Spontaneous writing and writing under dictation were normal, for the angular gyrus being intact the patient could evoke mentally the visual image of the word which he wished to write, just as in writing under dictation, the auditory centre of words could waken in the corre-

sponding angular gyrus the visual image of the word. On the other hand, the day when the angular gyrus became the seat of destructive lesion, ten days before death, the patient became suddenly and totally aphasic. After having been for four years affected with word-blindness with integrity of the faculty of spontaneous writing and writing under dictation, he became aphasic on the day when his angular gyrus was altered. This man then presented the one after the other, the two clinical forms known under the name of word-blindness, both depending on a different localization of the lesion.

EVOLUTION AND HEREDITY.

THE Cartwright Lectures for this year were delivered by Henry Fairfield Osborne, Sc.D., Professor of Biology in Columbia College, who took for his subject "Present Problems in Evolution and Heredity."¹

In the first lecture on "The Contemporary Evolution of Man," many anomalies are mentioned in connection with their possible or probable bearing upon the history of the human race. The lecture is interesting for those who have some knowledge of biology, especially in connection with the evolution of different species. The author says at the start that for the present purpose we must suppress our sentiment at the outset, and state plainly that the one interpretation of our bodily structure lies in the theory of our descent from some early member of the primate race, which may have given rise also to the living anthropoidea. From the mammalian standpoint, man is a degenerate animal. His senses are inferior in acuteness, his upright position, while giving a superior aspect, entails many disadvantages, his feet are not superior to those of many lower eocene plantigrades, his teeth are mechanically far inferior to those of the domestic cat.

If an unbiased comparative anatomist should reach this planet from Mars, he could only pass favorable comment upon the perfection of the hand and massive brain. Holding these trumps, man has been, and now is, discarding many formerly useful structures. By virtue of the hand and brain he is nevertheless the best adapted and most cosmopolitan vertebrate.

It is probable that none of our organs are absolutely static, and that the apparent halt in the development of some is merely relative. Upon proper investigation it is very difficult in many cases to determine whether an organ is actually developing or degenerating at the present time.

Variability of an organ or tendency to present individual anomalies, indicates that some change is in progress. It is a fixed principle that a part degenerating by disuse in individuals will also be found degenerating in the race. Degeneration is an extremely slow process. Both in the muscular and skeletal systems we find organs so far on the down-grade that they are mere pensioners of the body. One symptom of decline is variability, in which the organ seems to be

demonstrating its own uselessness by occasional absence. This long struggle of the destructive power of degeneration, which is essentially an adaptive factor against the protective power of heredity, is the most striking feature of the law of repetition. A careful study of our developing, degenerating, rudimentary and reversional organs amply demonstrates that man is now in a state of evolution hardly less rapid, the author believes, than that which has produced the modern horse from his small five-toed ancestor.

MEDICAL NOTES.

REGULATING PRESCRIPTION BLANKS.—A curious bill has been introduced in the New York Legislature, which proposes to make it compulsory for physicians to use for their prescriptions, blank forms to be supplied by the Board of Health. There seems to be very little danger that this bill will become a law.

YELLOW FEVER IN RIO JANEIRO.—During the first two weeks of March there were 775 deaths from yellow fever in Rio Janeiro. The crews of many vessels in port have been attacked with the disease. Cases have also been reported from Buenos Ayres.

CHOLERA IN ASIA MINOR DURING THE PAST YEAR.—The outbreak of cholera was first noticed near Aleppo on June 9th, and remained until November 9th, during which time 1,659 persons died. In Damascus, between October 15th and the 7th of January, 801 died. In the Hedjaz, 3,176 persons, or over two per cent. of the population, died in six weeks, in the middle of the summer. In Mecca, the mortality was three per cent. Between July and January there were probably about 10,000 deaths from cholera in Asiatic Turkey.

A PLEA FOR MRS. OSBORNE.—The *British Medical Journal* presents a plea for Mrs. Osborne, who has recently been sentenced to a term of nine months' imprisonment for stealing Mrs. Hargreaves's jewels. Letters have been written by various medical men showing that she is chronically subject to hystero-epilepsy and of a highly neurotic temperament, to such an extent that she could hardly be considered as morally responsible.

THE CUBAN DEGREE OF M.D.—The Spanish Minister of Foreign Affairs has proposed to take away the power of the University in Havana to grant the degree of M.D., thus reducing it to the position occupied by other Spanish Provincial Faculties which can only grant a license. A large petition has been sent begging that the Government will reconsider the proposal.

MEETINGS OF CONGRESSES IN EUROPE.—The sixth meeting of the French Congress of Surgery will be held in Paris on April 18th. The German Surgical Society will hold its Twenty-first Congress at Berlin, from June 8th to 11th. The question of "The

¹ Medical Record, February 20th.

"Surgical Significance of the New Firearms" will be discussed, and there will be a debate on anesthetics. The Congress of Criminal Anthropology will hold its third meeting at Brussels on August 28th. The International Congress of Experimental Psychology will meet in London on August 1st.

ANTISEPTIC TABLETS. — Attention has been called in England to the danger of putting up poisonous antiseptics in tablets of the same shape as those commonly used for internal medication. A good suggestion is made that such tablets should not only be colored, but that they should be made of a peculiar shape.

THE KOCH INSTITUTE. — Dr. Pfeiffer has published an account of the first year's work of this Institute. Almost all of the infective diseases have received more or less attention. There are two directors of departments and four assistants beside a number of volunteer workers. In the scientific department there is accommodation for twenty-five, all of whom receive appliances and attendance free of cost. All who work at the Institute are required to sign an agreement that any work which they may do shall be considered the property of the Institute, and that all discoveries shall be communicated to the directors; their notes also are the property of the institution. A weekly conference is held, in which all work of any importance is discussed. The connection between the hospital and the scientific department is a very intimate one.

THE NEXT GERMAN WAR. — At a recent meeting of the Reichstag, with reference to Billroth's lecture upon modern firearms, Major Gaede said that there was no doubt that in the next war, the number of wounded would be greater than heretofore, but the wounds would be of a less serious character. In the war of 1870 the number of wounded was about fifteen per cent. of the total number in the field, of whom a little more than two per cent. died at once. The present calculation of the next war is that twenty per cent. will be wounded, five-sixths of which number will come under surgical care. Each surgeon would have charge of about twelve seriously wounded men and twenty-six with slighter wounds. Professor Virchow said that although twenty per cent. would represent the average loss, the losses in many of the engagements would be much above the general average of the campaign. He recommended that the government should not rely entirely upon its military surgeons, but that it should establish some system by which civilian aid could be used.

BOSTON AND NEW ENGLAND.

BOSTON SOCIETY FOR PROTECTION FROM CRUELTY TO CHILDREN. — The annual report of this society shows that during the past year 4,700 children have come under its notice. The work of the society is much impeded by lack of necessary funds.

DEATHS IN BOSTON DURING THE WEEK. — The number of deaths reported during the past week was

223 against 170 the corresponding week of last year, making the death-rate for the week 25.2. The deaths due to consumption were 26, pneumonia 35. The number of persons over sixty years of age, 49. Two deaths were reported as due to influenza.

SEA-SHORE HOME FOR INFANTS. — This institution, which for several summers has done very successful work in the care of infants suffering from gastro-intestinal catarrh, in Winthrop, was a year ago not allowed to open, by vote of the Winthrop town meeting. The officers have now purchased thirteen acres of land on Weymouth Fore River, in Quincy, and will soon begin to erect buildings upon it. The new situation is decidedly better than the old one, and can be very easily reached by the Old Colony Railroad. It will probably be in working order before the continued hot weather of next summer.

TYPHOID FEVER AT BRADFORD ACADEMY. — On account of the appearance of four cases of typhoid fever at the Bradford Academy for girls, near Haverhill, the regular spring vacation has been begun a week earlier than usual.

MASSACHUSETTS LEGISLATURE. — The anti-cigarette bill was discussed and finally rejected by a large majority. The Judiciary Committee reported a bill regulating the use of embalming fluid in cases where persons were supposed to have come to their death by violence. A Committee on Public Reservations and Lands has listened to petitioners, that certain places in the State be set apart as public parks, and also for the establishment of a Metropolitan Park Commission. The Committee on Public Charitable Institutions has listened to the subject of the regulations of "baby farms." The same committee has reported reference to the next General Court on the report of the Commission on a State Institution for Epileptics. The Committee on Public Health reported a bill providing that every town in the State, of more than 2,000 inhabitants, shall elect a board of health by ballot at the annual town meeting or at a special meeting called for the purpose. The board is to consist of three members, for one, two, and three years respectively. Smaller towns "may" elect such a board, and if they do not, the selectmen shall act as such a board. The same committee reported inexpedient on the order allowing a town to impose the duties of a local board of health on the selectmen, so that it shall be permissive only in smaller towns.

RAILROAD ACCIDENTS IN MASSACHUSETTS. — According to the reports submitted to the railroad commissioners for the year ending September 30, 1891, the total number of accidents on the West End Street Railway was 204, of which 122 were by horse cars, and 82 by electric cars; 121 passengers were injured in getting off and on to cars, 45 persons on the street, and 38 by collisions with vehicles. The number fatally injured was 14, ten by horse cars and four by electric cars. Two accidents demonstrated that the wooden bar on electric cars, four inches above the rail,

may crawl up over and crush a person lying on the track, and cannot be considered a fender. Efforts are being made to provide suitable fenders for these cars. Accidents to passengers averaged one to 985,000 passengers carried, whereas in steam railroads they averaged one to 634,000. The percentage of horse cars in the total mileage of the company is 73 per cent, whereas the percentage of persons injured in getting on and off the horse cars was 58 per cent., of persons on the street, 67 per cent., and by collisions with vehicles, 58 per cent. The total number of passengers killed and injured by the steam railroads of the State was 134; employees injured 408, travellers at grade crossings and at stations 84, and trespassers 200. Of these accidents 269 were fatal.

NEW YORK.

THE WEEKLY MORTALITY. — The deaths reported in this city during the week ending March 12th, were 919, a decrease of two as compared with the preceding week, but 47 in excess of the mortality of the average of the corresponding week in the past five years. This represents an annual death-rate of 27.94 per 1,000 of the estimated population, against 26.51 for the average of the corresponding week for the past five years. Pneumonia caused 151 deaths, against 185 in the preceding week, and 120 for the average of the corresponding week of the past five years. Two hundred and thirty-three cases of scarlet fever, with 34 deaths, were reported against 224 cases and 37 deaths in the preceding week. There were 331 cases of measles, with 18 deaths, against 366 cases and 14 deaths in the preceding week. There were 107 cases of diphtheria, with 31 deaths, against 114 cases and 35 deaths in the preceding week. There were no deaths from small-pox, and only one new case reported, while in the previous week there was one death and nine new cases. For the first time during the present year there was no death from typhoid fever. During this week there were reported 941 births, against 1,043 in the preceding week.

TYPHUS FEVER. — There were eight deaths against two in the preceding week; but only 12 new cases were reported, while in the week previous the number was 30. Since March 12th only two or three new cases of typhus have occurred, and these have been exclusively among the attendants at the fever hospital on North Brother Island: so that it may be said that the *Massilia* outbreak is virtually at an end. On March 13th a newspaper reporter who contracted the disease while visiting the infected houses where the *Massilia* passengers were lodged, died of typhus; and on March 18th a policeman, who was on duty at the Reception Hospital, also died of it.

THE PASTEUR INSTITUTE. — Since the Pasteur Institute was opened, something over two years ago, Dr. Gibier has had about 1,500 patients, of whom about 300 have been inoculated by him. Although the building occupied, a small house in West 10th Street, is very poorly adapted for its purpose, the expenses of

conducting the institution have been very considerable, and as many of the patients treated were entirely unable to pay for the services rendered, it has been thought of late that the undertaking would have to be abandoned. It is now stated, however, that a large firm of contractors have expressed their willingness to erect a commodious building for this purpose near Central Park, and it is thought that with the improved facilities thus afforded the Institute may in time become self-supporting.

NEW YORK CANCER HOSPITAL. — The last annual report of the New York Cancer Hospital covers the fourth year of active work since the opening of the hospital. During the year 453 new patients were admitted, and there were performed 307 operations, one-third of which were capital. The two noteworthy incidents of the year were the completion of the Astor Pavilion for male patients and the opening of the Chapel of St. Elizabeth of Hungary, erected in memory of Mrs. Elizabeth H. Culum, from the property left by her to the hospital. The buildings of the hospital are therefore now all completed. During the year \$25,000 each was received from the estates of John T. Farish, Daniel B. Fayerweather and Mrs. Robert L. Stuart, and \$5,000 each from Mrs. Wm. Astor and Miss Mary Edson, for the endowment of beds.

PHILADELPHIA.

CHIEF TO BUREAU OF MEDICINE AND SURGERY IN THE NAVY. — Dr. A. L. Gihon, Medical Director United States Navy, stands next in line for promotion to the position of Chief of Bureau of Medicine and Surgery in the Navy Department at Washington. The term of the present incumbent expires at the end of this month, and it appears very probable that Dr. Gihon will receive the appointment, which will be a compliment to this city since Dr. Gihon is a native of Philadelphia, and for a period before the war held a professorship in a Medical College here. After entering the Navy as Assistant Surgeon, he did duty on board receiving-ship "Union," at the Philadelphia Navy Yard in 1850, and since then was continuously in active service until 1879, when he was commissioned Medical Director. Since 1888 he has been in charge of the Naval Hospital at Brooklyn, N. Y.

A JAPANESE LEPER. — In the last stages of the disease, has been admitted into the Philadelphia Hospital, where he is said to be in a dying condition. Much excitement has followed the discovery that he has been living for four or five years in this city, and that lately he has been working at a hotel in the capacity of assistant cook, making bread and pastry, dressing poultry and otherwise preparing food with hands disfigured and mutilated by the disease and in the ulcerating stage. The proprietor of the hotel was arrested and fined for not reporting a case of contagious disease, and will be further proceeded against for maintaining a nuisance. City councils have just authorized the erection of an isolated building of wood

for the accommodation of leper patients, of which there are two at present under treatment.

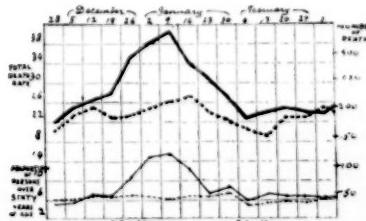

THE TROLLEY SYSTEM. — The Philadelphia County Medical Society held a special meeting on the 12th inst., to protest against the proposed introduction of the trolley system for the propulsion of street cars in this city. In spite of the opposition, which has been aroused against the overhead wires carrying heavy currents in our streets, the railway committee reported favorably upon the ordinance by an overwhelming majority, and councils will probably pass the bill which the Mayor may veto.

AN ENDOWMENT FOR A NEW MUSEUM. — The University of Pennsylvania has recently received a gift of nearly three-quarters of a million of dollars for the erection of a biological and anatomical museum to cost nearly \$200,000, and a yearly endowment of \$30,000 for its maintenance. The donor desired that his name should not be published until all the designs had been completed and the "Wistar Institute of Anatomy" founded; but it has transpired that the generous donor is General Isaac J. Wistar, of Philadelphia, whose uncle, Dr. Casper Wistar, was at one time professor in the medical department of the University, for whom the proposed building is intended as a memorial.

Miscellany.

THE RECENT EPIDEMIC OF INFLUENZA IN BOSTON.

THE following chart shows the total death-rate, from all causes in Boston, by weeks, from the week ending November 28, 1891 to that ending March 5, 1892. For comparison, the death-rate of the previous year is also shown, in dotted lines. The lower lines show the proportion to the total death-rate of those persons who died over sixty years of age. The death-rate, on the left, is calculated in the usual way, on the

basis of the annual death-rate per thousand inhabitants. The number of deaths is shown on the right. During the week ending January 9, 1892, the total number of deaths was 339, as against an average of about two hundred; while during the same week the number of persons of sixty years of age who died was 116, where-as the average is a little over forty.

The Boston City Board of Health have recently issued a set of tables classifying the deaths reported

as due wholly or in part to influenza from December 12, 1891 to February 29, 1892. From these tables the following figures are taken:

DEATHS DUE TO INFLUENZA, COMPLICATED AND UNCOMPLICATED.

	Males.	Females.
Influenza, non-complicated	21	41
Complicated with Phthisis Pulmonalis	2	6
" Bronchitis	8	19
" Heart Disease	4	16
" Arthritis	1	2
" Pneumonia	25	35
" Old Age	3	10
" Other Diseases	3	7
Total	77	128

DEATHS ARRANGED BY AGE.

	Males.	Females.
Under 5 years	.	.
From 5 to 10 years	.	.
" 10 to 20 "	0	7
" 20 to 30 "	5	7
" 30 to 40 "	4	13
" 40 to 50 "	6	15
" 50 to 60 "	9	12
" 60 to 70 "	16	19
" 70 to 80 "	16	32
" 80 to 90 "	9	16
" 90 to 100 "	1	6

DEATHS ARRANGED BY NATIVITY AND PARENTHAGE.

	Nativity.	Percentage.
United States	97	60
Ireland	77	48
England	8	9
Scotland	0	1
Germany	4	4

A SURGEON'S IMPRESSIONS OF AMERICA.

DR. RUTHERFORD MORISON, of Newcastle-on-Tyne, describes a visit of eighteen days in America, during which time he saw seven hospitals and met several American surgeons. He describes his visit somewhat at length in the *Edinburgh Medical Journal*. As a preliminary, he says that the American surgeon is a good fellow and it will be a Britisher's own fault if he cannot get along with him.

He seemed to be surprised that ether was always given and that chloroform is mostly regarded as unsafe. In connection with the Johns Hopkins Hospital, the technique of the common surgical proceedings is described. American surgeons claim that their hospitals and nurses are better than the English. The first claim he does not deny, he also acknowledges that the lectures at the training schools for nurses is an advantage which the English nurse does not have. Concerning the hospitals in Boston he says, everything including hospital staff, nurses and all else is decidedly English.

He expresses great surprise at the choice of the point of election, rather than for a lower operation in amputations of the leg. In conclusion, he gives his general impressions of American surgeons and instruments, as follows:

American much more resembles German than English surgery. Germans have an indescribable way of taking possession of an anesthetized patient, giving the impression that he is entirely their own, and that they mean to do just what they like with him. German instruments are much larger, forceps like tongs, scissors like sheep shears, retractors like garden rakes.

The German surgeon is seldom in doubt, and has an excellent embryological, bacteriological and pathological explanation of all his cases and results; if

there is a mistake, something is to blame, not the surgeon. Then there are other German specialties, such as, metal-handled knives, the invariable introduction of needles by a holder, the wearing of special operating apparel, and the selection of only such operations as can be performed with deliberation and in open daylight; all have more or less influenced American surgery. Results are after all the test, and on these a judgment must be formed; and from this standpoint, his belief is that if English surgeons do not wish to be overtaken, they must put their best foot foremost.

IN MEMORIAM. DR. JAMES AYER.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

In taking official notice of the death of Dr. James Ayer, the Society desires to record its high estimate of one of its oldest members.

By his constant attendance at the meetings of the Society, and by the high standard of his professional and his private character, he earned the respect and esteem of the Society, as well as of the community.

The Society respectfully tenders to the family of Dr. Ayer its sympathy with them in their bereavement.

THERAPEUTIC NOTES.

LYSOL.¹—Starting with Fränkel's view that the antiseptic properties of creolin depend upon some higher homologues of phenol, it was believed that the cresols in soluble form would be more active as disinfectants than in emulsion. The result of this study was the production of lysol, which contains fifty per cent. of cresols, is miscible with water, and forms clear solutions with alcohol, petroleum or benzene, chloroform, carbon bisulphide, and glycerine. Gerlach and others have found it active and prompt in arresting the development of microorganisms. Fürbringer believes that after cleansing the nails with a one-half to one per cent. solution, the hands being immersed two or three minutes, using a brush, other disinfection is unnecessary. This process does not attack the hands. For sterilization of instruments, one-fourth of one per cent. solution is sufficient. Cramer and Wehner believe that it is five times stronger than carbolic acid, and one-eighth as poisonous; considering the weak solutions necessary, it is relatively cheap.

EXTRACT OF A SHEEP'S THYROID FOR MYXEDEMA.—Murray² reports a case treated by injections of an extract from the thyroid of a sheep in which excellent results were obtained, and a second successful case is reported by Wallace Beatty, M.D.³ The lobe of the thyroid gland is taken from a newly-killed sheep. It is cut up into small pieces and placed in a test-tube, with 1 cubic centimetre of pure glycerine and 1 c.c.m. of .05 solution of carbolic acid. The tube is plugged with wool and allowed to stand for twenty-four hours. After this the mixture is pressed through muslin, and about fifty minims of a turbid pink liquid are obtained, which may be injected by means of a hypodermic syringe in two doses during the course of a week. All the steps of the preparation of this mixture are carried out with due precautions to ensure that the liquid is thoroughly sterilized as well as all the instruments employed.

Correspondence.

A POSSIBLE SOURCE OF ERROR IN USING THE FEVER THERMOMETER.

PEPPERELL, MASS., March 21, 1892.

MR. EDITOR:—About two months ago, after having my fever thermometer, a Hicks', seven minutes in the axilla of a man sitting in his chair, the bulb well up in the axilla, the stem down, I found the temperature indicated, 110.2° F. A second trial gave 109.4° F. Not believing the temperature to be so high, and examining the index carefully, I found that it had left the point where the mercury separates in the stem, and would run from the bulb or towards it just as it was placed higher or lower than the stem. Since that time I have had four similar experiences, and now if the temperature indicated is 104° F., or more, I do not feel sure that it is correct unless I find the mercury in the stem touching the point where it usually separates. How general this fault is with thermometers whose indexes are formed of a long column of mercury, or otherwise, I cannot say.

S. W. FLETCHER, M.D.

[It is safer to keep the stem up.—ED.]

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MARCH 12, 1892.

Deaths reported 2,935: under five years of age 1,062; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 401; acute lung diseases 530; consumption 346; diphtheria and croup 163; scarlet fever 89; diarrhoeal diseases 35; typhoid 10; 25 meningitis 12; typhus fever 8; malarial fever 3; cerebro-spinal fever 2.

From typhoid fever Philadelphia 7, Boston, Cincinnati and Lowell 3 each; St. Louis, Cleveland and Washington 2 each,

Brooklyn, Milwaukee and Springfield 1 each. From measles New York 18, Brooklyn 3, Philadelphia, St. Louis and Boston 1 each. From whooping-cough New York 8, Philadelphia 4, Boston, Cincinnati and Washington 2 each, Brooklyn, Cleveland, Lowell and Fall River 1 each. From typhoid fever New York 8, Philadelphia and Boston 2 each, St. Louis, Cleveland, Louisville, Nashville and Lynn 1 each. From cerebrospinal meningitis New York and St. Louis 3 each, Philadelphia, Brooklyn, Cleveland, Nashville, Lowell and Lynn 1 each. From typhus fever New York 8. From malarial fever Philadelphia, Brooklyn and Cleveland 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,185,736, for the week ending March 5th, the death-rate was 20.5. Deaths reported 4,013; acute diseases of the respiratory organs (London) 379, whooping-cough 158, measles 105, diarrhoea 45, diphtheria 41, scarlet fever 28, fever 13.

The death-rates ranged from 15.3 in Portsmouth to 32.5 in Preston, Birmingham 25.7, Bradford 19.0, Cardiff 20.3, Huddersfield 24.4, Hull 20.8, Leeds 18.9, Liverpool 21.2, Liverpool 27.8, London 18.5, Manchester 21.2, Nottingham 16.7, Sheffield 22.9, Sunderland 19.2, Swansea 28.8, West Ham 19.5, Wolverhampton 25.6.

METEOROLOGICAL RECORD.

For the week ending March 12, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 12, 1892, TO MARCH 18, 1892.

LIEUT-COLONEL FRANCIS L. TOWN, surgeon, U. S. A., while on duty at Headquarters, Department of California, in charge of the office of the medical director, will, in addition to said duty, examine recruits at the rendezvous in San Francisco, California.

FIRST-LIEUT. WILLIAM N. SUTER, assistant surgeon, U. S. A., granted leave of absence for four months, from March 22, 1892.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 19, 1892.

E. H. MARSTELLER, passed assistant surgeon, ordered to duty at the Naval Academy.

W. F. ARNOLD, passed assistant surgeon, from the "Virginia" and to the "Richmond."

C. H. T. LOWNDES, assistant surgeon, from the "Richmond" and to the "Vermont."

D. DICKINSON, surgeon, from the Navy Yard, Mare Island, and two months' leave.

A. M. MOORE, surgeon, from Naval Hospital, Mare Island, and to Navy Yard, Mare Island.

E. NORFLEET, surgeon, from the U. S. S. "Monocacy" and granted three months' sick leave.

G. T. SMITH, assistant surgeon, from the U. S. S. "Mohican" and to the C. S. S. "Hassler."

L. L. YOUNG, assistant surgeon, from the "Independence" and to the "Mohican."

W. K. SCOFIELD, medical director, granted one year's leave of absence with permission to leave the U. S.

SECTIONS OF THE AMERICAN MEDICAL ASSOCIATION.

The Committee appointed at the last meeting of the American Medical Association to consider the best means for promoting the prosperity of the sections of the Association will hold an adjourned meeting in the Hotel Cadillac, Detroit, Mich., June 6th, at 3 p. m.

Members of the Committee are requested to notify the Chairman of their intention to be present at this meeting.

The Committee would esteem it a favor if each member of the Association would communicate in writing his or her views concerning the best measures for promoting the development of the sections. Such communications may be sent to the Chairman of the Committee.

JOHN S. MARSHALL, M.D., *Chairman,*
9 Jackson Street, Chicago.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held on Monday, March 28, 1892, at the Medical Library, 19 Boylston Place, at 8 o'clock p. m.

Dr. F. B. Harrington, "A Case of Disseminated Fat Necrosis."

Dr. J. T. Bowen, "The Present Position of Electrolysis in the Treatment of Cutaneous Affections."

G. G. SEARS, M.D., *Secretary.*

SIXTH ANNUAL STATE SANITARY CONVENTION OF PENNSYLVANIA, PRELIMINARY ANNOUNCEMENT.—It is the intention of the State Board of Health of Pennsylvania to hold the Sixth Annual State Sanitary Convention in the city of Erie. The Board, as well as the local committee in charge, extend a hearty invitation to all persons in any way interested in sanitary matters to visit Erie upon this occasion. The convention will be held March 29, 30, 31, 1892. Arrangements have been made for a programme which will possess not only interest, but permanent value.

A full programme will be issued within a week of the convention meeting.

All boards of health and municipal councils are urged to send delegates.

GEORGE GROFF, M.D.,
PEMBERTON DUDLEY, M.D., } *Committee
of
Benj. Lee, M.D., Secretary, } Arrangements.*

RECENT DEATHS.

D. HAYES AGNEW, M.D., died in Philadelphia, March 22d, aged seventy-three years. Dr. Agnew was born in Lancaster County, Pa., in 1818, and received his degree of M.D. from the University of Pennsylvania in 1848. He became demonstrator of anatomy, and assistant lecturer on clinical surgery at the University, in 1870, professor of operative surgery, and the following year, professor of the principles and practice of surgery. He was also professor of clinical surgery at the University Hospital, and surgeon in the Wills Ophthalmic, the Pennsylvania and the Orthopedic Hospitals. During the war he was consulting surgeon in the great Mower Army Hospital at Chestnut Hill, a position which entailed the supervision of an enormous amount of surgery. When President Garfield was shot, Dr. Agnew was made consulting surgeon, and later was the chief medical adviser of the president, until his death. Dr. Agnew was the author of many papers and works on medical subjects, the principal one being a Treatise on Operative Surgery.

GEORGE MONTGOMERY, M.D., M.M.S.S., of Newburyport, died in New York, March 17th, aged fifty-seven. He graduated at Bowdoin in 1854, and practised medicine in New Hampshire until 1873, when he removed to Newburyport. During the war he was surgeon of a New Hampshire regiment.

JOSEPH DRAFER, M.D., M.M.S.S. (non-res.), died in Brattleboro, Vt., March 17th, aged fifty-eight. He graduated from Jefferson Medical College in 1858, and in 1872 became superintendent of the Vermont Asylum for the Insane, which position he has since held.

ALBERT THOMAS STAHL, M.D. (Bowd. 1875), M.M.S.S., died in Boston, March 16, 1892, aged forty-five years.

HENRY HAMILTON SPROAT, M.D. (Harv. 1865), M.M.S.S., died at Freetown, Mass., March 15th, aged fifty years.

JAMES ROSS, M.D., LL.D., F.R.C.P., Professor of Medicine; Victoria University, Manchester, England; the author of several works on Diseases of the Nervous System, died February 25th, aged fifty-five years.

HUBERT DE CHANGE, M.D., Inspector-General of the Medical Department of the Belgian Army, inventor of different surgical instruments, died early in March.

REFLEXES IN HIP-DISEASE.¹

BY E. G. BRACKETT, M.D.

In the examination of a hip-joint which is suspected of being the seat of disease, many of the signs upon which we must rely are what might be regarded as indirect, or caused by reflected action; and because the joint is so deeply placed, and not accessible to direct examination, these signs become the main source of evidence, not only as to the existence of disease, but also, in a great measure to its character, activity, etc.; as, for instance, the most valuable symptom, that of muscular spasm, which is purely involuntary in character, and is one of the most unfailing of signs in all stages. The mechanism of this is not satisfactorily explained, at least on good physiological grounds; but it must occur in some way through the intervention of the nervous system, and may be from either a condition of unusual irritability of the nerve-centres, or simply the result of over-stimulation. We have rather fewer reasons for considering it the latter, and yet the former is not proven. One condition, which must bear a close relationship in the method of its occurrence to this one of spasm, but which seems to have been in a great measure neglected, is that of reflex activity.

We may consider a physiological relation between the joint and the muscles governing it; and therefore the constant irritation of the diseased part results by cumulative action in a condition of hyper-excitability of nerve elements. It has been found by Iodowsky, that prolonged peripheral irritation results in an increased functional activity of the nerve cells, and the continued irritation from the diseased joint may thus find expression in unusual response to stimulus, as, for instance, in muscular spasm. Theoretically we may expect under certain conditions to find the reflexes rather more active than usual, such being those in which we have a sensitive condition of the joint, and which finds expression in the spasm of the muscles which guard the affected joint. Such alone would perhaps not be of special value, but of corroborative evidence—one of several symptoms which point to a diseased articulation. If, however, we could find that this excess of irritability was definitely localized, it would assume greater importance. For instance, if in a disease of one hip we may look to find them exaggerated on the affected side, it becomes a sign of value, and also for distinction from those cases of low spinal caries, which in their early stages closely simulate hip-joint disease.

In these observations from which the results are obtained, the tendon reflex was taken in the usual way, by tapping the patella tendon with the leg flexed. In those cases in which the knee could not be flexed, the attempt was made to elicit it by Gower's method of downward pressure on the patella by the forefinger, and tapping while this pressure is being made. Its response to this method is a sign of excess, but whenever it was not obtained, and the other could not be employed, the case was not used, as such failure could hardly be considered as evidence of its condition.

The cases are divided into those which were in a

¹ Read before the Surgical Section of the Suffolk District Medical Society, February 3, 1892.

quiet state, as shown by the absence of all subjective signs, and those in an irritable condition, as shown by the presence of pain, sensitiveness, etc., and each of those in turn according to whether there was present muscular spasm.

HIP-DISEASE (17 Cases).

Quiet Cases, without spasm,	16	Reflexes equal 15, unequal 1.
		Normal 11, increased 5.
" with "	19	Reflexes equal 3, unequal 16.
		Normal 6, increased 13.
Irritable Cases, with spasm,	12	Reflexes equal 3, unequal 9.
		Normal 2, increased 10.

SPINAL CARIES (21 Cases).

Quiet Cases, without spasm,	6	Reflexes equal 6, unequal 0.
		Normal 5, increased 1.
" with "	11	Reflexes equal 14, unequal 0.
		Normal 12, increased 2.
Irritable Cases, with spasm,	1	Reflexes equal 1, unequal 0.
		Normal 1, increased 0.

The table in this series of cases shows an almost constant relation between the spasm and the increased condition of the reflexes, and granting a value to one we must give the same to the other. The indications are that it is an evidence of an irritable condition of the joint, rather than of a sensitive condition, and would apparently be of value in determining the amount of freedom to be allowed to the diseased joint.

It will be noticed that in the "irritable" class, in which we should expect the amount of peripheral irritation to be much greater, the proportion of unequal reflexes is much less. This seems to be in corroboration of the theory, as we may suppose the irritation, being much greater, to have passed out of the reflex arc—which action is recognized to occur—and to have become more general, and we see its evidence in the greater activity of the knee-jerk on the other side.

This condition would be of no value as a diagnostic sign unless localized, that is, confined to its reflex arc, and not caused by the presence of disease. To prove this are given the results in cases of spinal caries, which are placed in the same table.

The inference which we have to draw is that the condition of the reflexes must depend on the same general causes as the muscular spasm; that in those cases which may be considered as quiescent and without muscular spasm, the reflexes are not altered from normal. When, however, the joint is in an irritable state, we may expect to find them increased on the side of the disease. The presence of subjective symptoms does not apparently affect the phenomenon. The value of this is two-fold. It becomes an indication of the irritability of the joint, in the absence of subjective symptoms, in the same way as does the involuntary muscular spasm, and also of diagnostic value in the early stages in the absence of other indications. In this it can be used as one of the evidences in distinguishing between early hip and low lumbar caries, for a marked difference is shown in the cases of spinal caries in this matter of reflexes, as these show an almost constant uniformity, and are not only equal, but much less likely to be exaggerated even with the presence of other disease.

To obtain satisfactory opinions of the condition of

the reflexes in children is frequently difficult, for the results do not always seem to be uniform, but the average of many trials will be found to be in the rule accurate. It is doubtful, however, if this symptom is of any value in cases of old disease, with very marked atrophy, for in these the reflexes are much more active than normal. The condition cannot be regarded as an infallible sign, but as one of the several of value, which are to be used in determining the existence of disease, and the condition of the joint.

THE OPERATIVE TREATMENT OF SPASTIC PARALYSIS.¹

BY CHARLES L. SCUDDEER, M.D., BOSTON,
*Out-patient Surgeon at the Massachusetts General Hospital, Assistant
in Clinical Surgery in Harvard University.*

LITTLE's disease, spastic paralysis, congenital muscular rigidity — these terms, from an etiological point of view, probably are synonymous. It is an affection of childhood, noticed at birth or soon after. It is characterized by a rigidity of certain groups of muscles, without wasting or loss of electrical reaction to faradism; by a peculiarly awkward gait, due to a loss of co-ordination in the muscles of the lower limbs; by an increase in the superficial and deep reflexes and by the presence of more or less mental impairment, which may be absent. Usually the adductors of the thighs, or the flexors of the arms or legs are involved, giving rise to a most distressing deformity.

Pathologically, as far as is at present known, the causative lesion is located in the motor tract of the central nervous system.

Spastic paralysis has been mistaken for certain conditions found in hip-disease, infantile paralysis, and the paraplegia of Pott's disease. But if care be exercised, the differentiation is easy.

Relief is sought for the progressive deformity which is the result of the rigidly contracted and shortened muscles.

Treatment by drugs and electricity has failed. Surgically, an attempt has been made to improve the muscular conditions, by attacking the cerebral lesion, but without success. Bullard and Bradford have reported such an attempt. As Bradford has suggested, when the surgery of the brain has become more advanced it may be possible in a few of these cases, to attack the central nerve lesion successfully.

At times progression is absolutely impossible, and at best it is much impeded. The deformity depends, of course, upon the groups of muscles concerned: if the adductors be involved, the child will stand with the thighs flexed and adducted. If the hamstrings be implicated, the feet are flexed, and, in walking, the child balances on the toes, dragging the feet close to the floor with a clinging gait and rubbing the knees together.

To relieve the deformity, apparatus has been used, but no matter how well fitted and carefully managed, it accomplishes nothing permanent, the deformity recurs immediately upon its removal. Forceful correction, with or without ether, and immobilization in plaster are of no service.

Rupprecht,² apparently recognizing this deficiency

in mechanical measures, calls attention to the good results obtained by tenotomy of the tendon of the gastrocnemius.

Bradford³ has added still further to the advantages to be derived from this procedure, by demonstrating the utility of an open and thorough division of all resisting structures, whether presenting at the groin or ham. In spastically contracted limbs, uniform success has attended thorough tenotomy and myotomy of resisting tendons and muscles complicated with immediate fixation. This success is, at present, an unexplained clinical fact. After tenotomy the muscles increase in size and strength.⁴

To the few reported cases of successful operation for spastic contraction of the lower limbs, let me add one more.

This case is made unique by the presence of a hydrocephalus, the existence of spina bifida, a rotary, lateral spinal curvature, and because mental impairment is absent.

The patient is twelve years old, a bright and intelligent girl, with a good family history. At birth, a soft spot, gradually increasing in size, was noticed in the middle of the back, becoming firmer, until, at present, in the lower lumbar region in the median line is a tumor the size of a flattened orange. The skin over this tumor is not thin, and fluctuation is distinct. There is no variation in the size of the tumor either upon pressure, manipulation, or forcible expiration. The base is broad.

While the patient was a baby this tumor was aspirated, and after "weeping" a clear fluid for some time, the opening spontaneously closed. When two weeks old the child's head was noticed to be increasing rapidly in size. In the second year of life the anterior fontanelle was closed. At present the head is large. The circumference is twenty inches plus. There have been no convulsions at any time. The spine presents a marked dorso-lumbar, lateral rotary curvature, which has developed gradually, and, at present, is rather poorly held by a steel waist-band, with crutches.

When two and a half years old the child walked. When eight years old the heel cords "began to grow tight," causing a talipes equinus. A little later the knees began to strike in walking, and permanent adduction occurred; then the knees began to flex, and remained permanently so. The gait gradually changed, and now the child walks on the toes with the feet inverted, the knees forcibly adducted, the thighs flexed on the trunk, a moderate lordosis in the lumbar region, and in the dorsal region, a marked rotary lateral curvature to the right.

Two years ago tenotomy was done on both ankles, with temporary benefit. At present the condition of the spastically contracted muscles is as follows:

The foot on the right side can be flexed beyond a right angle, that on the left to a right angle. Extension of the right ankle is possible to a little beyond ninety degrees. In the left ankle extension is practically normal. Abduction of the thigh is possible to a greater extent on the right than on the left. The right knee is flexed to about ten degrees, and the left to about twelve degrees. The muscular power of both thighs and legs is good. Ankle-clonus is present, and the knee-jerk is exaggerated on the right side. The ankle-clonus is absent from the left leg, and the knee-jerk is

¹ Read at the Surgical Section of the Suffolk District Medical Society, February 3, 1892.

² Volkmann's Klin. Vorlage, 172.

³ Transactions, American Orthopedic Association, vol. III, p. 7.

⁴ Adams: Lancet, September 27, 1890.

exaggerated very slightly. Both arms, and all other parts of the body, are in normal condition. The head has ceased to enlarge, so far as can be determined by external measurement.

The child, etherized, was placed prone. A shallow V-shaped incision across the ham exposed the popliteal fascia, which, with the hamstring tendons, was divided; the semi-membranous, biceps and semi-tendinous were severed partly in the tendinous, and partly in the muscular part. The tendo Achillis and the plantar fascia were divided on the right side, and the tendon of the adductor longus on the left. Both lower extremities were brought into normal position and immobilized in plaster-of-Paris from the tips of the toes to the groin. After a week the patient was allowed to be up and about with crutches, and retentive apparatus, consisting of an upright on either side of the leg, fastened to the shoe below and thigh-band above, a leather pad over the knee preventing flexion.

After about seven months she was allowed, a portion of the time, to go without the splints, and now, ten months after the operation, wears no apparatus. There has been no recontraction. She is learning to use her legs well, stands straighter, and walks with slight assistance without the use of crutches.

Mentally the child is brighter than children of her own age, and is enjoying the greater freedom of movement which she now possesses.

These cases of spastic contraction, being at present, incurable, are entitled to all the benefit that can be afforded by so safe an operation as above described. The spina-bifida having remained for several years quiet has demanded no interference, and considering the general good health of the child, operation of any sort is not justifiable. The spina-bifida is protected by a hard rubber pad.

In the *Boston Medical and Surgical Journal* for January 17, 1889, p. 61, Cabot has called attention to the necessity of dividing the tendons, where it is possible, near enough to the muscular belly to maintain a connection between the severed tendon and its muscle, thus preventing a matting together of the tendons in their sheaths, as happens when the division is lower. The same rule applies to the tendons of the ham. The division should be an open one, and through the tendons within the limits of muscular insertion.

SPASTIC PARAPLEGIA.¹

WITH REMARKS ON A CASE REPORTED BY DR. C. L. SCUDDER.²

BY WILLIAM N. BULLARD, M.D., BOSTON.

THE case previously reported by Dr. Scudder, I saw in consultation with him. Cases of spastic paraplegia in combination with spina bifida are very unusual. The origin of this form of paralysis in such a case is not at first sight plain, and it may be worth while to consider this subject shortly.

Before entering, however, into discussion of this special case, I should like to say a few words in regard to spastic paraplegia in general. By the term spastic paraplegia we designate a condition of the lower extremities in which their movements are more or less impeded by an increased tonicity or rigidity of the

muscles, causing a greater or less fixation of the limbs, and a resistance thereof to both active and passive motion. This condition is in such cases always connected with some paresis of the extremities, and it may precede or follow such paresis, but in the large majority of cases the rigidity and paresis coexist. When the rigidity of the muscles continues unrelieved for a considerable time, permanent contractures are often formed, and these are well known to every surgeon. The contractures due to spastic paraplegia must be carefully distinguished from those due to other causes. They are totally different from the contractures found in old cases of anterior poliomyelitis, the so-called paralytic contractures, and are not to be confused with the conditions existing in congenital varus and club-foot, which are usually due to wholly different causes.

Spastic paraplegia, when permanent, is always due to an affection of the lateral columns of the spinal cord. This affection may be primary or secondary.

Organic spastic paraplegia are of various forms. They may be of spinal or cerebral origin; they may be primary or secondary.

Spinal spastic paraplegia occurs in various affections of the spinal cord, but the contractures produced are rarely so great as to require or suggest operation.

In children — and it is of them only that I shall speak here — only one form of spinal spastic paraplegia is of ordinary occurrence. This is that occurring in transverse myelitis, the "pressure" myelitis of caries of the spine. It may be caused by any form of pressure on the spinal cord.

The form of spastic paraplegia due to transverse myelitis is readily differentiated from that due to cerebral affections, both by the presence of affection of sensation in the former cases, and by the greater predominance of the paralysis over the spasticity.

CEREBRAL SPASTIC PARAPLEGIA.

This form is very frequent, and nearly all spastic cases suitable for operation are of this class. This is both because the contractures in this form of paraplegia are more severe and more permanent and less amenable to treatment than those due to caries of the spine, and also because of the marked tendency to spontaneous cure in the latter cases.

(The term spastic paraplegia is sometimes used synonymously with cerebral spastic paraplegia. When used, as it sometimes is, improperly to designate a disease rather than a symptom, it assumes this significance. This involves, among other things, the error of assuming that all cases of cerebral spastic paraplegia are due to the same pathological condition.)

In children, in my opinion, practically all cases of spastic paraplegia not due to transverse myelitis (pressure paralysis) are of cerebral origin. (Primary lateral sclerosis is almost unknown in children, and hemorrhage into the spinal cord, producing this affection, seems to be very rare. The vast majority of cases of spastic paraplegia, not due to caries of the spine, present the characteristics of a cerebral and not of the spinal form.)

I shall not enter here into the causation of cerebral spastic paraplegia in children. It may be due pathologically to any destruction or lasting inhibition of the functions of certain portions of the cortical area, or of the fibres which pass from them through the internal capsule and pyramidal tract into the lateral columns in any part of their course. It is commonly the result

¹ Read before the Surgical Section of the Suffolk District Medical Society, February 2, 1892.

² See page 306 of the Journal.

of intra-cranial haemorrhage, usually meningeal, or of atrophy of the brain from whatever cause.

To return to the special case under consideration. To what in this case is the spastic condition due? Is it an exception to the general rule, and may a spina bifida so act upon the lateral columns by pressure or otherwise as to produce a spastic paraplegia, or is it due to some other cause?

In regard to the possibility that a spina bifida should cause a permanent spastic contracture in the lower extremities, I should not wish to express an absolute opinion, but in any case it is very rare. It is true that paralyses of the lower extremities are not uncommon in spina bifida, occurring according to the statistics of the Committee of the Clinical Society of London in about one-fifth of the cases — 53 out of 244 — and this percentage is probably much too small. But these paralyses are not spastic in character, and do not lead to spastic contractures.

(Certain cases have been reported in new-born children where with spina bifida the lower extremities were held in a position of flexion, the thighs flexed on the abdomen, and the legs on the thighs; but in these there does not appear to have been any true spastic contracture. Dolinger reports a case of temporary spastic contraction of the muscles of the lower extremities, which disappeared when the sac was emptied, and reappeared as it refilled. The sac was in the lumbar region.)

I have thus far been unable to find any account of spastic contractures occurring in uncomplicated spina bifida. In our case, moreover, several special reasons combine to render the hypothesis of its direct origin from the spina bifida improbable. In the first place, the paraplegia is of what we may call the pure type — that is, uncomplicated by symptoms referable to other portions of the cord than the lateral columns. This in children is practically always cerebral (primary lateral sclerosis in them being almost unknown); secondly, it is difficult to understand how a spina bifida in the lumbar region could cause an affection of both lateral columns of the cord without more evidence of the affection of other portions.

But if the spina bifida is not the cause of these contractures, to what then are they due? In this and in all similar cases I believe these spastic paraplegiae to be cerebral, and to be the result of the accompanying hydrocephalus. Spastic contractures in connection with secondary hydrocephalus are very common, but may, perhaps, more fairly be considered in many cases as the result of the primary lesion. In hydrocephalus, however, which appears idiopathic and primary, they are less common, but more frequent than is sometimes supposed.

Hydrocephalus connected only with spina bifida, as in our case, and not due to cerebral disease, must be considered primary. In connection with the late development of the contractures in our case that of Anton may be mentioned, where, in a case of congenital hydrocephalus, spastic contractions appeared in the previously unaffected extremities at the age of nine. This late appearance in primary hydrocephalus is probably not uncommon.

In this case, and in similar ones, therefore, I am inclined to believe that the spastic paraplegia is not directly due to any effect on the cord occasioned by the spina bifida, but is the indirect result of the accompanying hydrocephalus. The exact steps by which

this result is produced are not yet wholly proved, but the numerous investigations now going on, on this and analogous subjects, render it not improbable that we may before long obtain a more exact knowledge of them.

Clinical Department.

A CASE OF THE PHELPS OPERATION FOR TALIPES EQUINO-VARUS: RESULTS.¹

BY H. W. CUSHING, M.D.
Assistant Surgeon to the Children's Hospital.

The accompanying illustrations represent some casts of the foot of an otherwise well-developed patient, age eight years, which I thought might be of interest in connection with the "Phelps" operation. The first (Fig. 1) shows a congenital talipes equino-varus of the more severe type. A foot which was unyielding to any attempt at manual *redressement*. The patient walked, as the callus shows, almost on the dorsum of the foot. The toes point inward ninety degrees from the normal position, and are elevated. You can thus appreciate the amount of bony distortion and contraction of soft parts which must have attended such a deformity.

FIG. 1. The X is at a point on the anterior surface of the ankle-joint, midway between the malleoli.

This foot I treated by the "Phelps" method. An unsuccessful attempt at *redressement* under ether. Then a tenotomy of the tendo Achilles and plantar fascia. Then through the vertical incision, which Phillips has so well described, a division successively of the tibialis posterior, abductor pollicis, flexor longus digitorum, flexor longus pollicis, deltoid ligament, the inner half of the flexor brevis digitorum and flexor accessorius.

After division of each, an attempt was made to correct the deformity. Sometimes the foot yielded; at others no gain was attained. At length, as I was about to attack the astragalus, a final effort caused something to yield in the mid-tarsus, and the foot came easily into good position, leaving a wedge-shaped defect one inch wide at its cutaneous surface and ex-

¹ Read before the Surgical Section of the Suffolk District Medical Society, February 3, 1892.

tending from the centre of the sole to the level of the internal malleolus. During these manipulations the internal plantar vessels, which were unusually small and had been dissected free with great difficulty, were ruptured.

The wound healed in the usual manner, by the Schéde method (without complication), and was practically closed at the first dressing, twenty-one days after the operation. The complete organization of the clot and the final removal of all dressing was about the fortieth day.

FIG. 2.

Three and one-half months after the operation this cast (Fig. 2) was taken. During this time the patient wore a Taylor club-foot shoe. At this date all apparatus was omitted. The foot is perfectly straight, especially the anterior part so often seen still somewhat inverted after operative treatment. The sole is in its normal position. There is no equinus. The patient can flex the ankle beyond a right angle, and walks without a limp.

The points of interest in this case have been :

(1) The completeness of the reduction of the deformity.

(2) The small cicatrix, that is, small when the original gaping wound replaced by it is recalled.

(3) The amount of pain immediately following the operation. Quite marked for twenty-four hours. Then gradually diminishing, and finally ceasing at the end of the third day.

(4) The tendency at present of the foot to assume a position of valgus apparently from a lack of support of its inner edge. This happens at times in cases treated by torsion and other operative methods, and can be controlled in this case if it shows a tendency to increase. It may disappear as the cicatrix becomes firmer. It is now noticed only when the foot has to support the weight of the body as in standing, walking or similar attitudes.

I contribute this record as a proof of the efficiency of Dr. Phelps's method, and to show the result which may be attained by it.

THE LONG ISLAND (N. Y.) COLLEGE HOSPITAL.—The Thirty-third Annual Commencement was held on March 23d. The graduating class numbered 64.

A CASE OF DOUBLE CONGENITAL CLUB-FOOT IN THE ADULT.¹

BY A. THORNDIKE, M.D.

I HAVE always regarded it as a curious and significant fact that many of the severe and neglected forms of club-foot, those which defy the ordinary and more gradual methods of correction by mechanical appliances, can be cured and serviceable limbs obtained without any cutting or removing of bone; and I have ventured to present this report of a single case in order to illustrate this fact and see what deductions, if any, could be drawn from it for our guidance in treating club-feet of this so-called resistant class.

S. C., single, twenty-eight years old, was referred to me last June, by Dr. George Haven, and admitted to the House of the Good Samaritan, June 29th. She was the oldest of five children, who, with the parents, were all, excepting her, free from malformations; maternal impressions were not considered to have influenced her condition, and she was not otherwise deformed. She complained of pain and tenderness in her feet, and said that this was so troublesome that after doing a little housework on one day she usually was obliged to spend the next two on a lounge or in bed.

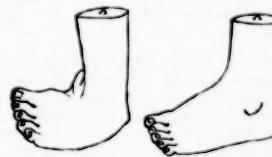

FIG. 1.

FIG. 2.

She was thin, poorly developed, and very short; she walked with a waddling gait, rolling considerably, and bore her weight on the outer sides of her boots; the toes were turned in, so as to point directly at each other. The feet were kept widely apart in stepping, and she required assistance to keep her balance. The deformity was precisely alike on both sides, and is best seen by referring to the cut, Fig. 1, drawn from a plaster cast of the left foot taken at entrance. Figure 2 is from a cast of the same foot made January 10, 1892. The heel was lifted posteriorly, and was twisted in, so that in standing the plantar surface of the heel was turned inward and backward, while the anterior sole was drawn in by the contracted plantar fascia, so that it lay in a plane facing directly backwards. The tarsus was very prominent, and the metatarsal bones and toes, instead of lying alongside of each other as in a normal foot, were rotated so as to lie vertically one above the other; the toes also pointed a little upwards as well as inwards. The outer malleolus nearly touched the ground in standing, and its outline was lost in a large tender callous which surrounded it and extended along the outer border of the foot. It was an equinovarus of a severe type. The deformity did not yield much to pressure with the hand; but very little force could be used without causing pain. Under ether, it was evident that her weight was borne chiefly on the anterior surface of the calcaneus and a part of the cuboid.

¹ Read before the Surgical Section of the Suffolk District Medical Society, February 3, 1892.

On June 30th she was etherized, and tenotomy done on the right tibialis anticus, and on both tibiales postici and both plantar facie. Dr. Bradford's modified club-foot lever, which is figured below, was applied, and by intermittent twistings (using considerable force) the malposition was so far reduced that the skin on the inside of the sole was beginning to split. Dr. E. G. Brackett and Dr. J. E. Goldthwait were present, and we all agreed to stop before actually splitting the skin, preferring to leave the completion for another time rather than incur the complication of an open wound and a scar which might be tender and painful and interfere with locomotion. The feet were accordingly enveloped in small baked-gauze dressings, and plaster-of-Paris bandages applied from the tips of the toes to six inches above the bent knees. Six weeks later she was again etherized and the feet easily over-corrected by the lever applied as before; similar dressings and plaster bandages were used; for a day or two immediately after the first operation there was some pain, none afterwards.

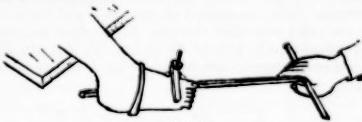

FIG. 3.

The subsequent history after removing the plaster bandages shows that she did toe-in a little with both feet at first, and there was also some edema and tenderness, otherwise everything progressed uniformly well. She wore a pair of Taylor club-foot shoes, with long outside uprights and a short posterior arm at the waist to evert the feet; after three months the long uprights were shortened to the usual size, and the Taylor shoes worn all day except for one hour, when she walked about in her stockings in order to gain suppleness and pliability. There has been no trouble from toeing-in since.

The improvement in the gait was quite rapid. Two weeks after the apparatus was applied she went down two flights of stairs and up again. It is now more than six months since the operation, and she returned for observation ten days ago. The cast (Fig. 2) taken at that time show the position of the feet; both feet could be raised beyond a right angle with the leg, and the motion of the right ankle-joint was fully normal, while the left was somewhat restricted. She had still further improved in walking, although she yet rolled a little from side to side. There was no sensitiveness except over a small area under the arch of the right foot.

In conclusion, it seems to me that many cases of severely resistant club foot, even in the adult, can be forcibly corrected, and should be so treated in preference to methods which mutilate the foot by the removal or division of bone. Dr. Bradford has alluded this evening to two adult cases of his own, one an unpublished case, the other to be found in the "Transactions of the American Orthopedic Association," 1889, Vol. 1; they were thirty-five and eighteen years of age respectively, and the final results in both were excellent. The method was essentially similar to the one I employed, and it is justifiable to infer from the consideration of these three cases that the severer operations should be restricted to resistant club-feet which

have failed to yield to this procedure, forcible correction supplemented, if necessary, by tenotomies; in other words, that this method should always be tried first before resorting to harsher and more radical measures. For I believe that congenital club-foot is to be regarded as a congenital dislocation of the mid-tarsal joint; that it should therefore be our aim to reduce the deformity if possible like a simple dislocation, and to hold it there by suitable apparatus until all danger of relapse is past. This risk, in adults at any rate, is not a great one provided the dislocation has been thoroughly and completely reduced. But if by the use of simple force and tenotomies a thorough and complete reduction cannot be accomplished, then, and then only, are those procedures in order which convert the simple dislocation into a compound one; namely, deep incisions into the joints, osteotomies, and excision of the astragalus. This appears to be a perfectly fair deduction to make, and I have ventured to call attention to it because the text-books say very little on this subject.

FAULTY POSITION OF THE HEAD AND NECK DUE TO THE EYES, AND CORRECTED BY TENOTOMY OF THE EYE MUSCLES.

BY E. N. JACK, M.D.,
Ophthalmic Surgeon to Out-Patients, Boston City Hospital; Physician
to Eye Department, Boston Dispensary.

I HAVE hesitated to report this case, for although the object in view has been attained, yet the eyes need further operation. As, however, the patient is getting along well, I shall do nothing more until he is able to bear operation without ether.

On February 10, 1890, the patient, a boy, nine years old, was referred to me by Dr. Bullard at the Dispensary. The history was of pain over the eyes, especially the right, every spring, lasting three or four weeks. Attention was soon called from this to the position of his head, which was constantly held bent to the right and slightly twisted on a vertical axis in the same direction. Dr. Bullard's examination of the neck and back was negative, I remember, though the records are missing. The left side of the face was slightly more prominent than the right. The end of the nose deviated a little to the right, and the mouth was drawn up a trifle in the same direction. The right side of the head behind was fuller than the left. The only history obtained from the parents was that the head had been held sideways from babyhood. Vision of each eye was 0.9 —, hypermetropia about 1.50 D., and some astigmatism, axes oblique. Fundus normal.

The boy was seen at short intervals for over a month and the following observations were made, there being but slight variation from time to time. There was habitual binocular single vision. He had the power of voluntarily producing vertical diplopia of about eight inches at eighteen feet. Could not unite in the stereoscope. There was a left hyperphoria or tendency of the left visual axis above the right, of 20°. This was the average result in all the testings. There seemed to be no eso- or exo-phoria tendency inward or outward. With the revolving prism over the left eye the test of the muscles was, base up, 3°, in, 6°, out, 10°, down, 15 to 20°.

On March 16, 1890, after several ineffectual attempts without an anesthetic, ether was given and the left superior rectus tendon cut. When tested two days

later no change from his former condition was noted. Judging from this experience and that of others the next step was taken. On April 18th ether was again given and the inferior rectus tendon of the right eye was cut completely off. Dr. Burr and Dr. Bullard assisting. For two weeks after this there was a constant vertical diplopia, which lasted in the early morning for a week or so more.

The last of May he had begun to hold his head perceptibly straighter. The eyes troubled him a little in the morning and in the evening if he sat up after eight o'clock. In September, his head had become perfectly straight, and has continued so until now. A recent examination of the eyes showed a condition about the same as the original, but reversed. He gets along perfectly well and has no trouble at school except that if he looks up suddenly the right eye deviates upward. This he easily overcomes.

A CASE OF TORTICOLLIS DUE TO HÆMATOMA OF THE STERNO-MASTOID MUSCLE.¹

BY R. W. LOVETT, M.D.

ALEXANDER P., six weeks old, was brought to the Carney Hospital Out-patient Department, in August, 1890, on account of a swelling which the mother had noticed in the neck. The child was healthy and well developed, and was born by an easy labor.

The examination showed a bunch in the left sterno-mastoid muscle, about the size of a hazel-nut. The muscle was slightly contracted, as a result of which the face was turned somewhat to the right. The head could be put into the normal position, but could not be over-corrected. The tumor was plainly to be felt, and did not seem to involve the surrounding structures, but to be limited strictly to the muscle. The case was seen by Dr. Burrell and Dr. Post, and child was put upon general treatment, which had little or no effect. The tumor gradually disappeared, and at the end of two months was no larger than a very small cherry.

The child was not seen again until sent for by the writer in January, 1892. The child now presents a well-marked case of torticollis due to the contraction of the left sterno-mastoid muscle. The head cannot be placed in a correct position, there is some asymmetry of the eyes, the tumor has entirely disappeared, and were it not for the early history, the case would pass for a routine one of torticollis.

The case is presented thus in detail because of the statement made by Dr. Whitman, in his recent exhaustive paper,² that no case of torticollis due to hæmatoma of the sterno-mastoid muscle is on record.

M. PREVOT DU HAUDRAY, following the method of Professor Garnier's studies of the Simian language, has carried his phonograph into the hen-coop. He places it in one hen-house where the "family," are at home, and when the receiver has been cackled into for half an hour it is taken away, and made to repeat all the gossip in a neighboring hen-coop. The results of the experiments are said to be marvellous, and the Académie des Sciences is awaiting a lecture on the subject with the greatest interest.

Medical Progress.

RECENT PROGRESS IN PUBLIC HYGIENE.

BY S. W. ABBOTT, M.D.

THE MANAGEMENT AND CONTROL OF INFECTIOUS DISEASES.

Influenza. — The Local Government Board of England, on the 25th of last January, issued a circular of precautions to be observed during an epidemic of influenza, from which the following extracts are taken.

(1) Influenza is spread by infection from person to person. Upon this point the medical officer of the board wrote:

"In its epidemic form influenza is an eminently infectious complaint, communicable in the ordinary personal relations of individuals one with another. It appears to me that there can be no doubt as to this fact. . . . In some circumstances it would seem that ineffectiveness of influenza through the atmosphere shows itself over a wider area than the limits of household life. Probably also there are other less direct ways by which the infection of the disease can travel; and ways, moreover, by which the infection can be retained for a time in a state of suspended activity." [Since the above was written, evidence has accumulated to indicate that influenza is infectious at quite an early stage of the illness, and may remain so as late as, at least, the eighth day from the attack.]

By having established a place for this influenza among infectious diseases, we assert a position for the disorder within a class of diseases over which we habitually exercise a measure of control. But, from what we have thus far seen of the specialities of influenza, we cannot feel particularly confident of our ability, under the existing conditions of society, to successfully defend ourselves against a further outbreak. A disease that can be absent in an epidemic form for thirty years together, cannot, even if a first attack confer immunity, avail to give the protection of a first attack to any large part of the population. [Abundant evidence has now accumulated to show that influenza does not, in any marked degree, or for any considerable length of time, confer immunity against another attack.] Early isolation-precautions, applicable perhaps to children suspected to have measles, cannot well be applied to persons suspected of influenza among the bread-winners of a community; and the singular ability possessed by influenza to disperse itself over a population, owing to its brief incubation period, must add to the difficulties of dealing with an infection that finds the bulk of the population susceptible to its attack. . . .

In view of the difficulties referred to, it is not practicable to devise any restrictive measures for the prevention of the spread of influenza which shall be universally applicable.

But, under some circumstances and certain classes of persons, some such measures should be resorted to, and this notably:

(a) For persons in whom an attack of influenza would be specially dangerous by reason of age or infirmity;

(b) For the inmates of institutions, the mode of life in which can be regulated and controlled;

(c) For the first cases of influenza in a locality or a household where the attacks are early recognized.

In such cases separation between the sick and the

healthy should, as far as practicable, be carried out. Measures to this end have, in some instances, been adopted with marked success. With isolation should be combined disinfection of infected articles and rooms.

Persons suffering from influenza should not expose themselves in public places. Since the propagation of influenza is known to be promoted by the assemblage of large numbers of persons in a confined atmosphere, it is advisable that when an epidemic threatens or is present, unnecessary assemblages should be avoided.

The ventilation and cleanly keeping of any building in which many people are necessarily collected together should receive special attention when influenza threatens or is present, with a view to secure that the air of the building shall be frequently changed, at any rate during the intervals of its occupation, and to avoid accumulation of dust and dirt.

(2) The liability to contract influenza, and the danger of an attack, if contracted, are increased by depressing conditions, such as exposure to cold and fatigue, whether mental or physical.

There is reason to believe that the development of an attack of influenza in a person exposed to the infection depends very largely upon the receptivity of the individual, and that the power of resistance varies, not only in different persons, but also in the same person from time to time, being diminished by any conditions which depress the general bodily vigor. It is, therefore, important that at the time of an epidemic all persons should, as far as they are able, pay attention to such measures as tend to the maintenance of their health, wearing clothing of suitable warmth, and avoiding unnecessary exposure to cold and fatigue, unwholesome food, and excessive use of alcoholic liquors. Similar principles should be borne in mind by those who, as managers of institutions and establishments, have to make regulations for others.

The risk of a relapse and of the occurrence of those pulmonary complications which constitute a chief danger of the disease is increased by anything which involves exposure to cold or fatigue before complete recovery.

*The Prevention of Tuberculosis.*¹—Prof. M. L. Bard, of Lyons, France, proposes two essential measures for the prevention of tuberculosis in hospital practice:

(1) The disinfection of sputa and spit-cups by means of boiling water. For this purpose the apparatus consists of an iron tank for the boiling water, and racks of galvanized-iron wire, each rack holding sixteen spit-cups so that the whole rack can be immersed in the boiling water at once. Dr. Grancher advised, in addition, that some carbonate of soda should be added to the boiling water so that the boiling point could be raised several degrees, but Professor Bard thinks this to be unnecessary.

(2) The other measure has reference to the care of the floors. Instead of sweeping for the removal of the dust, moist cloths are employed. After trial of several different substances in his hospital for the purpose of making the floors impervious, he found that paraffine answered the purpose best. He found the expense to be about 38 centimes per square metre (seven cents per square yard) when applied hot, and 24 centimes per square metre (four cents per square yard) when applied in a petroleum solution. For very large floors the cost would be less.

¹ Revue d'Hygiène, January, 1892.

THE DISINFECTION OF DWELLING-HOUSES IN THE CITY OF BERLIN.²

By a decree of the police authorities of Berlin, dated February 7, 1887, it was rendered compulsory to disinfect the dwellings as well as the effects of patients suffering from a lengthy category of infectious disorders. Not only were the clothes, bedding and all articles used by the sick person to be operated upon, but the walls of the sick-chamber were to be rubbed down with bread, as prescribed by Pistor, this plan being preferred to the use of the corrosive sublimate spray which was advocated by the author, and all the furniture was to undergo special treatment. The house disinfection is carried out upon a plan devised by the author by the experienced trained staff. It was arranged that the services of a certain number of workmen should be obtained from an existing society upon a fixed payment of six marks per head per diem. These men had to receive special instruction to qualify them for their duties; and they were furnished with the requisite appliances, chemicals, etc. The precautions to be observed in the case of utensils, polished furniture, floors, etc., are laid down. All fabrics, bedding, clothing, etc., are packed up by the workmen, and disinfected by steam at the central station. In certain cases respirators of peculiar construction are worn by the operatives. The official instructions for the work are printed in full, and a list is given of sixty-three articles of dress, pieces of apparatus, etc., required by the staff. A tariff has been drawn up for the payments to be made for the work. Statistics are given, of the number of rooms and dwellings operated upon, and of the cubic contents, etc., of the fabrics disinfected.

THE DISPOSAL OF REFUSE AND DUST.

A new process for the disposal of refuse and dust was shown to the Congress of Hygiene at London. It is now in successful operation at Chelsea. The refuse sorting is almost entirely mechanical; nine-tenths of the material is never touched by hand. The dust-carts deliver their loads into a revolving cylinder, containing bars of wood, which is used to prevent bottles from being broken. The material thrown in from the dust-cart passes out at the other end, in two or three minutes. The part which does not drop through the meshes of the first cylinder is taken out and sorted by hand. That part which passes through is received into a second cylinder or screen, a powerful blast of air meets the material coming from the second cylinder and blows the paper away from it to be utilized elsewhere. The heavier material is raised by an elevator and falls upon an iron revolving table, around which boys sit and sort out the refuse. A third screen receives all that passes through the second. The meshes of the first screen are three inches square, of the second one and one-fourth inches, and of the third three-eighths of an inch. The utilized materials consist of rags, paper, and bags for paper-making, these being reduced to pulp and made into wrapping-paper on the premises. They are also bones, bottles, tin, scrap iron, boxes, straw, vegetable and animal refuse, cinders, etc. The coal is all saved, and so are the iron, boots and shoes, etc.; while much nondescript material is ground up in a mill. The organic refuse delivered at the end of the third screen is used as fuel for working the engines on the premises, and a part is sold to the

² H. Merke: Vierter Jahrschrift für off. Gesundheitspflege, 1891, p. 258.

brick-makers for fuel. The dust is conveyed by means of a blast to the furnace fires. Cinders are mixed with pitch and made into briquettes for fuel. The works are lighted by electric lights generated by the fuel obtained from the refuse, and the company hopes in the future to be able to utilize the contents of the London dust-bins to light the streets of the city.

FILTERING ESTABLISHMENTS FOR MUNICIPAL WATER-SUPPLIES.²

At a meeting of the German Health Society held in September last the following propositions were discussed :

(1) All surface-water must, before being used for drinking purposes, be freed from any possible sources of infection.

(2) For this purpose, in all cases in which large volumes of water have to be dealt with, filtration through sand may be deemed to be the most practicable and perfect process under existing circumstances.

(3) The sand filter is not, as it is generally assumed to be, thoroughly efficacious under all circumstances. Sand filters are by no means capable of extracting all germs, but when intelligently worked, it is possible by their means to confine the germs within very moderate limits.

(4) The following are the conditions for satisfactory working : (a) Good raw material (unfiltered water), so far as possible free from pollution. (b) Moderate filtering speed. (c) Regularity in the working of the filter. (d) The rejection of the water supplied at the beginning of each filtering period.

Recent experiments has shown that a sand filter is not absolutely *germ-tight*. It depends largely for its impermeability upon a thin stratum of impurities and micro-organisms entangled in its upper layers or deposited as a net-work upon its surface, and for this reason, until a considerable body of water has been passed through the filter, leading to the formation of this preservative layer of organic matter, the water yielded is liable to contain many germs. This network, however, greatly retards the passage of the polluted liquid, and in the course of time opposes such obstacles to the action of the filter that the filtration has to be discontinued in order that the filtering substance may be cleansed.

Professor Pieck, in continuing the discussion, said it was a matter of extreme importance to render the speed of filtration independent of the fluctuations in the daily rate of consumption, which varies very considerably. For this purpose a compensation-reservoir is necessary. He also called attention to the superior quality of the water yielded by covered filter-beds to that obtained from open filter-basins. Their freedom from ice is also an advantage.

THE WATER-SUPPLY OF PARIS.³

The water-supply of Paris is divided into two distinct services, one for streets, yards, stables, gardens, and industrial purposes, and the other for house-supply. For the domestic-supply the pure and fresh spring-waters of the Vanne and Dhuis are led from their source to covered reservoirs by closed aqueducts, and conveyed to the consumer without contamination ; while the public service is supplied by the waters of the Seine, the Marne, and the canal de l'Ourcq (which

is also used for navigation), and there are some other sources, including artesian wells.

In 1878 these combined resources were equal to a maximum daily yield of 270,000 cubic metres for domestic-supply, the total of 397,000 being equivalent to 198 litres per head of the population of two millions. The works for obtaining this supply comprised the artesian wells, the aqueducts (old and new), and twelve pumping-stations working at a total of 2,130 horse-power.

The insufficiency of this system of water-supply had already been recognized ; and in 1879 the Municipal Council decided upon a scheme for extending the works in several directions, so as to provide a daily delivery of 70 litres of spring-water, and 200 litres of river-water per head of the increased population. The works contemplated in this programme were at once begun, and may now be said to have been completed, although the details have in the meantime been considerably altered.

The paper describes the works that have been actually carried out, including three new pumping-stations on the Seine, the addition of further motive power to existing stations, the collection of some other sources of spring-water, and the extension of the reservoirs. There are now on the Seine seven new pumping-stations, equipped with twenty steam-engines and thirty-nine boilers, working up to 2,400 effective horse-power ; on the Marne three stations, containing twelve hydraulic machines and five steam-engines with ten boilers, working altogether up to 1,500 horse-power ; and in the valley of the Vanne four stations, containing six hydraulic machines and four steam-engines working up to 450 horse-power.

Of the new pumping-stations, the most important is that at Ivry, situated on the left bank of the Seine, and just above the confluence of the Marne.

(To be continued.)

In Memoriam.

DAVID HUMPHREYS STORER.

BORN March 26, 1804. DIED SEPTEMBER 10, 1891.

GEORGE HINCKLEY LYMAN.

BORN JULY 17, 1819. DIED AUGUST 19, 1891.

MEETING of Wednesday, January 20, 1892.

DR. LYMAN.

DR. C. ELLERY STEMDAN read an interesting sketch of Dr Lyman's life :

George Hinckley Lyman was born in Northampton, July 17, 1819, the son of Jonathan Huntington and Sophia (Hinckley) Lyman. He was educated in the Round Hill School in Northampton, and was then

² Deutsche Vierter Jahresschrift für Gesundheitspflege, 1891, p. 38.

³ Annales des Ponts et Chaussées, February, 1891.

obliged to pass several years in Ohio and other Western States, on account of his health, before beginning his professional studies in Philadelphia. He took his medical degree at the University of Pennsylvania in 1843, served as interne at Blockley Hospital, and passed nearly two years in medical studies in Paris, returning to Boston in 1845. He married, first, October 14, 1846, Maria Cornelia Ritchie, daughter of James T. Austin: she died in 1864, leaving two sons and two daughters; he married, second, February 13, 1879, Henrietta, daughter of Samuel T. Dana, who survives him.

He began practice in Boston on his return from Europe, and while enduring the tedious waiting for patients which is the lot of young doctors, busied himself in study and writing. Patients, however, were not long in coming to one so well equipped for his work, and although Dr. Lyman's *clientèle* was never large, owing to his four years' absence in the army, it was of the most satisfactory kind. It is not improbable that he was disappointed in finding that his professional line was likely to be the physician's rather than the surgeon's, for he had fitted himself especially for surgical work. But surgery in Boston was at that time in the hands of a few men, who did not look favorably on new aspirants.

His first paper was on "Non-malignant Diseases of the Uterus," and won the Boylston Prize for 1854. His second contribution to medical literature was an essay which gained the prize offered by the Massachusetts Medical Society for a "Dissertation on the History and Statistics of Ovariectomy, and under what Circumstances the Operation may be regarded as Safe and Expedient." This was in 1856, when ovariectomy was yet looked on with no little distrust and even with dread. By its painstaking research and well-argued positions, the essay contributed in a signal manner to a consideration of the operation more serious and more favorable than it had yet gained. A list of his writings is appended to this notice; among them, besides those here named, is one on "A Case of Embolism of the External Iliac, followed by Gangrene, Loss of Leg, and Recovery," which has an interest in connection with his own last illness.

When the war of secession broke out, Dr. Lyman was one of the first to offer his services to Governor Andrew in response to his call for volunteers in April, 1861. He co-operated with Dr. William J. Dale in organizing the State Medical Bureau. Dr. Lyman's work was here of high importance, system having to be evolved out of disorder, and discipline to be enforced on people who were surprised to learn, for the first time, of the duty called obedience. Dr. Dale says in a letter to Adjt-Gen. Schouler: "Whatever of success attended the preparation of the troops prior to my commission is attributable to Dr. Lyman, who showed great energy and good judgment, and was constantly in consultation with the Governor." Dr. L. V. Bell, Dr. Henry Bryant and Dr. Lyman were the first candidates to appear before the Medical Examining Board in Washington. His name was reported at the head of the list, which gave him rank over all civil appointments in the medical service during the war. On September 7th, he was assigned Medical Director of Gen. Fitz John Porter's entire division. On the march to Yorktown, where his duties were arduous, Dr. Lyman contracted a severe dysentery, which seriously disabled him at the time,

and in the form of chronic diarrhoea continued to annoy him for years after the war. After the retreat from Yorktown, Dr. Lyman became Medical Director of the Fifth Corps when General Porter took command of it. On June 27th, the whole corps of twenty-six thousand men received the attack of double its number at Gaines's Mill from noon till dark, when it was withdrawn across the river. At Gaines's Mill two hospitals were established. In full operation until the fight was nearly over, the heavy fire rendered these at last untenable. A part of the surgeons were captured as they left one door, while the rest escaped from the other. The fatigues and exposure of the surgeons busied about the work after these battles were exceedingly great, and in Dr. Lyman's case terminated in such complete collapse as to make rest imperative. Fortunately for him, the opportunity was afforded by a recent law adding to the regular army eight medical inspectors with the rank of lieutenant-colonel, four from the old army surgeons and four from civil life. Assuming the duties of the new rank, he was ordered to inspect the hospitals in Baltimore, Philadelphia, New York and Washington. Thence, with headquarters at Louisville, he had monthly to inspect and report on medical work in Kentucky, Tennessee, West Virginia, Ohio, Mound City, and as far South "as our lines may extend." In December, he found in Nashville, the churches, many houses and warehouses overflowing with wounded. In such duty Dr. Lyman continued till he was transferred to the Department of the East, to inspect New England, New York and New Jersey. Extra duty of inquiry into alleged abuses in the large hospitals at the East gave him in the department three thousand five hundred miles of railway travel. In December, 1864, Dr. Lyman was ordered to the Department of the South, for inspection of hospitals and to await the arrival of General Sherman's army at the sea, and report on its sanitary condition. He remained in this department until he resigned in November, 1865.

On leaving off his uniform, Dr. Lyman returned to Boston, where private practice soon claimed almost all his time. During the war a hospital for the city of Boston, the need of which had been talked about for years, was planned, built, and opened in 1864. Dr. Lyman was consulted in its rise and progress, and on its completion was offered the post of visiting surgeon, but he did not clearly see his way to undertake the arduous work which the appointment would bring. But in 1871, on being made visiting physician, he assumed that position and filled it with energy and devotion; he was particularly interested in its gynaecological work, and never tired in studying and treating, with sedulous attention, the class of cases which form so interesting a department of hospital experience. In all the affairs of the hospital his judgment was sought and followed, and his interest in all that concerned its administration and its usefulness never abated.

In 1879, he was elected President of the Massachusetts Medical Society, and brought to its varied and far-reaching work the same zeal and thoroughness which characterized his hospital service. He was a good presiding officer, ruling strongly, with impartiality and coolness. Before this, in 1870, he acted as anniversary chairman, and in 1875 he had pronounced the oration, his subject being "The Interests of the Public and the Medical Profession." This topic he handled in a broad and vigorous manner, having the

courage of his convictions in no feeble degree. He did not believe in women practising as physicians, and was not at all afraid to say so, fortifying his positions with arguments well considered for that time. He was not given to yielding any opinion which he had thoughtfully adopted, and the writer does not know that he materially modified his views of that question, as increased experience has led most of us to do. The address was characterized by good sense, and its recommendations of legislation in medical matters were important. It brought him, besides the applause of the Society, many letters of congratulation from the best-known men of the profession.

Veterans of the war are prone to weary a younger generation with their reminiscences, as Thackeray says the Peninsular and Waterloo veterans did in his day. The writer thinks, however, that he is not mistaken in considering that the most valuable and most readable of his writings is a paper which he presented to the Military Historical Society of Massachusetts, on "Some Aspects of the Medical Service in the Armies of the United States During the War of the Rebellion." The subject gave him opportunity of greater freedom in style, and allowed some play of the humor which helped to make his company so agreeable to those who saw most of him, no trace of which was permitted to appear in his scientific writings. A study of this paper, in the event of another war, would be of inestimable aid to the organization of a large surgical service, the very foundation of which may have to be laid in the midst of alarm and confusion.

Dr. Lyman was one of the founders of the American Gynaecological Society, and among his public associations he belonged to the Obstetrical Society of Boston, with which he seldom failed to meet, and where his voice was frequently and respectfully listened to; the Boston Society for Medical Improvement; the Suffolk District Medical Society; the Military Historical Society of Massachusetts; and the Military Order of the Loyal Legion of the United States. He was an Honorary Member of the Harvard Medical School Association, and for many years he was vestryman of St. Paul's Church.

Dr. Lyman went abroad in the spring of 1890; passed the winter in good health in Dresden, Florence, Rome and Venice, the early summer of 1891 in Switzerland and Paris. On his way home he was suddenly seized with facial erysipelas, of which he had survived four previous attacks at long intervals. The disease had cost him the sight of an eye ten years before by sequence of an orbital abscess. This attack abolished the sight of the remaining eye, and an embolism of the femoral artery occurred before he succumbed, on August 19th and the tenth day of his illness. His friend Dr. Priestley, and subsequently Dr. William Ord, and his son Dr. William Ord, Jr., were unremitting in their attendance at his bedside. He was buried at Mount Auburn, September 21, 1891.

Dr. Lyman's presence was singularly fine, his physical strength was great, his step was active, his manner alert. He was proud and sensitive, and very decided in all his views. His absorption in his duty made him sometimes abrupt. He could put up with no disobedience, delay, neglect, or inaccuracy, and thought every one was as young and energetic as himself. He was a loyal friend, and his love for his profession, instead of diminishing with advancing years, ripened into an enthusiasm which younger men could not

always attain to. If he took little pains to conciliate those whom he disliked, yet an unjust attack on a brother physician, even on one whom he did not esteem, would rouse his keenest indignation. His mental activity led him to read almost every new medical book in the English tongue, and very much of current general literature.

This love for his profession, his earnestness and thoroughness, his large sense of honor, and his exalted and unselfish patriotism are denied by none who knew him, and are a model for all young men, for all soldiers, and for his countrymen.

Dr. H. W. WILLIAMS spoke of Dr. Lyman as follows: Dr. Lyman was a distinguished instance of what may be done, in exceptional and unusual ways, by one of our quiet profession.

After receiving his degree of M.D. at Philadelphia in 1843, Dr. Lyman spent a long time in careful observation of the phenomena and the treatment of disease in the great hospitals of Europe, before returning to establish himself at Boston. Here, he very soon attracted deserved attention, by the publication of two essays, to both of which prizes had been awarded for their conspicuous excellence, by our medical societies. These were not only valuable for their accurate statements of facts and observations regarding a class of cases then little understood by the majority of our practitioners, but they showed evidence of the author's discrimination in the garnering of the store of practical wisdom which was there accumulated, — and, moreover, they charmed the reader by their clearness and elegance of style.

These essays evinced such a thorough knowledge of their subjects, and so much of candor in discussing them, that they at once gave to Dr. Lyman a high position among his professional brethren. They appreciated his alertness of observation and his enthusiasm; and noted his thorough preparation for his work, which gave fair promise of his success as practitioner. These expectations were not disappointed.

Others have done justice to Dr. Lyman's patriotism in placing his time and his skill, his comfort and his health, upon the altar of his country, during long years of war. And this was done, — not in any outburst of youthful enthusiasm, or ardent hope of distinction; but with the calm resolve of sacrifice. Here, his great executive ability and his matured professional experience were alike serviceable; and the duties of high military positions were performed with prompt self-devotion.

Resuming his home-life, with well-won laurels, Dr. Lyman's administrative talent and professional standing marked him for the highest offices within the gift of the medical fraternity. As President of the Massachusetts Medical Society he was dignified and faithful in the discharge of his duties, and vigilant in promoting its welfare. As one of the seniors of the Visiting Staff of the Boston City Hospital he was courteous towards his colleagues, and skilful in his treatment of the patients under his charge.

Dr. Lyman ardently supported what he deemed was for the honor and welfare of the profession; and in administrative matters, he gave candid attention to advocates of a different policy than his own, and heartily adopted other opinions and plans when satisfied of their greater merit; — thus showing himself wise as well as efficient in fulfilling the duties devolving on him.

Dr. Lyman was an active and interested member of societies for medical improvement; where his vigor and originality of thought, his ripe experience and his clearness of expression in debate gave weight to his opinion.

He was one of the founders, and was Vice-president of the Massachusetts Medical Benevolent Society, established thirty-four years since for the purpose of aiding worthy members of our Profession, or their families, who from illness or misfortune have fallen into distress; — and was zealous in its behalf as a much needed means of usefulness.

As a representative of the amenities of the profession, Dr. Lyman was without a rival. He had large acquaintance with notable men of the medical world, in this country and abroad, — and many of these were recipients of the graceful and elegant hospitalities he delighted to offer.

In the course of nearly fifty years of professional life, Dr. Lyman was called to perform functions quite apart from the ordinary routine of a physician's duties. He never hesitated to undertake or failed to accomplish these services, devoting to each his abundant energy, discretion and loyalty: affording to us an example of fidelity, and of zeal in every good cause, which is not often found even in our own self-sacrificing profession.

I can but add my personal tribute to Dr. Lyman's high qualities as a comrade and friend. Returning from my first visit abroad, where I had spent nearly three years, I found myself almost a stranger in my natal city: fortunately for me, I came to reside in the same district with Dr. Lyman, and we were introduced to each other by mutual friends, — our seniors in the profession, — finding in our recent experiences in European hospitals many subjects of interest to both of us.

The ties of friendship then formed were never loosened during the many years which have intervened, until they were lately so sadly sundered.

DR. COTTING, unable to be present, sent the following:

In the death of Dr. George H. Lyman, the medical faculty lost an associate of generous impulses, gentlemanly bearing, of marked ability, and of exemplary loyalty to the profession. A believer in nature, he was no disbeliever in art. Quick to detect the dangerous tendencies of disease, he was actively alert in efforts to avert them. In public service, and in private practice, with the rich, and among the poor, he was alike diligent and devoted. Ambitious for usefulness, sympathetic in action, he ennobled his calling by published precepts and personal example. He was faithful in friendships, considerate of others, truthful and trustworthy. He will be long remembered.

DR. JOHN G. BLAKE said: I have already paid my tribute to the memory of our dear friend and associate in the columns of the *Medical Journal* in behalf of the staff of the City Hospital. But I would like to emphasize again the qualities of mind and heart for which we who knew him best, most esteemed him. The two strongest points in the character of Dr. Lyman are easily discerned. They were cheeriness and thoroughness. His comforting presence in the sick-room was very marked. It dispelled care both for patient and friend. We, who ought to know so well what anxious eyes follow every look and tone of the physician by the bedside, sometimes forget the importance

which those who are watching lay upon our manner. It is from it they are to derive strength and courage, or the reverse. Dr. Lyman never forgot this; and his cheerful nature never failed to leave the sick-room brighter for his presence. We all know how much this element of hope has to do with the well-being of the patient.

His thoroughness showed itself in every detail of his work. His few papers show not only the foresight which gathered information, but the sound judgment which made it available. Whether as historian or essayist, his work was always sure of respect. It was forcible and clear. In the more active duties to which he was called, as Medical Inspector during the war, as President of the Massachusetts Medical Society, and the Obstetrical Society, his time and thought were honestly given to whatever came within the province of his department. Those of us who remember his record in these places of trust, will not forget the painstaking attention to duty with which he filled his place. He was always in earnest. In these two respects alone, his life is a valuable lesson to the younger men of the profession who are about to enter upon active life. Enthusiasm and earnestness are two great factors of success in any profession, but especially in ours. Dr. Lyman possessed both; and it is largely for this reason that his memory will remain honored and beloved beyond ordinary limits among his colleagues.

DR. A. L. MASON said: My relations with Dr. Lyman were those of a friend of many years, as well as an intimate professional associate. His friendship, from my boyhood, was always sympathetic, considerate and constant, and I have a deep feeling of personal loss in his departure from among us. To his friends and to his patients Dr. Lyman was truly self-sacrificing and loyal. In their welfare he was untiring. With intense pride in his profession, he was zealous in maintaining its prestige and its honor. Although his death was in one sense premature, for he was still strong, erect and vigorous, he had already received the rewards of a life well-spent, in those substantial honors which gratified the ambition of his nature.

Dr. Lyman's early life was by no means without its struggles. He was born in 1819 at Northampton, and attended the Round Hill School, then famous. But, owing to his father's early death he adopted business pursuits which carried him to the far West, and he then acquired those habits of self-reliance, as well as a fondness for out-door sport, which he retained through life.

But, business was uncongenial to him and, in 1842, he joined an elder brother in the Medical Department of the University of Pennsylvania, where he graduated in the summer of 1843, and at once entered the Philadelphia Hospital as resident physician.

In November of the same year, however, he went to Europe, and to that time in his life he always looked back with pleasure. The journal which he kept in those days gives the picture of an enthusiastic, but discriminating, student, who made many friends, saw most of the distinguished teachers of the day in Paris, London and Dublin, and took in much that was entertaining and valuable in his two years of foreign study and travel.

But he was a strong and patriotic American. At first he was somewhat depressed by the loneliness which comes over a stranger in London. In his jour-

nal, under date of November 30, 1843, he says, "Although I am so old a traveller, I have slept on a blanket on the floor of a log cabin in Iowa Territory, miles from any other house, with less feeling of loneliness than I have to-night in the heart of the largest city in the world." This was at the age of twenty-four, nearly fifty years ago, when Iowa was indeed a wilderness. However, he soon adapted himself to the environment, and in writing of the great parks of London, says: "They are all rich and magnificent and their immensity in this crowded city would amaze our American citizens. Strange that we do not take advantage of the abundance of room which our cities afford, and that too at a comparatively small price, for the establishment of similar ones. Fifty years hence the want of them will be much felt." And so it is with us to-day, or has been until recently.

February 5th, he saw a murderer guillotined at the Barrière St. Jacques, and thus describes it:

"A firmly-built fellow of perhaps thirty years of age, stepped onto the platform very gaily, accompanied by the priest and one or two others. His neck was bared immediately and bent over into the clasp by the executioner, when by the touch of a rope the axe fell and severed his head from his body as smoothly and quickly as if it had been an apple. The head fell into a basket of sawdust on one side, and his body was at the same time pushed into a box of water like a bath tub on the other. He did not make a single struggle. Indeed, from the time the cart was escorted onto the ground by the mounted troops, until all was over and his body in the cart again, did not exceed five minutes. An awful sight from its very rapidity, though probably the most humane way of execution. Saw his body at dissecting-room this evening, hardly yet cold. He had committed many murders and the family are notorious villains. The first execution I have ever witnessed, and I hope it may be the last for I have had very queer sensations in the region of my neck all day. Noticed a gentleman and a lady there (at least to all appearance such), she with white gloves and an opera glass seemingly enjoying it very much. A worthy descendant of old Mother Eve."

After a visit to Père la Chaise Cemetery, he remarks that: "Not infrequently American names meet the eye, and one's sympathies are involuntarily excited by seeing the names of one's countrymen who have died so far from their firesides, with perhaps none but strangers to smooth their pillows."

Dr. Lyman himself died far from his fireside, but not among strangers, for everything that was possible was done by his professional brethren in London to relieve the sufferings of his last days.

Many interesting incidents, hospital experiences, meetings with celebrated people, and historical reminiscences are thus recorded from day to day.

Among Dr. Lyman's classmates and early associates was Dr. John T. Metcalfe, the distinguished physician of New York, who writes as follows to a member of Dr. Lyman's family:

"We entered the University of Pennsylvania in the fall of 1842. Our acquaintance began then, from the fact that we were under the same teachers and attended the same 'quiz.' Our private tuition was under the supervision of the late Drs. William W. Gerhard and W. Poynette Johnston, very eminent men. In the spring of 1843 we were graduated by that most ancient and honorable Medical School, diplomas from which

were reckoned generally to be second to those of no other American School of Medicine.

"After graduation we parted, to meet in Paris in December, 1843. There, too, we were thrown together by a community of masters. After a year in the French capital I induced Lyman to go with me to Dublin, where were to be found especially great facilities for the study of fevers and of practical obstetrics. . . . As a student, he was devoted to the work of his life. It was our habit to go to the hospital at 6 a. m. for clinical lectures from the great masters in medicine and surgery of those days. . . . In one way or another we worked honestly until 6 o'clock when our modest three-and-one-half-franc table-d'hôte dinner was disposed of. After that, as a rule, books were discarded for the day. . . . The thorough-bred gentleman, the man of wide reading, the *good, good* physician, the true friend, the honest man,—why should I mention those attributes with which all his *confrères* and friends were so familiar?"

Toward the end of 1845, Dr. Lyman was glad again to seek his own shores, and, from that time on, his life is a familiar one in this community.

After establishing a practice, he left it in 1861 to go to the war, during which he did his part.

Among the earlier acts of Congress, in 1861, was one providing for twenty brigade-surgeons to be commissioned by the President after an examination by a board of army surgeons. Dr. Lyman was the first to appear before them, and *this* commission was the first one signed by the great President Lincoln under that act, a matter of no little pride to its possessor.

In the Army of the Potomac throughout its organization, through the disastrous campaign on the peninsula, afterward as medical inspector in all portions of the country, he did efficient service, and after the end of the war he returned, like so many other gallant men, to find his practice broken up and his place filled. But, with renewed energy, he soon entered upon his later career, which was all the more honored and honorable from his past record, and this was to him in his final years a source of satisfaction beyond the transient disappointment which he felt on his return from the war.

In the Massachusetts Medical Society, and in the City Hospital of Boston he took the liveliest interest, and at the time of his death was on his way home to take his final term of hospital service before the completion of his fiftieth year in his chosen profession.

DR. J. C. WHITE made the following motion: "That a committee be appointed by the Chair to take action in connection with the recent death of our beloved and honored associate, Dr. Henry I. Bowditch." Seconded and voted.

The Chairman appointed as the committee, Drs. F. Minot, J. C. White, C. F. Folsom, F. C. Shattuck, R. W. Lovett.

DR. E. H. BRADFORD read a paper on

OPERATIONS ON THE TARSUS FOR CLUB FOOT.¹

DR. A. M. PHELPS, of New York, read a paper entitled

A METHOD OF OPEN INCISION FOR CLUB-FOOT.

The following is a summary:

Nearly thirteen years have elapsed since first I performed the operation of open incision for club-foot. The first cases were reported to the New York State Medical Society in a paper read in 1881.

These cases were treated before I knew anything about antiseptic surgery, and, strange but true, the results were almost equally as good as in the cases upon which we are now operating, following rigid antiseptic rules.

The dressings employed in these cases were splints, which fitted imperfectly, causing considerable pain. The incisions were much too long and more tissues were cut than necessary. The change in the operation as then performed, consists in making an incision commencing in front of the inner malleolus and extending one-third the distance across the sole of the foot, carried down to the neck of the astragalus, on its inner side. Through this small wound the abductor pollicis, tibialis posterior tendon, the plantar fascia, the flexor brevis muscle and long flexor tendons of the toe and finally the deltoid ligament, with all its branches, if necessary, can be cut.

Nothing will be gained by cutting the soft parts more extensively. This, of course, is done after subcutaneous tenotomy of the tendo-Achillis has been performed. Great force is used to rupture the deep ligaments, and if the foot cannot now be drawn to a supercorrected position easily, a linear osteotomy should be made through the neck of the astragalus. If this fails, a V-shaped piece should be removed from the os calcis, the point of the V meeting the linear osteotomy. This failing, the removal of the cuboid and scaphoid is indicated. And, as a last resort, Pirogoff's amputation should be resorted to.

In 198 cases of severe club-foot, nearly all of which had either been operated upon or treated for years

¹ To be published later.

with braces, I have found it necessary in only twenty-two to perform osteotomy. Osteotomy, including astragalus resection, ought never to be performed as a primary operation.

In a large number of pathological specimens which I have in my possession, the contraction and deformity of soft parts is out of all proportion to the deformity of the bone, and in two or three specimens of very severe talipes varo-equinus but slight deformity exists in any bone, but rather a dislocation of all bones, one upon the other, and slight changes in their articular facets.

An operation once decided upon, the foot should be supercorrected. Following this rule, cut the parts which first offer resistance, cutting in the order of those parts which first contracted when the deformity was produced, beginning with the tendo-Achillis. The equinus should be overcome as far as possible, first, for the reason that the ligament, extending from the tibia to the os calcis, when short, which it is in about one case in ten, must be ruptured, and not cut, because the nerves and blood-vessels lie close to it. The foot can be used as a lever, and with the hand or with a machine this ligament can be ruptured. If, as has been advised by some, an open incision is first made in the foot, and it is so weakened by an open cut that a sufficient amount of force cannot be applied to rupture the ligament without doing injury to the foot, the equinus cannot be corrected, and a relapse must follow. After subcutaneous tenotomy of the tendo-Achillis, if the skin is found short, make an incision, beginning in front of the inner malleolus and extending at right angles with the foot, one-third the distance across the sole, and carry it down to the inner side of the neck of the astragalus. Through this incision the tissues can be cut in the order already given. Great force should be used after cutting each tissue. If the foot cannot now be placed in a supercorrected position, linear osteotomy with the chisel should be performed through the neck of the astragalus.

If this fails, the next step is the removal of a V-shaped piece from the body of the os calcis, the point of the V meeting the linear osteotomy. If this fails, remove the cuboid and scaphoid bones, which I have found necessary to do in two cases, in adults.

It will be observed that the operation begins by manipulation, taking the various steps up to extensive osteotomy, and in exceptional cases, Pirogoff's amputation may be performed as a last resort.

If these steps are followed, osteotomy will be found necessary in only about ten or twelve per cent. of all cases, and in one-half of these a simple linear osteotomy, the least severe of all the bone operations, will suffice.

There has thus far been no death following the operation of open incision. As I have already stated, the mortality from osteotomy, or from astragalus resection, is from three to five per cent.

Inasmuch as the open incision method furnishes as good results as any operation known, is unattended with danger to the patient, and more than ninety per cent. of all cases are straightened without osteotomy, it certainly should be resorted to before osteotomy is attempted.

In the management of all cases of club-foot, begin with manipulation and fixed dressings; then subcutaneous tenotomy; open incision; and the various forms of osteotomy already enumerated. Thus you

will see that the legitimate place for open incision is between subcutaneous tenotomy and osteotomy.

Osteotomy should never be resorted to as a primary operation — not until the soft parts have been lengthened. The foot must be shortened in proportion to the amount of bone removed, or in removing the astragalus the entire limb will be shortened. It is not necessary to perform osteotomy in a greater percentage than ten, in all cases under the age of fifteen years.

To summarize my results up to the time of my report made at the International Congress (I have operated upon thirty-seven since reading that paper), I find that: In 93 cases there were 161 operations performed, the average age being six and a half years; the average time of healing the primary wound was four weeks; there were 117 cases of blood-clot organization; 4 cat-gut; and 19 failures of blood-clot organization in 140 cases.

The duration of after-treatment was ten months; on the fourth month after operating, the feet were all straight. Out of the 140 cases traced after one year, 10 cases were found relapsed, or partially so, from neglect. I will say that relapses, when they occur, take place during the first year after the operation, as a general rule.

DR. AUGUSTUS THORNDIKE read a paper on

A CASE OF ADULT CLUB-FOOT.²

DR. H. W. CUSHING reported

A CASE OF CLUB-FOOT CORRECTED BY OPEN INCISION.³

DR. A. M. PHELPS: Dr. H. W. Cushing said there was pain in this case. I have observed that in all cases where the operation has been performed so that the foot is supercorrected, if the foot is dressed in that position, there will be pain; but if you dress a little short of that, I do not think pain will be found. There are gentlemen who believe in the contractile treatment of club-foot, and I fully agree with them. We are, however, discussing a class of cases where we expect that the ordinary means of traction, etc., must necessarily fail. These are the relapsing forms. I do not believe it is a good plan to treat a club-foot seven or eight years with a club-foot machine when you can gain as good a result in much less time. The youngest case in which I have performed open incision was in a child of seven months. In any given case if the skin is short, it had better be cut. I place great emphasis upon that. I want to lay special stress on the fact that I do not think primary osteotomy is right. I think that the principle involved in Dr. Bradford's machine is excellent. I fully agree with Dr. Bradford as to the etiology of club-foot, and as to almost everything he said, but the osteotomies I should do as a secondary operation. I believe that is clearly right; and the sooner the profession is educated to that, I think the fewer deaths we shall have. If you take all the cases I have reported and do primary osteotomy, there must have been six to ten deaths, and it is a question how far we are justified in jeopardizing the life of the patient. If we can cure the patient and get equally good results without jeopardizing the life of the patient, I believe we should do that.

DR. E. H. BRADFORD: I have been misunderstood if I have been supposed to advocate primary osteotomy in this class of cases. All these relapsing and severe

cases of club-foot are those in which other methods have been tried.

In regard to open incision. In one or two of the cases where I have employed this method, I have made this modification of the method of Dr. Phelps which seemed to me to have a little advantage, and that is that the incision through the skin should be parallel with the axis of the foot, namely, on the outer edge of the foot. Instead of making a transverse incision, I have made the incision a little longer, and by hooks drawn it apart, then inserted my knife and cut a cross incision. In the cases I have done, I have had room enough to divide and cut down to the bone.

DR. A. M. PHELPS: The object of the incision is not for the purpose of getting at the tissues underneath, but to cut the skin because the skin is too short. That incision when made is for the purpose of lengthening the skin. If the wound gapes wide open, it easily fills in, and the scar is of no importance whatever.

DR. WM. N. BULLARD and DR. C. L. SCUDDER reported

A CASE OF SPASTIC CONTRACTION OF THE LOWER EXTREMITIES WITH REMARKS IN THE ETIOLOGY AND SURGICAL TREATMENT.⁴

DR. P. C. KNAPP: I agree fully with Dr. Bullard in the pathology of these cases of spastic paraplegia in children. I go even farther in being extremely sceptical as to the existence of any primary lateral sclerosis even in adults. The cases of spastic paraplegia in adults are in the vast majority of cases to be referred to a combined sclerosis or to the secondary changes in the lateral columns, following some other disease either of the brain or of the cord itself. I would agree also in his case that the hydrocephalus is far more likely to be the cause of the paraplegia than the spina bifida, but there is one point which occurred to me as a possibility. We have in the case a congenital enlargement, congenital dilatation of the ventricles of the brain in the hydrocephalus. We have, furthermore, a deformity in the lower portion of the cord in the spina bifida, and there is a possibility that there may also be an enlargement of the central canal of the cord with a hydromyelia, which would naturally give rise to symptoms similar to syringomyelia, perhaps spastic paraplegia. I think the neurologists are at fault for not referring many of these cases to the orthopedic surgeons for correction of the deformity. In some cases considerable can be done to make walking easier. When spastic paralysis affects the arms, it is in my mind a question whether much can be done. I recall one case, a woman with spastic hemiplegia whose hand was contracted in the usual position, and she was anxious to have something done for cosmetic reasons. The tendons were cut with partial success. It is in my mind somewhat doubtful whether that operation is one to be advised, because a hand contracted in the ordinary position of flexion is certainly a more useful hand than if the flexor tendons are cut, and in most of the cases there is still a little power to the flexor tendons, enough to get a little grasp and hold an object steady in the hand, and if those tendons be cut the power is very much less, and although it may make a little better looking hand to have it straightened out, the use of the hand is not nearly so great.

DR. BULLARD: There were no symptoms of hydromyelia, and no reason to suppose anything of the kind.

⁴ See pages 306 and 307 of the Journal.

DR. E. G. BRACKETT read a paper on
REFLEXES IN HIP-DISEASE.⁵

DR. LOVETT: I would like to know whether he has gone far enough to know whether that is an early symptom or not, whether it precedes the muscular spasm.

DR. BRACKETT: I think it is a condition that depends upon the same condition as that of muscular spasm. I think it is not of value in the old cases where there has been a great deal of atrophy. In those it is almost always a fact that the reflexes are very much increased.

DR. W. N. BULLARD: In cases where there is pain, the very fact of the pain is liable to increase the reflex. When there is very severe spasm, the reflex is not only increased upon the side in which the spasm is the worst, but you are liable to have a cert'n amount of increase of reflex in the other leg.

DR. E. G. BRACKETT: I have found that so in two cases.

DR. R. W. LOVETT read a paper entitled

A CASE OF TORTICOLLIS DUE TO HEMATOMA OF THE STERNO-MASTOID MUSCLE.⁶

DR. E. E. JACK read a paper on

FAULTY POSITION OF THE HEAD AND NECK, DUE TO THE EYES, AND CORRECTED BY TENOTOMY OF THE EYE-MUSCLES.⁷

DR. RICHARDSON showed a

RECURRENT TUMOR IN THE THROAT,

removed fifteen years after the original operation. The patient, a woman of about fifty, had had a small growth removed by Dr. Knight many years before. The pathologists in New York pronounced the disease a fibroma, while in Boston the tumor was considered a round-celled sarcoma. Dr. J. C. Warren made the microscopic examination. The tumor was so large that in the first place Dr. Charles Homans was obliged to put it in a tracheotomy tube, which she has worn ever since. About two years ago the mass began to trouble her again. It grew rapidly and could easily be seen and felt on the right side of the throat involving at least the pharynx and possibly the larynx. She consulted McKenzie last summer, and was advised by him to have an attempt made to remove the tumor. She decided to come home and have the operation performed here.

The growth was easily exposed by external incision, and delivered in front of the sterno-mastoid, the belly of which muscle was pressed outwards very noticeably. The pedicle was separated from the pharynx and oesophagus only by taking with the tumor a large portion of the pharyngeal mucous membrane. Haemorrhage was alarming, and the blood was kept out of the larynx and trachea only by holding the finger over the opening below the epiglottis. A catheter was left in the oesophagus.

The tumor proved to be a round-celled sarcoma, and its gross appearances before removal were very suggestive of this disease. The brilliant operation on a similar mass a little higher up which Dr. Warren easily removed, a large sarcoma of the tonsil, encouraged me very much in undertaking this case.

Recent Literature.

The Anatomical and Histological Dissection of the Human Ear. By DR. ADAM POLITZER. Translated from the German by GEORGE STONE. London: Ballière, Tindall & Cox. 1892.

Mr. Stone's by no means easy task, has been faithfully carried out and successfully accomplished. The character of the original work, its thoroughness, its attention to detail and the mass of minute and accurate information it contains, have required of the translator, a very careful following of the text and this has been done with due regard also to clearness and smoothness.

The first part is devoted, after a description of the necessary instruments, to an account of the various methods followed in the removal of the organ of hearing, with or without the naso-pharynx and Eustachian tubes, from the cadaver, either simply for anatomical purposes or without externally visible injury. This is followed by a chapter on dissection of the macerated temporal bone in the new-born infant and adult, and by nearly one hundred pages of text devoted to a most precise description of anatomical and pathological-anatomical preparations of the organ of hearing, and the first part of the book concludes with directions for making topographical sections for instructive purposes, and corrosive preparations, and with the consideration of the subjects of mounting and preservation, while the sub-chapter on histological examination includes the necessary advice as to fixing and hardening, decalcification, embedding, sectioning and staining. This is followed by the special chapters, about sixty pages, on the histological examination of the parts of the organ of hearing in succession, passing from the auricle inward, which include, as indeed does the whole work, the latest authoritative information on the subject.

The importance of a publication of this character to the aural surgeon to whom "practice in dissection work is indispensable," is justly set forth by the author when, in his introduction to the original work, he says, "The complicated character of the structure of the organ of hearing, and the involved nature of its connections with the adjoining structures and cavities, are such that they can only be intelligently studied by frequent practice in the preparation of specimens and it is only by unremitting study and manipulation of such specimens that it is possible to obtain the degree of confidence necessary to produce satisfactory results when performing an operation in such close proximity to organs of vital importance.

Treatise on Diseases of the Ear. By D. B. ST. JOHN ROOSA, M.D., LL.D. Seventh revised edition. New York: William Wood & Co. 1891.

The seventh edition of this valuable text-book has fourteen new illustrations and about twenty pages of additional reading-matter. The text is substantially the same as in the preceding edition, the more important changes being the addition of a paragraph on the subject of the removal of the ossecula in cases of suppurative middle ear disease and an enlargement of the chapters on the diseases of the mastoid process and on necrosis of the temporal bone and its consequences, both of which, containing as they do the author's experiences as well as liberal quotations from other recognized authorities, well repay careful reading and add much to the value of the present edition.

TUBERCULOSIS IN JERSEY CATTLE; TUBERCULIN AS A DIAGNOSTIC AGENT.

SOME instructive reports by experts and a judicious editorial upon an outbreak of tuberculosis among a herd of Jersey cattle, owned near Philadelphia, are published in the *Medical News* (March 26, 1892). The herd, known as the Clairemont, was established about 1882-83, and springs from a number of imported cows bought at that time. Frequent additions to the herd have been made, from time to time, of animals bought in various places, and none but the choicest individuals have been selected, for which high prices have been paid. All of the leading strains of Jersey bulls have been used.

Every precaution has been taken to preserve the health of the stock and to increase their constitutional vigor. Inbreeding has never been practised, and the stables and animals have always been cared for in the best manner.

The herd has been regularly examined by experts, and the present outbreak of tuberculosis was recently discovered. In the rare cases in which the disease has heretofore been detected, the affected cattle have been destroyed at once, and their places in the stable disinfected.

The use of tuberculin as a diagnostic agent was an interesting feature in this outbreak. Dr. Pearson, of the veterinary department of the University of Pennsylvania, was requested, several weeks ago, to examine a cow in this herd which did not seem to be doing well, and found it suffering from tuberculosis. The animal was killed the next day, and the diagnosis was confirmed by the post-mortem examination. Thereupon he made a careful physical examination of the entire herd, and found five cows affected with the same disease, all of which were promptly destroyed. A short time after this, a fat cow that would not breed was killed for beef, and it was discovered to be in a highly tuberculous condition. This caused him to suspect

that the disease might be more prevalent than he heretofore had reason to suppose, and with the object of detecting the affected animals it was decided to use tuberculin as a diagnostic agent. In all, seventy-nine cattle were tested with tuberculin, and of these thirty reacted in a manner that was interpreted as indicating the existence of tuberculosis. Six of these were slaughtered, and of this number five presented macroscopic evidence of the existence of tuberculosis: in regard to one animal there was some doubt, which a microscopic examination was expected to set at rest.

It was decided to kill all the suspected animals, to place the remaining healthy animals in disinfected stables, to have them frequently examined, and kept strictly apart from other animals.

The ultimate result in this instance should be instructive, as throwing further light upon the value of tuberculin for diagnostic purposes, and upon the possibility of thoroughly eradicating tuberculosis from a herd where it has once established itself. The example of the owner of the herd is a good one, and his action was at once public-spirited and intelligent.

This outbreak of tuberculosis calls to mind similar ones which have occurred from time to time among herds of Jersey cattle in this State — herds which, as with this Clairemont herd, were supposed to be under the best hygienic conditions. The questions of the ways by which tuberculosis is acquired, of the necessity for the inspection of meat and dairy products, of the assumption by the State treasury of the loss entailed by slaughtering infected animals, have occupied these columns at various times.

Last September we reviewed editorially the subject of tuberculosis in all its relations, as discussed at the International Congress of Hygiene; and, in the same and the preceding issue of the JOURNAL, a paper, by the late Dr. J. A. Jeffries, upon the ways in which tuberculosis is acquired, was published.

While indirect infection is probably the chief mode of infection, there is doubtless enough direct infection to make State inspection of meat and dairy products, and a system of adequate compensation desirable. It is easier, however, to affirm this general proposition than to define the conditions and limitations under which it should be exercised, or to find expert agents for the judicious and satisfactory execution of such provisions.

NEURALGIAS AND NEURALGIC AFFECTIONS.

At a recent meeting of the Medical College of Vienna, Benedikt read a paper on the above subject, in which he distinguished three kinds of neuralgias: (1) Of the nerve-trunks or plexuses; (2) of the nerve-rods; (3) of the terminations of the nerves.

In neuralgias of the nerve-trunks and plexuses there are not only pains during the attacks, but apart from the attacks there are painful points over the tract of the nerve. In most cases all the nerves which issue from a plexus are more or less affected.

The prognosis of idiopathic affections of the nerve-trunks and plexuses is very favorable when the specific treatment is applied from the first. Among the specific medicines, Benedikt mentions in terms of special approbation iodine and subcutaneous injections of phenic acid. The salicylates and antipyrine have a curative effect only when the natural duration of the affection is short. Narcotics should be given as little as possible, as they produce only a deceptive lull. The truly specific modes of treatment are galvanization and punctiform cauterizations. Benedikt compels the eschar following the cauterizations to suppurate for eight or ten days by means of an epispastic application, and never has recourse to more than one cauterization. This treatment is, in his estimation, so efficacious that when it fails one may affirm that there exists in the neighborhood of the nerve a lesion not yet appreciable, or a constitutional disease, and that this is the cause of the neuralgia.

Neuralgias of the nerve-roots are characterized by very intense intermittent pains without *points doloureux*. The nerve is painful to the touch, but this pain is alleviated by pressure. This variety of pain is met with in ataxia and in certain painful tics. These neuralgias at the commencement are unilateral; they denote often an alteration of the spinal meninges, in which case they do not coincide with neuralgias of the nerve-trunks and plexuses—while the eccentric idiopathic neuralgias are often associated with peripheral pains or invade the nerve terminations. The unilateral, eccentric, idiopathic neuralgias of the roots have no tendency to follow an ascending course. Galvanization employed against these neuralgias gives no result, while faridization *loco dolenti* exercises a calmative, but not curative, action. On the other hand, the electric cauterizations over the seat of these neuralgias have a very favorable action. The cauterization must be applied over the roots which contain the sensory fibres of the region affected.

In the neuralgic affections of the nerve terminations (arthralgias, aphalgalgias) cauterization has also a very satisfactory effect. Faradization and the electro-static douche are very efficacious against migraine. As most patients cannot stand the treatment during the attack, it is better to carry it out in the intervals of the pains, beginning with three *séances* per week, then two, then only one; but the treatment must be persevered with a long time, from nine months to a year in many cases.

THE WORK-VARIATION OF A CHILD'S HOUR OF STUDY.

THE investigation of this question,¹ the results of which are published by Dr. Burgerstein, of Vienna, in a paper originally submitted to the Section on Infancy, Childhood and School Life, at the International Congress of Hygiene at London, in August last, was under-

taken by him to determine the time during which a pupil should be kept at work continuously in one line of mental work. For this purpose two classes of girls and two classes of boys were selected; in all 162 children of from eleven to thirteen years of age. These children were kept at work upon simple mathematical problems (addition and multiplication) for one hour, the hour being divided into four periods of ten minutes each, with five-minute intervals of rest.

During the whole period these 162 pupils worked out 135,019 figures making 6,504 mistakes. It was found that the total number of calculations made by all the children increased, roughly speaking, 4,000, 3,000 and 4,000 in the different periods. During the third period of work, the increase of work done was not so great as during the other periods. The number of mistakes also increased 450, 700 and 350 in the different periods. Here again, during the third period, the quality of the work was at its lowest. From this experiment it would appear that children of the ages stated become fatigued in three-quarters of an hour; that the power of work gradually diminishes to a certain point during the third quarter of the hour, returning with renewed force in the fourth quarter. The author concludes that continuous work for children of these ages, even though the tasks are not difficult, should not last longer than three-quarters of an hour.

MEDICAL NOTES.

THE WOMAN'S MEDICAL SCHOOL AT JOHNS HOPKINS UNIVERSITY.—The trustees of the medical department of Johns Hopkins University received last May, about \$111,000 as a preliminary endowment obtained by the Woman's Fund Committee, for the purpose of securing for women medical instruction at the University. They also received a promise of \$100,000 to be paid in February of this year, on condition that the sum necessary to make up the half-million dollars should be raised by that time. The time is now past, and the money has not been raised.

A PLEA OF INSANITY.—At a recent trial in Wisconsin, at which number of men were indicted for murder on account of having taken part at a lynching case, the jury returned a verdict, finding that at the time of the lynching all of the defendants were insane, and therefore not guilty. They also found that since the crime was committed all but three had recovered their sanity, and were therefore discharged from custody.

DR. SHIBASABURO KITASATO.—Dr. Kitasato, who for six years has been doing bacteriological work in Berlin, largely in Koch's laboratory, and whose name has become widely known in connection with his work on immunity, has been recalled by the Japanese Government to take the direction of an Institute for Infectious Diseases in connection with the University of Tokio.

¹ Die Arbeits Kurve einer Schultunde, von Dr. phil. Leo Burgerstein, oberreal Schulprofessor in Wien, etc. Hamburg und Leipzig: Verlag von L. Voss, 1891, p. 46.

PROF. W. T. GAIRDNER, OF GLASGOW.—This year Professor Gairdner completes a period of thirty years continuous service at the University of Glasgow, as Professor of the Principles and Practice of Medicine. A committee has been formed to place on record the esteem and regard in which he is held by his former pupils, by presenting to the university a portrait of Dr. Gairdner, and also to found a scholarship in clinical medicine in the university.

RUSSIAN JEWS STOPPED ON THE GERMAN FRONTIER.—Owing to the prevalence of typhus fever, the German Government has prohibited Russian Hebrew immigrants from crossing the frontier. In consequence, the Russian frontier towns have become very much crowded, and it is feared that typhus fever will spread through all of the border towns. Most of the immigrants who have been stopped were on their way to America.

RIGID ENFORCEMENT OF IMMIGRATION LAWS.—Acting under orders from the Assistant Secretary of the Treasury, no more immigrants will be allowed to land simply on the assurance from some society that they will not become public charges. Any one who does not possess \$10, or who does not have a railroad ticket to his destination, will be detained and sent back to the country from which he came. It is said that under this rule the number of immigrants who may be sent back often amounts to as many as 500 on the days of the week when steamers are due.

RABIES IN PARIS.—According to the statistics of the Prefecture of Police, rabies has increased considerably during the past ten years. In 1880 there were 201 cases of canine rabies, and 61 persons were bitten. In 1891 there were 400 cases of canine rabies, and 143 persons were bitten.

THE ENGLISH PUBLIC EXECUTIONER.—Berry, who for some time has been well known in England as the public executioner, has resigned his position on account of the issuing of an order, authorizing medical officers of prisons to regulate the length of the drop required at executions. Berry has hanged two hundred criminals during the time in which he has held office. He has invented a few devices connected with the scaffold. He will now go on a lecture tour, and write a book.

NEW PUBLICATIONS.—With the month of March, the first copy of a new monthly appeared in Kingston, N. Y. It is to be known as the "Practitioners Monthly," and is edited by C. L. Dodge, M.D. and J. Chambers, M.D. *Annales de la Polyclinique de Lille*, a quarterly devoted to work done in the polyclinic at Lille, appeared for the first time in January. The Philadelphia *Polyclinic*, a journal of practical scientific medicine, edited by a committee of the Faculty and published quarterly by the Philadelphia Polyclinic and College for Graduates in Medicine, appears for the first time in March.

A PRODIGY CALCULATOR.—The Académie des Sciences, in Paris, have been examining Jacques In-

audi, the celebrated calculator. The most difficult problems in square and cube roots were given to him besides many such questions as, "If a person were given five francs every minute since the year one, how long would it be before he had the amount paid by the French to the Germans?" All questions asked him, he answered in an incredibly short space of time.

ANTI-CORSET MEETING.—We learn from a foreign contemporary that for a long time there has been a strong feeling in America against the corset, especially among the women of Canada. Recently in a town in Ottawa a largely attended anti-corset meeting was held, at which all the ladies present made a vow that they would no longer be slaves to that particular fashion. In the vicinity of the building in which the meeting was held, a large bon-fire was built, in which all the corsets belonging to the party were thrown.

INFANT MORTALITY IN FRANCE.—At a recent meeting of the Society for the Protection of Children in France, Dr. Rochard (Chairman) stated that France loses every year 250,000 infants, and that out of this number there are at least 100,000 whose lives could be saved with intelligent care.

THE TOXICITY OF THE BLOOD IN CASES OF ACUTE SUPPURATION.—Nissen¹ reports a number of experiments in which the blood of persons suffering from suppuration was injected subcutaneously and into the peritoneal cavity of mice. In all cases, blood from patients in the same clinic, but without suppuration, was injected as a control experiment, but in none of these cases was any effect produced upon the mouse. From the patient with suppuration, the blood was taken from a part of the body distant from the seat of the pus. In most of the cases, the mouse died within from two or three to twenty-four hours after a series of characteristic symptoms. After death, the mice showed hemorrhagic exudations, hepatization of large portions of the lung, enlargement of the spleen, and other indications that the injected poison may have been fatal by its action upon the blood of the animal.

BOSTON AND NEW ENGLAND.

MORTALITY FOR THE WEEK.—The death-rate for the past week in Boston has been unusually high, the total number of deaths reported having been 237, as against 196 the corresponding week last year, making the death-rate for the week 26.8. The number of persons who died over sixty years of age was 45.

DANGER FROM FUMIGATION.—In a small town, not many miles distant, a house was found to be on fire a short time after it had been fumigated. The following explanation, given at the investigation as to the cause of the fire, is an extract from the local paper: "The doctor thinks the fumes drove the rats from their holes, and becoming blinded, they jumped into the pan of burning sulphur, which adhered to their skins, and the rats returning to their holes, carried the blazing sulphur on their backs, thus setting the house on fire."

¹ Deutsche Med. Woch., No. 2.

MASSACHUSETTS LEGISLATURE. — The Committee on Public Charitable Institutions reported a bill authorizing the Governor to appoint seven trustees to erect at Medfield an asylum, at a cost of \$500,000, for one thousand chronic insane. The same committee reported an appropriation of \$10,000 for buying land and buildings at Westborough Insane Asylum. It was moved in the House to substitute a bill for the report of the Committee on Public Health leave to withdraw on the repeal of the compulsory vaccination laws. The substitute bill provides that school committees may exercise their discretion in allowing unvaccinated children to attend school. The matter was put upon the table. The same committee also reported inexpedient on the order prohibiting the manufacture of household articles in which arsenic is used. The Committee on Judiciary reported a bill providing that no attorney-at-law shall solicit employment for the purpose of enforcing a claim for damages against a person or corporation based on the negligence of any person or corporation. To violate the act, the solicitation must take place outside of the attorney's office.

TRICHINOSIS IN COLERAINE, MASS. — The epidemic of trichinosis which was reported a few weeks ago from the town of Coleraine is at an end, the last victim having died of the disease. There were in all four deaths, and about forty cases, most of which occurred in one large tenement block. An examination of the muscles of the case which has recently died showed them to be filled with trichinae.

NEW YORK.

A DEATH FROM CHLOROFORM occurred in the practice of Dr. A. H. Goelet on March 20th. The patient was a man of middle age, and the anesthetic was given by Dr. E. N. Delphy, in order to perform an amputation of the finger for gangrene.

A FALL FROM A WINDOW. — A man, thirty-four years of age, recently sprang, while delirious, from the window of an apartment on the third floor of his residence in Harlem, and his wife, while endeavoring to prevent him from doing so, was herself drawn out, and fell with him a distance of forty feet to the stone flagging below. Strange to say, neither were killed, and the husband was but little hurt. The wife was somewhat more severely, but not fatally, injured.

TYPHUS FEVER. — In his report on the health of the city for the week ending March 19th, Dr. John T. Nagle, Deputy Registrar of Records, says: "The deaths from typhus during the week were 13, which makes a total of 20 deaths from this disease since January 1st. Of the number of fatal cases, four were employees of the Board of Health, two employees of Riverside Hospital, North Brother Island, one of the Reception Hospital, and a policeman of the sanitary squad. These contracted the disease while in the service of the Board of Health, and their lives were heroically given as a sacrifice to their zeal in the discharge of their duties in guarding and protecting the public

from this terrible infection. Besides the four employees who have died in its service, there are still three of the employees of the department sick with typhus fever — one a sanitary policeman, and two employees of the Riverside Hospital, who contracted the disease while in the discharge of their duty. The disease, owing to the excellent and vigorous management of the Board of Health, seems to be stamped out, and the city saved from a typhus epidemic, which would not alone destroy many valuable lives, but would injure the commercial prosperity of the city. A singular observance of this disease was the very high percentage of deaths of the employees of the Board of Health, who contracted the disease from the Russian immigrants, and the low death-rate among the immigrants themselves. Whether this is due to enervation caused by overwork or to national characteristics, is not clear at present." Within a few days after this report the number of deaths from typhus was swelled to 29. As the total number of cases reported up to this time was 184, this is a mortality of 17½ per cent., and it may yet be increased to something like 20 per cent. by deaths among the quarantined patients and the attendants at North Brother Island.

Miscellany.

DRUNKENNESS AND CRIME.

SIR HENRY JAMES,¹ in response to a request for his opinion whether there is any general principle which is accepted by judges to regulate their decisions in cases where drunkenness seems to be an incentive to crime, has written a letter, in which he summarizes his views to the effect that in determining the legal character of the offence committed, drunkenness may be taken into account where it has established a condition of positive and well-defined insanity, or if it produces a sudden outbreak of passion occasioning the commission of crime under circumstances which, in the case of a sober person, would reduce the offence of murder to manslaughter; but in the case of minor assaults and acts of violence it can never form any legal answer to the charge preferred, but it may aggravate or mitigate the character of the act committed, probably aggravate it. As to the effect that should be given to drunkenness when determining the amount of punishment to be inflicted, he thinks no general rule can be laid down. Its existence may be considered, and may tend either in the direction of increasing or diminishing the punishment.

LESIONS PRODUCED BY THE TOX-ALBUMEN OF DIPHTHERIA.

WELCH² makes a further communication upon the work done under his charge in connection with the bacillus of diphtheria. Inoculation of the tox-albumen, free from bacilli and sterilized, were injected subcutaneously into guinea-pigs. The animal not only died but presented certain lesions in various parts of the body.

¹ Editorial, British Medical Journal, January 10th.

² Johns Hopkins Bulletin, March.

In cases in which animals have been inoculated with the bacilli, death usually occurs in one or two days. In inoculation with the toxic products alone, the inoculation period exceeded three weeks. The author concludes that it may be considered as established that the toxic products and not the bacilli themselves invade the tissues in diphtheria. This fact would at once suggest that the general lesions, (those produced at a distance from the seat of inoculation in animals and the situation of the local process in human beings), were the effects of the soluble poison diffused through the body. Hence it was desirable to demonstrate this assumption experimentally; and it is not unimportant to know that the lesions in the tissues produced by the bacilli and the toxic principle on the one hand and the toxic principle alone on the other are in perfect correspondence with each other. And, moreover, it would seem not to be superfluous to emphasize the occurrence of definite focal lesions in the tissues of the body produced by a soluble poison circulating in the blood.

THERAPEUTIC NOTES.

DISINFECTION OF THE MOUTH. — Dellevie¹ calls attention to several conditions, in which the mouth should be made as aseptic as possible. Several infectious micro-organisms are capable of living for indefinite periods in the mouth, in condition to carry infection if the opportunity presents itself. He has found that the following antisepsics may be used as mouth washes without injuring the teeth : corrosive sublimate 1 : 1500, B. naphthol 1 : 1000, thymol 1 : 1000, salicylic acid 1 : 350, saccharin 1 : 250, benzoic acid 1 : 100.

BENZOSOL, which has been introduced in Germany as a substitute for creasote, for the treatment of tuberculosis, is a white powder which is a chemical combination of guaiacol with benzoic acid.² It is said to possess all the therapeutic properties of creasote without its disadvantages. Hughes administers it as follows :

R. Benzosol	gr. lxxv.
Ess. menthae piperita	
Div. in trochesi no. x	gtt. ij.

M.

Sig. One or two tablets, immediately after meals, three times daily.

For a week, the patient takes three tablets daily ; during the next three weeks, six are taken daily ; during the fifth week, three are again taken daily ; finally, during the sixth week, none are taken ; then the same course is followed over again.

ACTION OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, UPON THE DEATH OF DR. D. HAYES AGNEW.

A SPECIAL meeting of the College of Physicians was held to take action upon the death of Professor Agnew who last year was President of the College. Dr. S. Weir Mitchell, President, occupied the chair. In opening the meeting he said :

" I have only to announce officially to the Fellows what is already known — the death of D. Hayes Agnew, sometime President of this College, and a Fellow since 1859.

" I leave to others to express in full the feeling of regret with which all medical men have heard of this loss. My own relations were those of friendly acquaintance and

more or less constant official connection as a Trustee of the University. I was made to feel that Dr. Agnew carried into his medical and official relations all the best qualities of a strong and vigorous manhood, and that the faith and creed by which he lived made itself distinctly felt wherever he went and whatever he did.

" Dr. Agnew seemed to me one of those well-balanced characters to whom the most brilliant success and the esteem of a nation bring no element of moral weakness.

" As a hard-working teacher of anatomy, from whom I rented a laboratory when neither of us was much known of men, I used to see him daily. In the closing years of his life of vast utility I was often called upon, as Chairman of the Committee on the Medical Department of the University of Pennsylvania, or as Vice-President of this College, to act and work with him. In the long interval of years between our early work and achieved success, we met but rarely, or as busy doctors do meet, but on renewed and closer intercourse I found him still the same man — stronger, more competent, but morally unchanged from what he was when we first met.

" As President of this ancient College I like to think of him as continuing the long line of illustrious physicians who have given to this chair an ever-growing value. Dr. Agnew was, I find, the third surgeon who had the honors of your Presidency. William Shippen, 1805, was second President ; Thomas Hewson in 1835, succeeded as sixth President. Then, save Dr. Ruschenberger, a naval surgeon, all have been physicians until Dr. Agnew's date. He became the thirteenth President in 1883, and served his full term."

This was followed by brief addresses by Dr. John Ashurst, Jr., Dr. W. W. Keen, and Dr. Alfred Stille, who submitted the following minute, which was adopted :

" The death of Dr. Hayes Agnew, recently President of this College, in the seventy-fourth year of his age and after a life crowned with honor and usefulness, calls for an expression of the sense entertained by the College of the gravity of the loss which it suffers, in common with the profession he adorned, the charitable institutions he served, and the community in which his skill did so much to lessen suffering and death.

" He began his professional life with no adventitious aid, yet by incessant industry, indomitable perseverance and singleness of purpose he attained to its highest rank. No temptation distracted his attention from the goal of his life ; neither extraneous sciences, nor general literature, nor the allurements of art, nor the pleasures of society. The undivided strength of his mind and his affections were devoted to enlarging the domain of surgery, not only in its operative methods, which he always subordinated to the welfare of his patients, but also in preparing for his profession a literary monument that might speak for him when his voice should be no longer heard.

" His minute acquaintance with anatomy, and his ambidextrous skill enabled him to perform with ease to himself and safety to his patients, operations which less accomplished surgeons hesitated to undertake.

" He possessed a certain magnetism of manner, quite independent of formality, that evidently proceeded from the heart, and drew all hearts to himself. Never frivolous, but always cheerful, he was dignified, grave and earnest, making all who heard him as a teacher and speaker, or in familiar intercourse, recognize in him, above all other things, the upright man. For he possessed the eloquence of conviction and the force of absolute honesty in all his statements, and thereby drew to himself an enthusiastic admirers and disciples the successive classes of students whom he taught."

Professor Agnew was in the seventy-fourth year of his age. He suffered some months since with influenza, resulting bronchitis, but believed that he was recovering from it, and was about as usual, attending to his patients, when about a week before death he grew worse. It was not thought that the illness would be fatal until two days before death occurred, when angina attacks supervened, and he finally died of uræmia. At the autopsy it was

¹ Deutsche Med. Zeitung, February 22d.

² La Semaine Médicale, January 13th.

found that his suffering was partly due to atheroma of the cardiac valve and coronary arteries. There was marked renal degeneration, and pelvic inflammation caused by a renal calculus.

The funeral services were held at the Second Presbyterian Church, of which he had been a member, and were largely attended by his medical friends, among whom were noticed Dr. A. Jacobi, of New York, and Dr. Hunter Maguire, of Richmond, Va.

OBITUARY. JOHN AMORY JEFFRIES, M.D.

JOHN AMORY JEFFRIES, M.D., M.M.S.S., died of pneumonia, in Boston, March 25th, aged thirty-two years. Dr. Jeffries graduated from Harvard College in the class of 1881, and from the Medical School in 1884. After a year spent in Europe he settled in Boston, where he had since practised. At the time of his death he was Physician in the Department of Nervous Diseases at the Boston Dispensary and Assistant Physician to the Nervous Department of the City Hospital. He was a member of the American Neurological Association, the American Pediatric Society, the American Association for the Advancement of Science, the American Association of Naturalists, and of several Boston medical and scientific societies. He had written several papers both on medical and on scientific subjects, and had been a frequent contributor to the *Journal*.

Dr. Jeffries had, from an early age, been a student of natural history. Even before he entered college he was well known as an ornithologist. In college he did much original work and received highest honors in natural history. After graduating from the Medical School his previous training and his familiarity with the microscope led him to devote what time he could spare to bacteriological study, in the School laboratories. In practical medicine he was especially interested in nervous disease.

He was a hard worker. As a student of science his judgment was good, his reasoning clear, and his methods thorough; he was not led astray by enthusiasm. Had he lived he would undoubtedly have made valuable contributions to scientific medicine.

He leaves many friends both in and out of the profession who sincerely mourn his loss.

Correspondence.

FEMORAL AND VENTRAL HERNIA IN WOMEN.

NEW YORK, 18 East 32d St., March 22, 1892.

MR. EDITOR:—Having read the recent paper upon "Femoral and Ventral Hernia in Women" by Dr. H. O. Marcy, of Boston, I beg the courtesy of your columns for a few remarks suggested by that paper; and I trust they will be received by the author of it in the same friendly spirit in which they are given.

Without attempting any thorough review of the paper, I desire simply to point out certain defects, or, perhaps better, certain omissions which to my mind seriously weaken the arguments which Dr. Marcy has set forth in favor of operative procedure in the treatment of femoral and ventral hernia.

The first and most important omission is in regard to the result of his operations. Although he states that he "began to use the buried animal suture in operating for the cure of hernia in 1871," and has continued to use it since, nothing is said as to results other than the general statement, that, so far as he has been able to learn, there has not been a single recurrence. Without giving the number of cases operated upon, as well as the number followed beyond the

¹ Reprint from Transactions of American Association of Obstetricians and Gynecologists, 1891.

period when relapses may occur, such general statements are valueless so far as any scientific estimate of the efficacy of the operation, is concerned.

Although Dr. W. T. Bull's results are seriously criticised, it is well to bear in mind the fact that his is the only large collection in this country, where the cases have been followed a sufficient length of time to enable one to draw satisfactory conclusions. In his article, "On the Radical Cure of Hernia, with Results of One Hundred and Thirty-four Operations,"² Dr. Bull stated that with the methods he had tried there was no prospect of attaining a radical cure of any form of hernia; yet he admitted that the attempt to cure was desirable and every worker in this field has been watched with the greatest interest, in the hope that some one would one day discover the prize that others had looked for in vain.

Yet one who is familiar with the literature of hernia, who has followed the history of the so-called "Radical Cure," and has seen one method after another evolved, run a similar course of praise, approval, neglect, and then after a brief life-history pass into the list of obsolete operations — such a one will be pardoned for being somewhat skeptical, or at least not over-sanguine, when a new method is proposed, particularly when that method has not been subjected to the test by which the preceding methods have been tried and found wanting, namely, the test of time.

The history of Wood's operation, which has been more extensively tried, and received perhaps more nearly universal approval than any other, is significant. To quote a recent writer: "Many tried it, and as now with the open method, asserted their success; but Mr. Kingdon of the London Truss Society demolished their pretensions one after another by the stern logic of facts, and the men who were reported as successful examples of the radical cure were fitted by him with trusses. Time has proved the truth of its failure."

It seems to me that no new method should be entitled to serious consideration until it has been subjected to this test of time.

It must not only show, as many other methods have shown, seventy, eighty, or ninety per cent. of so-called "cures"; but, sufficient time having intervened, those "cures" must be followed up, and shown not to have relapsed. Dr. Bull, in his paper upon "Cases of Hernia which have Relapsed after Various Operations for Radical Cure,"³ emphasized the importance of this element, time; and he showed that until the five-year limit had been passed a *cure* could not be asserted with confidence. During the past year upwards of fifty cases of relapsed inguinal and femoral hernia have been treated at the Hospital for Ruptured and Crippled. Among these were many that had been published as "Cures."

In regard to the method of operating upon femoral hernia advocated by Dr. Marcy, there is nothing essentially new in this method. The principle of closing the femoral canal by means of buried sutures, both silk and animal, has been repeatedly tried, and the recent statistics of hernia operations at Billroth's Klinik, from 1877 to 1889, reported by Haidenthaler,⁴ are directly in point. Of fifty-four cases of femoral hernia treated in part by suture of the canal, and in part by simple excision of the sac and closure of the external wound, thirty-seven and one-half per cent. of the cases in which the canal had been sutured relapsed, while only twenty per cent. of recurrences followed the simple excision of the sac.

If better, or even as good, results follow the simpler operation, it may well be doubted if it be wise to attempt a complicated suture which in the hands of any but the skilled anatomist would add to the risk of the operation.

The principle of operating upon most cases of ventral hernia is open to serious objections. The risks associated with conservative treatment in these cases are, I think, greatly over-estimated. In a very large number of cases of adherent and irreducible umbilical hernia treated at

² Medical News, July 5, 1890.

³ New York Medical Journal, May 30, 1891.

⁴ Archiv. f. Klin. Chirurg., 1-90.

the Hospital for Ruptured and Crippled, strangulation is an extremely rare occurrence. This, added to the fact that ventral hernia, by no means infrequently follows abdominal section, even in the hands of the best surgeons and in favorable cases, makes it reasonable to doubt the advisability of extending the "Radical Cure" to the class of cases in question.

In conclusion, let me say that I hope this will not be regarded as an attempt to discourage the operative treatment of hernia in general, but only an effort to emphasize the importance of submitting all methods of operation, to the test of time, and of judging their relative merits by the number of relapses. Very truly yours,

WILLIAM B. COLEY, M.D.,

Assistant Surgeon to the Hospital for Ruptured and Crippled of New York (Hernia Department).

INDUCEMENTS FOR ADVERTISING.

BROOKSIDE, MASS., March 23, 1892.

MR. EDITOR:—Well knowing your progressive spirit, which enables you to keep the JOURNAL abreast of the times, I send you the enclosed, which may supply a few hints for the advertising department.

Louisville, Ky., March 17, 1892.

DEAR DOCTOR:—If you will advertise with us, we will take three-quarters of the amount of advertising out in board and medical services, and one-quarter in cash; the boarder to be a deserving and agreeable one. We could not well enter into an arrangement differing from the above unless you desired to pay all cash, in which case you will please notify us of your desire. Independent from the above, could you propose a compensation for any business we might send you through personal efforts. We reach every one of the 3,117 doctors in Kentucky and circulate extensively throughout ten Southern States. Enclosed please find rates. Send for a sample copy. It is a stylish one. Observe its editorial management and the good business it contains. Although you are some distance from here, the reputation of your institution should fill it with patients from all parts of the country. A reply by return mail will greatly oblige.

Your friends, THE M. P. CO.

Board and washing will be exchanged hereafter for half-page advertisements. The rates will vary according as the person to be boarded and washed is simply weak-minded or very much excited. In the latter case I should expect a cut to be furnished with the advertisement. Driveling idiots with large appetites will not be admitted. Towels and soap furnished by the management, but patients are expected to bring their own water. How does this kind of exchange strike you? Yours truly, C. W.

A GERM MANIAC.

NEW YORK, March 22, 1892.

MR. EDITOR:—I enclose some verses entitled, "A Germ Maniac," which were written when taking a course in bacteriology in the Michigan University Medical School.

For five long hours I work on germs

In hanging drop of rich beef-tea;
Germs which, beneath the microscope,
I strain my eyes to see.

I bake them, boil them, roast them too,
Or poison those I find;
I steam them, cage them, then go home,
And leave the germs behind.

Behind! Oh woe, oh woe is me!
They go where'er I go,—
Before, behind, without, within,
Around, about, below.

Thousands and thousands in my mouth,
And thousands in my hair!
I fear to breathe them in my lungs,
With every breath of air.

I know they rest upon my cheek,
I brush them with my hand;
They're on the hand! — I wash them off;
But water is their land.

I seek the cooling air of night;
The earth is dark, the hour is late;
The stars upon the heavens lie,
Like germs upon a plate.

Germs, germs by day and germs by night,
Germs in my brain must be,
Unless I think of something else
They'll make a "stick" of me!

I have felt that they might express enough of the universal feeling of beginners in bacteriological studies to find a place in your Journal. Respectfully, H. B.

RECORD OF MORTALITY FOR THE WEEK ENDING SATURDAY, MARCH 19, 1892.

CITIES.	Estimated population for 1890.	Reported deaths	Percentage of deaths from					
			Deaths in sev. under five years.	Infectious diseases.	Acute lung diseases.	Scarlet fever.	Diarrhoeal diseases.	
New York	1,515,361	885	32	16.83	20.46	2.75	2.69	4.73

Deaths reported 3,028: under five years of age 1,121; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 452, acute lung diseases 601, consumption 331, diphtheria and croup 171, scarlet fever 54, typhoid fever 46, diarrhoeal diseases 43, measles 33, erysipelas 23, cerebro-spinal meningitis 22, whooping-cough 16, typhus fever 13, malarial fever 6, puerperal fever 3, small-pox 2.

From Typhoid fever Chicago 18, New York 7, Springfield 4, Brooklyn 2, Cincinnati and Washington 3 each, St. Louis 2, Cleveland, Pittsburgh and Charles'ton 1 each. From measles New York 24, Brooklyn 6, Chicago 2, Cleveland 1. From erysipelas New York 8, St. Louis 4, Boston 3, Chicago and Brooklyn 2 each, Milwaukee, Worcester, Cambridge and Quincy 1 each. From cerebro-spinal meningitis Chicago 7, New York 6, Brooklyn and Washington 2 each, St. Louis, Cleveland, Worcester, Taunton and Gloucester 1 each. From whooping-cough St. Louis 4, New York 3, Chicago, Boston and Washington 2 each, Brooklyn, Cincinnati and Pittsburgh 1 each. From typhus fever New York 13. From malarial fever New York and Brooklyn 3 each. From small-pox New York 2.

In the thirty-three greater towns of England and Wales with an estimated population of 10,185,735, for the week ending March 12th, the death-rate was 22.9. Deaths reported 4,469: acute diseases of the respiratory organs (London) 454; whooping-cough 170, measles 113, diphtheria 48, diarrhoea 42, fever 15, scarlet fever 13, small-pox (London and Liverpool 2 each, Oldham 1) 5.

The death-rates ranged from 16.5 in Newcastle-on-Tyne to 32.8 in Swansea; Birmingham 20.5, Bradford 24.7, Hull 19.9, Leeds 23.6, Leicester 19.7, Liverpool 30.0, London 22.1, Manchester 27.2, Nottingham 26.7, Portsmouth 19.1, Sheffield 19.9.

METEOROLOGICAL RECORD,

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 19, 1892, TO MARCH 25, 1892.

CAPTAIN BENJAMIN MUNDAY, assistant surgeon, U. S. A., granted leave of absence for one month with permission to apply for an extension of one month.

FIRST-LIEUT. F. DE WITT, assistant surgeon, U. S. A., granted leave of absence to include May 16, 1892, at which date his resignation has been accepted by the President to take effect.

PROMOTIONS.

LIEUT-COL. JOSEPH C. BAILEY, assistant medical purveyor, to be surgeon with the rank of Colonel, March 9, 1892, Vice Morris retired from active service.

MAJOR WILLIAM D. WOLVERTON, to be assistant medical purveyor, with the rank of Lieut-Col., March 9, 1892, Vice BAILEY promoted.

CAPTAIN JOHN O. SKINNER, assistant surgeon, to be surgeon, with the rank of Major, March 9, 1892, Vice WOLVERTON promoted.

APPOINTMENTS.

To be assistant surgeons with the rank of First-Lieut., FRANCIS A. WINTER of Alabama, March 9, 1892, VICE DE HANNE retired from active service. WILLIAM E. PURVANCE, of Illinois, March 9, 1892, Vice STEINMETZ, retired from active service.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 26, 1892.

A. A. HOELING, medical inspector, ordered as president, Naval Medical Examining Board.

J. L. NEILSON, surgeon, ordered as member and recorder of Naval Medical Examining Board.

T. C. WALTON, medical inspector, granted six months' extension of leave, with permission to remain abroad.

CHARLES PERRY BAGG, of Los Angeles, Cal., commissioned an assistant surgeon in the Navy.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF PHYSICAL EDUCATION.

The Seventh Annual Meeting of this Association will be held April 7-9, 1892, at the Drexel Institute of Art, Science and Industry, Philadelphia.

Five sessions of the American Association for the Advance-

ment of Physical Education will be held at the Drexel Institute, beginning on the evening of Thursday, April 7th, which evening will be devoted to an address by the President of the Association, and to a reception given by the Drexel Institute to the members of the Association and invited guests. At the second session, on Friday morning, April 8th, topics of a general nature will be considered. The afternoon session on Friday will be devoted to papers and discussions (a) on Delsartism and its Relations to Physical Education, and (b) on the Athletic Question. The evening of Friday will be given up to an exhibition of School Gymnastics. The fifth public session, on Saturday morning, April 9th, will be devoted to the consideration of some Educational aspects of Physical Training. Free discussion of all papers will be invited.

The Pennsylvania Railroad Company offers special rates to parties of fifty or more.

The Continental Hotel, Philadelphia, which offers a per diem rate of \$2.50 (American plan), will be the headquarters for visiting members of the Association.

A cordial invitation has been given to the members of the American Association for the Advancement of Physical Education, by the Woman's College, the Bryn Mawr School for Girls, and the Maryland Asylums for the Blind, all of Baltimore City, Maryland, to visit and inspect the grounds and the above-mentioned institutions on Thursday, April 7, 1892.

Members may arrange to accept the Baltimore invitation, and proceed to Philadelphia in season to attend the first public session of the Seventh Annual Meeting of the Association at 8 P. M.

Inquiries and applications for membership may be addressed to the Secretary of the Association, at Cornell University, Ithaca, N. Y., or to the President, 5 Brimmer Street, Boston, Mass., or to Mr. Thomas, Chairman of Local Committee of Arrangements, Girard College, Philadelphia.

EDWARD M. HARTWELL, *President.*

EDWARD HITCHCOCK, JR., *Secretary.*

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.—The annual meeting will be held Monday, April 4, 1892, at 8 o'clock, at 19 Boylston Place.

Dr. W. H. Baker: "Hypertrophic Elongation of the Cervix Uteri, a new operation for its relief!" Discussion by Drs. C. P. Strong, G. H. Washburn and F. H. Davenport.

Dr. C. J. Blake: "Acute Congestion of the Upper Portion of the Tympans."

Selection of officers.

Electoral of honorary and associate members.

Report of auditing committee.

JOHN C. MUNRO, M.D., *Secretary.*

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.—There will be a meeting of this Section at 19 Boylston Place, on Wednesday evening, April 6, 1892, at 8 o'clock.

Dr. Alfred Worcester, of Waltham, will report cases of Appendicitis, and will urge early operation.

Dr. J. W. Elliot and Dr. M. H. Richardson: "Conclusions from a Study of Cases of Appendicitis."

Dr. E. O. Otis: "A Case of Broken Neck with Autopsy."

Dr. W. L. Walton will report additional cases of Cervical Dislocation, with Recovery, and will show photographs illustrating the characteristic deformity.

CHARLES L. SCUDDER, M.D., *Secretary*, 94 Charles Street.

RECENT DEATHS.

J. ROBERT EMBREE, M.D., died in Colorado Springs, on March 20th, aged thirty-three years. He graduated from the College of Physicians and Surgeons in New York, in 1883. He served as house-surgeon at the Chambers Street Hospital for three years and later as physician at the New York Hospital.

John AMORY JEFFRIES, M.D., M.M.S.S., died March 25th, aged thirty-two years.

DAVID C. COMSTOCK, M.D., of New York City, died March 24th, aged fifty-two years.

LEDYARD VAN RENSSLAER, M.D., of Burlington, N. J., died March 24th, aged forty-eight years.

CARL CHEDÉ, M.D., Professor of Obstetrics at the University of Leipzig, died March 14th, aged seventy-two years. He had achieved a world-wide fame in obstetrics, his name being associated especially with a method of expressing the placenta.

NOTES ON TYPHOID FROM 676 CASES ADMITTED TO THE BOSTON CITY HOSPITAL IN 1890 AND 1891.¹

BY A. L. MASON, M.D.

As typhoid fever is chiefly a hospital disease, few physicians being called upon to treat a large number of cases in their private practice, it is interesting from time to time to compare the hospital reports from various sources with reference to the average results attained, so that by the light of general experience and progressive therapeutics we may try to determine how far our methods may be improved, and whether it is a duty to insist upon any systematic plan of treatment with the hope that a further saving of life may be effected as has been elsewhere claimed. I refer especially to the bath-treatment of Brand, and to intestinal antisepsis. With the exception of 87 cases reported by Drs. Edes and Stedman, in the Boston City Hospital Reports, Vols. II, III, Brand's system of immersion in the cold bath has not been adopted at the City Hospital, but pyrexial symptoms have been met by cold sponging and affusions, with the internal administration of antipyretics, antisepsics and tonics. Such other dietetic, stimulating and symptomatic measures have been applied as each individual case has demanded.

With the co-operation of my colleagues and the valuable assistance of Dr. Augustus S. Knight, who has given much time and attention to this subject, I am able this evening to present the results in a series of cases extending through the last two years.

During 1890 and 1891, 676 cases of typhoid fever were entered upon the records of the City Hospital. Of these, 70 were fatal, 10.4%. This includes all cases, mild, moribund and doubtful, which entered the hospital during those years.

The diagnosis, "typhoid fever," is made provisionally in a certain number of cases which result fatally, but which present symptoms by no means always typical of that disease, some entering in a moribund, others in a delirious or unconscious state. Of such cases there were 18 in the present series, 15 moribund, that is, dying within three days after admission, and at least three of doubtful diagnosis. There were autopsies in three of them only, and where post-mortems are few, owing to the law which requires the written consent of friends, verification of the diagnosis is often impossible. Indeed, there were but 15 autopsies out of the 70 fatal cases, therefore the notes which follow must be mainly clinical rather than pathological.

During the same period, 47 cases were classed as "febricula," a diagnosis which probably covers some abortive typhoids.

In 33 cases, according to the charts, defervescence took place before the sixteenth day, but the date of commencement was often inexcavably determined, and these cases, which were entered in the books as "typhoid fever," are included in the series.

So many accidental circumstances affect the result in typhoid fever that it seems almost impossible to determine numerically the proportion of recoveries which may be due to therapeutic measures. Such factors are the age, sex, and previous condition of the patient, the

period of the disease when he comes under treatment, and the concurrence of other afflictions which lessen the chances of recovery. The virulence of the disease may vary at different times and in different countries, so that no practical conclusions can be drawn from a small number of cases. How large that number should be in order to eliminate chance is also uncertain.

Thus if we divide our 676 cases into thirteen series of 50 cases each, it is found that the mortality in the different series varied from 6% to 20%.

Between six series of 100 consecutive admissions each the death-rate ranged from 6% to 14%; whereas three series of 200 cases each differed by one per cent. only, namely: 10%, 10.5% and 11% respectively. But in two series of 300 cases each there was a difference of more than two per cent in the mortality, namely: 9½% and 11½% respectively.

In the hospital there are three medical services to which the cases, as admitted, are allotted in turn. To show still further the fallacy which may arise from the attempt to draw conclusions from small numbers of cases I may state that one of the services received 54 consecutive cases without a death. Six of these patients had relapses. Again there were:

31 cases without a death.
42 " with one death, equal to 2.4 per cent.
30 " " one death, " 3.3 " "
46 " " two deaths, " 4.3 " "
39 " " one death, " 2.5 " "
326 cases, with five deaths, equal to 2 per cent.

These figures do not compare unfavorably with some results of which we read as having been brought about by Brand's method in no larger numbers of cases. But as before stated the mortality in our whole series was 10.4%.

For purposes of comparison, I have selected the very interesting statistics of Dr. F. E. Hare, of the Brisbane Hospital, Queensland,² as being impartial, logically drawn up, and relating to a sufficient number of cases to admit of practical conclusions. In that institution before 1887, under the expectant plan, it was found that in three series of 600 cases each the death-rate varied between 14.3% and 15.3%, or only one per cent. So the conclusion was that groups of 600 cases were large enough to allow an estimate of the comparative effects of treatment when Brand's method was adopted, since the probable error from accidental causes would be small.

Therefore our series of 676 cases may be regarded as a suitable number for comparison in the future or with the records of the past, while the results in smaller groups of 100, 200, or 300 cases may so vary as to be of little value.

GENERAL CONSIDERATIONS.

Season.—Although typhoid fever is an autumnal disease, I think that more cases than formerly come to the hospital in the winter and spring months. Thus in these two years the admissions have been as follows:

January	17	July	63
February	16	August	97
March	20	September	165
April	12	October	139
May	22	November	63
June	27	December	29
Total, 676; 40, or 60% in August, September and October; 227, or 33%, between July 1st and November 1st.			

¹ Read before the Boston Society for Medical Improvement, January 25, 1891.

² The Practitioner, March, 1891.

Locality. — The records contain little evidence that typhoid fever was contracted away from the city in any large proportion of cases. About ten per cent. were recently arrived immigrants or "transients," that is, persons who had been in Boston less than one month. Some of these may have brought the disease with them, and others may have picked it up during visits to the country, but probably nine-tenths of the cases originated in Boston.

The 70 fatal cases were distributed as follows:

City proper	33
South Boston	12
Roxbury	8
Charlestown	6
East Boston	4
Suburban	4
Hull	1
Unknown	2
Total	70

Among these were:

Recent immigrants, or "transients"	6
Residents of less than 1 year	6
" " 5 years	20
" " 10 years	10

Total	42
-----------------	----

The birth-places of the fatal cases were as follows:

Massachusetts (11 of foreign parents)	19
British Provinces	19
Ireland	19
United States (outside Massachusetts)	7
England	1
Scotland	2
Sweden	1
Russia	1
Unknown	1
Total	70

Age. — Early age has an important bearing on the prognosis, as has been a matter of common observation. Hölscher's 2,000 autopsies in patients who had died of typhoid showed but six girls and two boys under ten years of age. Among these were two infants of two months and nine months respectively. Fifty-six cases were over fifty years of age, and three over seventy years.

The mortality according to ages in our series is appended.

Age.	Cases.	Deaths.
Under 5	2	0
5 to 10	18	6
10 to 15	45	2
Totals	65	2 = 3%
15 to 20	120	13
20 to 25	207	25
25 to 30	137	9
30 to 35	59	8
Totals	523	55 = 10.5%
35 to 40	32	1
40 to 45	14	1
45 to 50	9	2
50 to 55	8	2
55 to 60	2	1
60 to 65	2	0
70 to 75	1	0
Unknown	20	6
Totals	88	13 = 14.8%

It will be seen that the small fatality among children and the high death-rate after thirty years of age counterbalance each other, leaving the general mortality as stated above at 10.4%.

Of the two patients who died before or within the

^a Münchener Med. Wochenschrift, January, 1891.

sixteenth year, one was a boy of fifteen who entered during a relapse in the fourth week and died on the thirtieth day from pulmonary oedema and exhaustion. The other was a girl of thirteen years who came in on the sixth day and died on the twenty-ninth day of simple pyrexial exhaustion.

Between the ages of fifteen and twenty there were 120 admissions and 13 deaths. Seven of these were females, all of whom died of pyrexial exhaustion, complicated in one case by tuberculosis and in another by pneumonia and pregnancy. Of the six males two had no complications. One was a very doubtful case with symptoms indicating meningitis, fatal on the ninth day. Two died from perforation of the bowel at the age of nineteen, and one from intestinal hemorrhage at the same age, this being the earliest period of life at which these fatal accidents occurred.

Between the ages of twenty and thirty, 344 patients entered and 34 died, namely, 12 males and five females from febrile exhaustion; two males and three females from perforation; nine males and one female from intestinal hemorrhage; two with chronic Bright's disease. Of the above number, two had also delirium tremens and two pneumonia.

Beyond the age of thirty were 127 cases with 15 deaths, or 11.8%. With advancing years other degenerative changes were more frequent factors in producing the fatal result. Thus phthisis, chronic Bright's disease, chronic mitral insufficiency and sudden syncope from cardiac weakness were accountable for one death each. Two died with delirium tremens; two from perforation of the bowels; three from hemorrhage; six from febrile exhaustion, which was complicated in one case by pneumonia and in one by syphilis.

Time of Admission. — Other things being equal, delayed admission is regarded as greatly increasing the danger of death from exhaustion in typhoid fever.

Let us see the bearing of our figures upon this point. The records state that the patients entered as follows:

DATES OF ADMISSION.		
	Cases.	Deaths.
First week	269	30 = 11%
Second week	294	22 = 7.4%
Third week	87	9 = 10.3%
Fourth week	12	3 = 25%
Not stated	14	6 = 43%
Totals	676	70

Thus more than one-third of our cases entered during the first week, but still the mortality was higher than among those who entered during the second and third weeks. This may be accounted for in two ways: (1) By error in statement as to the beginning of the disease; (2) By the fact that the severer the onset the earlier patients seek the hospital.

The mortality was highest among those who entered in the fourth week and those about whom no information on this point was elicited.

Moribund. — Fifteen patients were in such bad condition on admission that they died within three days, namely:

Died within twelve hours	4
Died within twenty-four hours	2
Died within forty-eight hours	3
Died within three days	6

Sex. — Of the total admissions 445 were males, 231 females; nearly two to one. This is about the usual proportion. Forty-three males died, or 9.6%; and 27 females, or 11.6%. The mortality among the women

was two per cent. greater than among the men, as is usually the case in this disease, and this disproportion is in no way due to the intestinal lesions, which are much more fatal to men, as the following table shows :

Recognized perforations of bowel:		
Males 6 = 1.3%	Females 3 = 1.3%	Total 9 = 1.3%
Intestinal haemorrhages:		
Males 27 = 6%	Females 5 = 2.1%	Total 32 = 4.7%
Haemorrhage was fatal in 14 cases:		
Males 11 = 2.6%	Females 3 = 1.3%	Total 14 = 2%

Intestinal accidents as a whole, occurred in 41 cases, namely : males 33 (7%), females 8 (3.5%), total 41 (6%). They were fatal in 23 cases : males 17 (4%), females 6 (2.6%), total 23 (3.4%).

If then we deduct from the general mortality the mortality from intestinal lesions *per se*, we have for the two sexes the following :

Males:		
General mortality in 445 males	9.6%	
From intestinal lesions	4%	
From other causes	5.6%	
Females:		
General mortality in 231 females	11.6%	
From intestinal lesions	2.6%	
From other causes	9%	

Thus it appears that the death-rate, apart from intestinal perforation and haemorrhage, is 3.4% higher among the females than the males.

Effect of Cold Baths on Intestinal Ulcers.—Although Brand, in his earlier publications, thought that his method would greatly reduce the frequency of relapses and the danger from the intestinal lesions, this has not been borne out by later experiences on the part of others. To compare, for instance, our 676 cases with 1,173 cases treated after Brand's method by Dr. Hare at the Brisbane Hospital, with a mortality of 7.84%, we find the following results :

Brisbane Hospital:		
Males 739.	Fatal cases 69 = 9.3%	
Females 454.	Fatal cases 23 = 5.3%	
Boston City Hospital:		
Males 445.	Fatal cases 43 = 9.6%	
Females 231.	Fatal cases 27 = 11.6%	
Perforations of the bowel:		
Brisbane. Males 27 = 3.6%	Females 7 = 1.6%	
Boston. Males 6 = 1.4%	Females 3 = 1.3%	
Fatal hemorrhages:		
Brisbane. Males 13 = 1.7%	Females 3 = .69%	
Boston. Males 11 = 2.6%	Females 3 = 1.3%	
Fatal intestinal lesions, as a whole:		
Brisbane. Males 5.4%	Females 2.5%	
Boston. Males 3.7%	Females 2.6%	
Total mortality from intestinal lesions:		
Brisbane Hospital (Brand's method)	4.2%	
Boston City Hospital	3.4%	

From this comparison it will be seen that under Brand's method of bathing, the death-rate among males was about the same as ours, while among females it was not half as high as that which obtained at the City Hospital. The mortality from the severity of the intestinal lesions was somewhat in our favor, therefore, the reason for our higher death-rate must be sought chiefly in the large number of females who died from other causes, that is, from conditions peculiar to their sex and from their feeble resistance to pyrexial exhaustion. It is in preventing this exhaustion that the virtue of Brand's method seems to lie.

Perforation.—Nine cases, six males, three females. This accident occurred in two patients within forty-

eight hours after admission; twice in relapses, and in one patient who had aborted. Several other fatal cases presented symptoms of perforation, not in a typical manner, and autopsies were not obtained. The earliest recognized perforation occurred on the nineteenth day of the disease.

Haemorrhages.—Of the 32 cases of haemorrhage from the bowels, 14 were fatal. One died within forty-eight hours after entrance. The earliest fatal haemorrhage was on the twelfth day of the fever and no patient died from the effect of a single haemorrhage. Two had also delirium tremens and died on the fourth and sixth days after admission respectively. Two others, with complicating nephritis, had fatal bleeding from the bowels. Transfusion of a saline solution was resorted to in three cases, two males and one female. One recovered and two died from recurrent haemorrhage.

GENERAL COMPLICATING CONDITIONS.

Phthisis.—There were seven cases of phthisis of whom three succumbed.

Pneumonia.—Thirty-four cases had pneumonia; 28 recovered and six died.

Pleurisy complicated 11 cases, of whom three died.

Bronchitis was noted as a severe symptom in 74 cases (11%); and in two this was a complication which had much to do with causing death.

Edema—Dangerous edema of the lungs occurred in 25 cases, of whom 10 died.

Nephritis.—In 60 cases (nearly 10%) the urine had albumen and casts. At least three of these had chronic Bright's disease and proved fatal. Twelve others died, in whom the nephritis was probably an acute process. Besides, there were many cases of febrile albuminuria.

Cardiac.—There were 12 cases of chronic valvular disease, of whom two died; and two cases of acute endocarditis, one fatal. One patient had acute fibrinous pleuritis and pericarditis, and acute nephritis.

Diarrhaea was present in about half the cases, but was the chief cause of exhaustion in five cases only.

Hyperpyrexia was noted in but three fatal cases, two males and one female. The latter had extreme distension. The highest temperature recorded was 108° F.

Delirium Tremens.—Alcoholism was one of the gravest sources of danger in a large number of cases, and was no doubt responsible for many of the cardiac, renal and pulmonary complications which contributed to fatal exhaustion. Delirium tremens was present in eight cases, of which five resulted fatally at an early period, twice accompanied by intestinal hemorrhages and once by chronic Bright's disease. Three cases recovered.

Parotitis.—Of two cases of parotitis one died.

Pregnancy complicated the fever in seven cases: six normal pregnancies, one fleshy mole. Four recovered without aborting. One gave birth to a seven months' child weighing two and a quarter pounds, at the beginning of convalescence, which went on to complete recovery. The child also lived, and, at the end of seven months of careful rearing, weighed twelve pounds. One pregnant patient died from pneumonia, as mentioned elsewhere, without aborting; and the patient with fleshy mole had septicemia and perforation. Thus, of these seven cases, miscarriage occurred in two only. It is interesting to note in this

* Practitioner, March, 1891.

connection that the advocates⁵ of Brand's method have not hesitated to plunge menstruating, nursing and pregnant women, who had typhoid, into the cold bath, and without ill result it is said.⁶ Still, the pregnant state must be regarded as a dangerous complication, and Hölscher's analysis of 813 autopsies in women showed that two were pregnant, two had just aborted, 27 were in the puerperal period and four had puerperal fever.

Phlegmasia alba dolens. — Thrombosis of the iliac or femoral veins occurred in nineteen patients, of whom four died, two from consequent embolism of the pulmonary arteries and two from exhaustion.

Embolism, resulting in gangrene of an extremity, did not occur in this series of cases, but the following case was in my service in 1889:

Gangrene of the left Leg from Femoral Embolism; Recovery. — W. S., age twenty, entered the hospital September 21, 1889, on the sixth day of typhoid. Heart weak and irregular. Urine: acid; 1028; trace of albumen; a few hyaline and granular casts. On the 15th day of the typhoid the left leg became cold and very tender over the calf. On the 18th day it was cold, and discolored for ten inches above the malleoli. No pulsations had been felt below the middle third of left thigh. Mildly delirious. Skin of foot became dry and hard, like parchment. Circumference of left calf two inches more than right. October 9th (24th day) line of demarcation formed between the upper and middle third of leg. The affected part was kept clean by charcoal poultices. November 12th (58th day), all tissues gone at demarcation, except bone. Operation by Dr. Cheever. Pulse 156, and feeble at beginning. Sawed through, one and one-half inch above the bare bone, about four inches below knee-joint. Operation hurried because of patient's poor condition. He recovered well from ether. Wound healed gradually by granulation. Good stump. On November 29th (75th day), he was about the ward on crutches, improving in general condition very rapidly. Discharged.

Dr. Cheever had seen one or two similar cases, and thought delay less dangerous than amputation during the fever, as the event proved.

Dr. Drewitt⁷ reports the case of a girl, age twelve, in whom on the 26th day of the fever, absence of femoral pulsation was noted. Three weeks later, the fever having abated, amputation above the knee was performed. Recovery in three months.

Murchison, Liebermeister and Rousseau relate similar occurrences, and the latter author states that when the upper extremity is involved death is almost inevitable. Sphacelation of the cheek and ear may occur.

Doubtless this accident has been occasionally recorded in other hospitals, but this, I believe, is the first instance at the City Hospital in 4,250 cases of typhoid. Hölscher reports but four cases of iliac and femoral embolism in his 2,000 typhoid autopsies.

Neuritis. — Peripheral neuritis caused much pain in the legs with delayed recovery in 21 cases, 3%. The usual duration was from two to four weeks, but in one case, at least, there was much wasting of the calves of the legs and contracture at the knee-joints, which lasted several months before the patient could walk. Her mind also was very much weakened, but eventually she recovered.

⁵ Ziemssen and Immermann: *Kaltwasserbehandlung d. Typhus Abdominalis*, p. 20.

⁶ Bouveret: *Lyon Medical*, April 26, 1891.

⁷ The Lancet, November 8, 1890.

Insanity. — Two cases of post-typhoid insanity were transferred to other institutions, and the result is not known.

Otitis. — Twenty-two cases of purulent otitis, about 3%, are recorded, and there were probably more, as such cases usually passed into the hands of the aural surgeons, Drs. Green and Leland, whenever typhoid deafness occurred.

Peritonitis. — As stated above there were a few cases, mostly fatal, in which there may have been perforation or perhaps appendicitis, but the symptoms of this latter condition were marked in one case only and that recovered.

Relapses. — One hundred cases had relapses, 15%, and of these, three relapsed twice; two, three times. Eighteen were under fifteen years of age, none fatal. But one boy in his sixteenth year, who entered in a relapse in his fourth week, died on the 30th day. Three adults died in relapse, namely; one male and one female from perforations, and one female of twenty years from simple exhaustion; 6% of the deaths occurred in relapse; Hölscher gives 8%.

Prolonged Pyrexia. — In 35 cases the initial fever did not fall to the normal point for thirty days or more, and in nine cases it continued without defervescence for more than forty days.

(To be continued.)

THREE RECENT CASES OF ESOPHAGOTOMY.¹

BY GEORGE W. GAY, M.D.,
Surgeon to the Boston City Hospital.

The operation of esophagotomy is not common enough to render any apology necessary for reporting all of the cases which come to us. It has fallen to my lot to do the operation three times within the past year; twice for a foreign body, and once for stricture of the gullet, which could not be overcome by bougies alone. Two of the patients recovered, and one died. A brief report of these cases is submitted, in the hope that other equally interesting instances may be brought out in the discussion, which I trust may follow the reading of the paper.

On Friday, October 16, 1891, Lena —, aged three and one-half years, was brought to me by Dr. Francois, of Saugus Centre, with the following history: About eight months ago the child was given an ordinary cent, a coin three-quarters of an inch in diameter, to play with. Within a few moments the child was seized with a "choking fit" and the cent was missing, and was not again seen till the day of the operation. The choking symptoms soon subsided, and the child was apparently in her usual health for about six months when she began to reject a part of her food soon after swallowing it. This gradually increased until the time I first saw her, when she apparently rejected a very large portion, from the fact that she was emaciating and she was constantly tormented with hunger and thirst. All solids and much of the liquids were regurgitated easily in less than a minute after being swallowed.

The child was put under the influence of chloroform, rather than ether, to avoid the danger of spasm of the glottis, and also of the profuse secretion of mucus in trachea and bronchi. An esophageal bougie with

¹ Read before the Boston Society for Medical Improvement, January 25, 1892.

an ivory tip readily detected the foreign body at the lower end of the gullet.

An incision an inch and a half in length was then made upon the left side of the neck, midway between the median line and the anterior border of the sternomastoid, from the top of the thyroid cartilage downwards and inwards towards the sterno-clavicular articulation. The three muscles, sterno-hyoïd, and thyroïd and the omo-hyoïd were upon the inside, the sternomastoid with the carotid sheath and its contents were to the outer side of the incision. The thyroid gland was quite large, and was raised and drawn over to the median line. The deep fascie having been divided, the œsophagus was made prominent with a uterine sound introduced by the mouth. An opening was made into the gullet upon the sound, and the sides of the tube caught in a loop of silk. There was no hemorrhage, and not a ligature was required.

The foreign body was detected with the sound, apparently lodged upon the anterior wall of the lower end of the œsophagus, about two inches below the top of the sternum, and from three to four inches below the opening in the neck. The foreign body was apparently dislodged or tipped from the anterior to the posterior part of the tube, and after a little trouble it was seized with a pair of slightly curved forceps and withdrawn. It was an ordinary cent coin together with the skin of a grape. The coin seemed to just fill the œsophagus as it was being removed. It was blackened but not eroded.

The wound was left open, and a small drainage-tube inserted for twenty-four hours. The little one rallied well from the chloroform, and at once and persistently cried for drinks. For a few hours nothing was given by the mouth. Ice and cold water were then allowed in small quantities, and the next day she was allowed all the water and milk she wanted. A considerable portion escaped from the wound every time she drank, but a little probably slipped by the opening. At all events the child was much gratified by this feeding, and rested much better in consequence. The wound behaved kindly, did not slough at all, nor suppurate very freely. Enemata of peptonized milk and cream every two or three hours were given from the first.

Two days after the operation the temperature went up, the child was dumpish, and secreted very little urine. A poultice containing digitalis leaves was applied to the loins. Twenty-four hours later she was bright and lively, and convalescence progressed favorably.

Liquids escaped from the wound pretty freely for about five days, when suddenly the amount became very slight and ceased altogether about ten days after the operation. The child was up and about the ward in thirteen days, and went home October 31st. The wound was then merely a line of granulations. Ten days later, twenty-five days after the operation, she was brought to the hospital for inspection. The wound was soundly healed, the child was eating solid food, and was as well as ever.

CASE II. James C., aged twenty-eight years, was thrown from his cart on the 18th of last June. He fell upon his face, and a plate, upon which were four teeth, was literally "knocked down his throat." His attention was first drawn to the loss of his plate by pain at the epigastrum. He was able to swallow only liquids, and these with much effort and difficulty. He bore evidence of suffering on entering the hospital,

tal, four days after the accident, due in a measure to insufficient food, intemperate habits, and the usual irritation of a foreign body in that locality.

The plate was easily detected with an ivory-tipped bougie, and was situated thirteen inches from the upper incisors and about four inches below the top of the sternum. There was moderate swelling of the neck just above the sternum and clavicles.

The patient was etherized at once and the operation of œsophagotomy was done upon the left side in the usual manner. The œsophagus was brought up into the wound with a pair of curved esophageal forceps introduced from above. The opening of the gullet was thus rendered much easier than the method of cutting upon a stomach tube or bougie. There was no hemorrhage of consequence.

The plate was detected about seven or eight inches from the wound, seized with a pair of long forceps, and after a little trouble was removed. The dimensions were one and a half by one and three-quarters inches.

The wound was closed with silk sutures. This treatment had succeeded admirably in a previous case, but this patient was not in a favorable condition for it. The open method is undoubtedly the best for these cases, as free drainage is necessary in most instances.

The patient rallied from the operation very imperfectly, in spite of frequent injections of food and stimulants. Delirium soon came on and a typhoid condition became established. On the third day after the operation the wound was reopened and the tissues found to be infiltrated and on the eve of sloughing. There was no pus. The septic state present at time of operation was profound. Large quantities of food and stimulants were given by a stomach-tube. The symptoms steadily progressed to the end, which occurred five days after the operation. Death was due to septicemia and exhaustion.

CASE III. Mr. K., aged forty-eight, began to notice difficulty in swallowing about four months before coming under observation at the City Hospital. The dysphagia gradually increased until he could not swallow even liquids. Emaciation and debility were pronounced. Repeated efforts were made by Dr. Mixter and myself to pass a bougie through the stricture into the stomach, without avail. Bougies were arrested eight inches from the teeth. Patient struggled and became cyanosed at every attempt at entering the stricture. The pouch above the constriction held about two ounces. Some relief followed our efforts at dilation, but it was only temporary.

On May 17, 1891, the patient was reduced to such extremes, that more radical measures for his relief were imperative. The question to be decided was, whether to approach the stricture from the stomach, or by the neck. I chose the latter operation because less damage would thereby be done to healthy and important strictures, and because the after-treatment and course of the affection would in all probability be more satisfactory.

The œsophagus was opened upon the left side in the usual manner, and the finger readily entered the pouch above the stricture. The hard, lobulated mass about the size of a small orange was readily felt, but the opening to the lower portion of the gullet was only found after careful exploration with a long probe. It was located, not at the bottom of the pouch, but upon the anterior wall about an inch above the lowest portion. The opening to the lower part of

the tube having once been located it was not a difficult matter to pass a bougie down from the mouth and with the finger in the pouch to guide the point into the lower part of the canal, and so on into the stomach. This having been accomplished, Dr. Mixter very readily passed a No. 19 Symond's tube into the oesophagus, and placed it in its proper position.

The patient having now rallied from the chloroform, drank a glass of milk very easily, a very little escaping from the wound. The wound was left open and the patient given all the milk, and brandy and water he wanted. A considerable part of the liquids drank escaped from the wound for about a week, but he gained in strength and spirits, and was up, dressed and about the ward in eight days. He was out-of-doors in a little over two weeks, and the wound in the neck was healed in three weeks.

The tube was changed in two weeks with considerable benefit to the swallowing, as the old one had become foul. Nine days later another tube was put in, which was allowed to remain till the patient's death, five weeks later, for the reason that it was impossible to remove it by any reasonable efforts. A bougie was passed into the stomach every two or three days towards the last for the purpose of keeping the tube clear.

This patient improved so much that he left the hospital a month after operation, and remained at home with his family during the last weeks of his life. Two days before death he returned to the hospital, emaciated, weak to the last degree, and suffering horribly from dyspnoea upon the least exertion. He was given a few whiffs of chloroform, and tracheotomy was quickly performed with some relief. On opening the trachea about two ounces of the most fetid pus escaped, mixed with a little blood. He had raised blood at times in small quantities ever since the operation first or soon after. He died quietly from exhaustion July 15th.

This man lived two months after the operation, and it is fair to say that half of that time, and most of his comfort, were due to the treatment. The relief of his hunger, thirst, weakness, nervousness and general irritability was very marked and satisfactory. The pangs of starvation were thus greatly relieved until the disease had made such inroads upon his vitality that he was largely oblivious to his surroundings. The inevitable result was delayed, and his last days were made very much more endurable by the above procedures, which is all that can be reasonably expected of any treatment for this affection at the present day.

Intubation of the oesophagus for stenosis bids fair to rival in usefulness its twin invention of Dr. O'Dwyer for the relief of laryngeal obstruction. The tolerance of the tube is as surprising and as satisfactory in the one case, as in the other. The facility with which our patient drank through the tube was very gratifying to all concerned. After a day or two very little pain or soreness was complained of, except when the tube was removed. This procedure was always attended by violent spasms of the glottis, difficult breathing and cyanosis. Fortunately the tube may be allowed to remain in place a fortnight under ordinary circumstances, although it gets pretty foul in that time. It would be better to remove the tube every week, if it can be done without too much disturbance.

In closing, the writer wishes to make his acknowl-

edgments to Dr. Mixter for his valuable assistance in this case, as well as for his most ingenious and useful instrument.

THE MANAGEMENT OF COMPOUND DISLOCATIONS OF THE ANKLE-JOINT.¹

BY CHARLES L. SCUDDEER, M.D.
Assistant in Clinical Surgery, Harvard University; Out-Patient Surgeon, Massachusetts General Hospital.

By dislocation of the ankle I understand a displacement of the upper articulating surface of the astragalus from the lower articulating surface of the tibia, so as to carry the whole foot either forward or backward of the median lateral plane, or to the inner or to the outer side of the antero-posterior plane of the leg; that is, the position of the foot determines the dislocation.

By a compound dislocation of the ankle I understand a dislocation in which at least some one of the ankle-joint surfaces is exposed to the air through a wound.

Hippocrates, in his article on the treatment of compound dislocations at the ankle-joint, as translated by Francis Adams, says:

"In case of complete dislocation at the ankle-joint, complicated with an external wound, whether the displacement be inward or outward, you are not to reduce the parts, but let any other physician reduce them if he chose. For this you should know for certain that the patient will die if the parts are allowed to remain reduced, and that he will not survive more than a few days, for few of them pass the seventh day, being cut off by convulsions, and sometimes the leg and foot are seized with gangrene. But if not reduced nor any attempts at first made to reduce them, most of such cases recover."

"The leg and foot are to be arranged as the patient wishes, only they must not be put in a dependent position, nor moved about. On no account is a bandage or compress to be applied. Certain of the dressings used in recent wounds are suitable in such cases, but those into which rosin enters as an ingredient do not agree with them; for the cleansing of the sore is a slow process, and there is a copious discharge for a long time. It ought to be well understood that the patient must necessarily be much maimed and deformed; for the foot is retracted outward, and the bones that are displaced protrude outward. But the wound heals by thin and feeble cicatrices, provided the patient keep quiet for a length of time; but otherwise there is danger that a small ulcer may remain incurable."

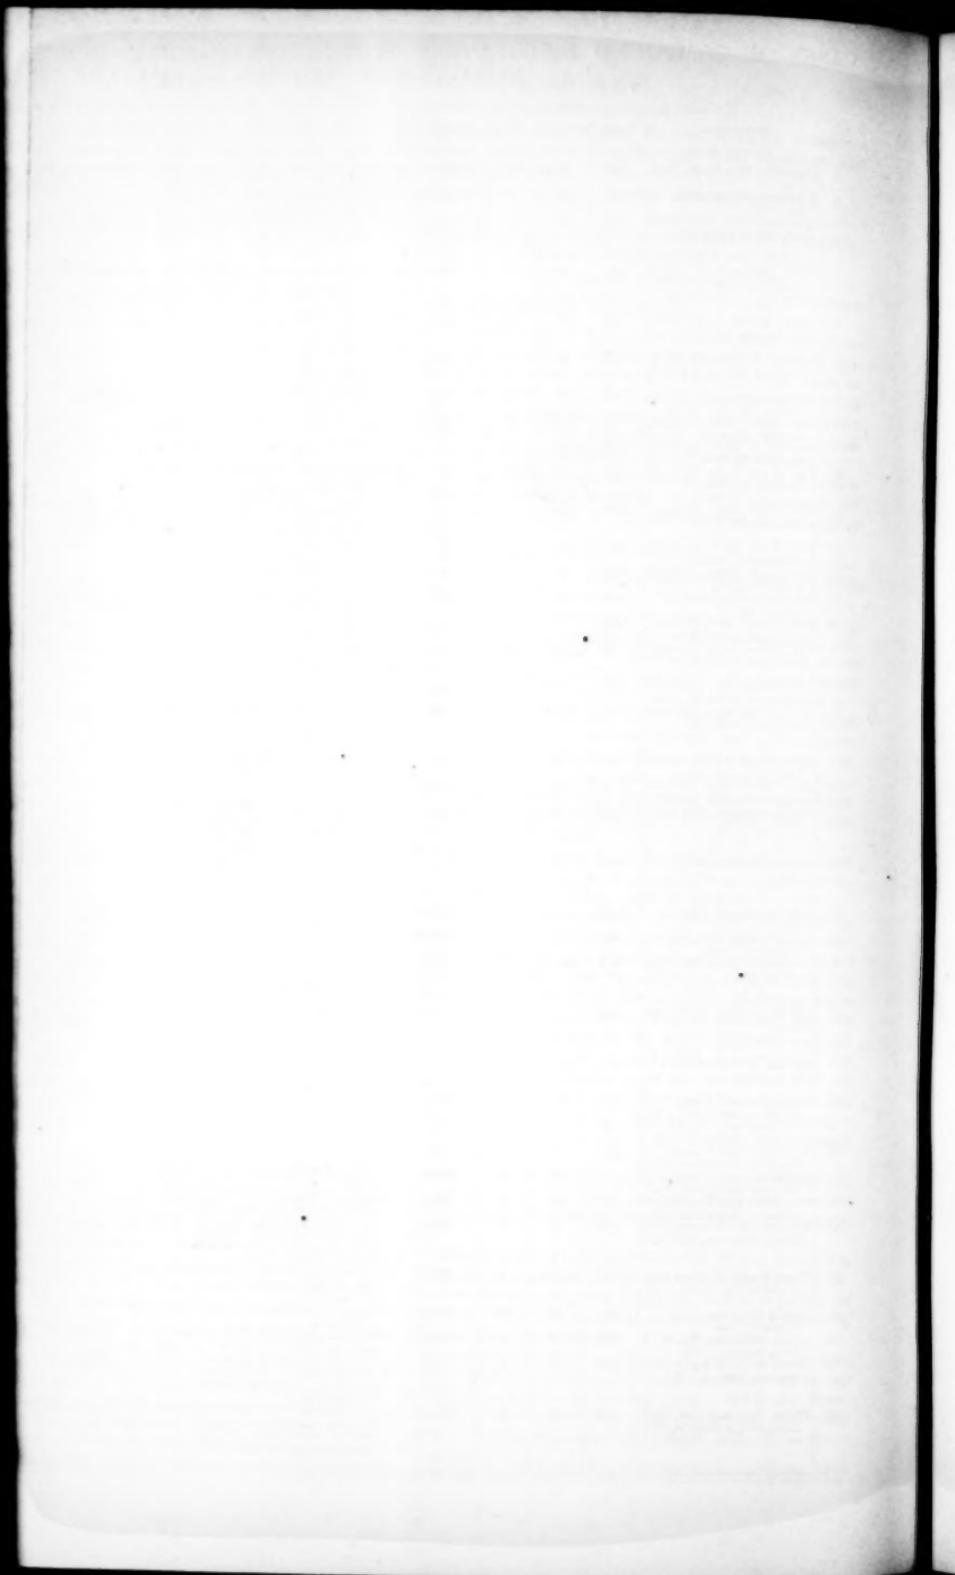

"And yet in the case we are treating of, those who are thus treated are saved, whereas when the parts are reduced and allowed to remain in place, the patients die."

Hippocrates is very decided in his advice as to the treatment of compound dislocations of the ankle-joint. He saw the necessity for drainage, and recognized its presence when the dislocation is left unreduced, and its absence when reduced. The amputation of a limb was looked upon with horror until the times of Ambrose Paré, the opinion of Hippocrates controlling the action of surgeons for a long time. With the introduction of the ligature, amputation became more common. Desault advocated the reduction of dislocations

¹ Read before the Boston Society for Medical Improvement, January 5, 1892.

CASES OF COMPOUND DISLOCATION OF THE ANKLE-JOINT, IN WHICH THE END-RESULT IS KNOWN,
REPORTED IN MEDICAL LITERATURE SINCE 1877.

No.	Reference.	Year.	Age.	Sex.	Accident.	Injury.	Operation.	Result.	Usefulness.	Remarks.
1	Louisville Med News, 1879, p. 54.	1879	26	M.	Fall.	Right foot turned inward. No fracture.	Reduced without cutting.	In 2 mos. discharged well.	Slight limp. Walks easily.	
2	American Homeopath., May, 1881.	1881	24	M.	Crushed.	Fracture of fibula. Tibia through the wound.	Reduced.	Well.	Motion.	
3	Liverpool Med. Chir. Jour., and, 1884, IV, 439.	1884	44	M.	Fall.	Foot turned outward. Right astragulus through skin.	Astragulus removed. Drained.	Healed in 2 months.	Slight limp. Slight motion at ankle.	
4	Amer. Pract. and News, Louisville, 1887, III, 103, 109.	1887	50	F.	Fall.	Foot turned outward. Fibula protruded 2 in. Fracture of tibia above malleolus.	Int. mal. and articular surfaces of tibia and astragulus removed. Drained.	Healed in 2 months.	Walks without a cane Fair amount of motion at ankle.	
5	Amer. Pract. and News, Louisville, 1887, III, 103, 109.	1887	17	M.	Fall.	Left ankle. Tibia fract. at lower end. External malleolus fractured above malleolus.	Joint surfaces was removed.	Well. Crutches 6 months.	Useful foot.	Posterior tibial artery torn. Abscess on outer ankle. Increased motion at tarsometatarsal joint.
6	Buffalo Med. and Surg. Journal, 1881-82, xxi, 515.	1881	38	M.	Fall.	Foot turned outward. Tibia 2 in. protruded. External malleolus fractured.	Reduced.	Well.	Five months afterward good motion and use of limb.	Operation 3 wks. after injury. Abscess opened up the leg.

of the ankle, and then amputation ceased to be the common practice. Sir Astley Cooper advised resection of the joint in almost all cases. Since his day surgical opinion has fluctuated, no definite course being laid down.

There are to-day for consideration three methods of treatment: (1) Reduction; (2) partial or complete separation with reduction; (3) amputation, primary or secondary.

The comparatively modern authorities in surgical literature in America—Ashurst, Hamilton, Gross and Agnew—advise strongly that, as a rule, amputation be done. The English authorities, on the other hand,—Holmes, Bryant, Holthouse and Erichson—are very conservative, advising an attempt to save the limb by excision, reserving the badly comminuted cases for amputation. These views merely repeat what the profession has for a long time maintained. No very definite rules of procedure have been laid down by any one. This may be impossible and impracticable; but it seems that to-day this may safely be done.

There are two things to be considered in deciding what to do with any case of this injury: (1) The extent of the laceration of the soft parts; (2) the amount of injury to the bones.

(1) If the laceration is so great that the foot is useless, amputation is indicated; and amputation is indicated in only two other instances—old age and sepsis.

(2) If this laceration is not great, and the dislocation can be reduced, it should be reduced without excision, proper drainage being provided both anteriorly and posteriorly to the joint.

(3) If the laceration is not great and reduction is impossible, then an excision should be done, either partial or complete.

(4) If there is great injury to bone whether the dislocation can or cannot be reduced, a partial or complete excision should be done.

Aseptic surgery regards all fresh accident wounds, particularly those connected with the joints, as comparatively safe so far as immediate danger to life is concerned, and if expectant treatment, as indicated above, is instituted in these cases, the chances for a useful foot and ankle-joint are very great. The best results from expectant methods of treatment of compound dislocations of this joint are due to aseptic methods in every instance. All compound dislocations of the ankle-joint, however small the wound in the soft parts, should be thoroughly cleansed. In order to insure an aseptic wound, the small opening should be enlarged so that the joint may be thoroughly examined and cleansed in every part.

I have carefully examined the records of all cases of compound dislocation of the ankle reported in the medical literature since 1878. I found a total of thirty-eight cases, in which the end-result is known. Twenty-two were reduced without operation. In eight the astragalus was removed. In six a partial excision was done. In two a complete excision was done. The end-result in these cases were, as to usefulness of the foot, excellent. As to the mortality, one case died of sepsis, aged 64, in 1883; one case in 1877, came to amputation. The age of the oldest was sixty-four years; of the youngest, fifteen years. Only those cases were taken for study in which the end-results were known.

Through the kindness of Dr. H. H. A. Beach, under whose care the case came at the Massachusetts General Hospital, I am allowed to make the following

report of a case of forward compound dislocation of the ankle-joint which under conservative and non-operative treatment recovered with a useful though stiff ankle-joint.

E. D., age ten years.

April 24, 1888. Caught foot between the tracks of a railroad turntable; was held fast and thrown violently to the ground. Shortly afterward an antiseptic dressing and side splints were applied to the foot. He was brought to the accident-room five hours after the injury. On examination, a compound dislocation of the right ankle backward, with fracture of the internal malleolus was found. There was an extensive laceration of skin across the dorsum of foot from one malleolus to the other forming a gaping wound two inches wide, exposing the extensor tendons. The anterior tibial tendon was torn, and the dorsalis pedis artery ruptured. The tip of the internal malleolus was found broken and the bones of the leg displaced backward—the heel being shortened and the upper articular surface of the astragalus lying anteriorly.

May 4th. A small abscess was opened at the tip of one malleolus.

July. Entirely healed. Extensive cicatrix across dorsum of foot. Complete ankylosis at ankle-joint.

August 1st. Up and about on crutches.

March, 1891, two years and nine months after the wound healed, the boy uses the injured foot and leg as well as the other. The tibiae are of the same length. The right calf measures 10 inches. The left calf measures 11½ inches. He walks with a slight limp, which is not noticeable to many. There is a slight tendency to walk on the outer edge of the foot. After walking all day, particularly in damp weather, there is some pain and a little stiffness about the foot.

In conclusion, extreme conservatism should characterize the treatment of recent compound dislocations of the ankle-joint. Such treatment as is emphasized above should, in the large majority of cases, result in a useful ankle-joint and foot.

Clinical Department.

TWO CASES OF COMPOUND FRACTURE AND DISLOCATION AT THE ANKLE-JOINT.¹

BY ANTHONY PORT, M.D.,
Visiting Surgeon, Boston City Hospital.

THESE two cases were shown to the Society for Medical Improvement, to illustrate the fact that very serious compound dislocations may recover under modern wound treatment.

In the first case the accident occurred on August 20, 1890. The patient, who was a teamster, was thrown from his wagon on to the pavement. When brought to the hospital, there was a wound below the external malleolus of the left tibia. The astragalus was broken, and one-half of it protruded through this wound, and the foot was strongly inverted. Before any surgical procedure was begun, all the parts about the wound were carefully cleansed and washed with a solution of corrosive sublimate of a strength of 1 to 3,000. The wound was then enlarged. It was absolutely impossible to replace the misplaced portion of the astragalus, and it was removed. The foot was restored to its normal position, and a dressing of gauze soaked in a 1

¹ Shown before the Boston Society for Medical Improvement, January 25, 1892.

to 2,000 solution of corrosive sublimate applied. A plaster-of-Paris bandage was then applied over all, exactly as might be done for a simple fracture.

On the evening of the 21st the temperature was 100°; on the evening of the 22d 101°; on the morning of the 23d it fell to 99°. On the 25th it was between 100° and 101°; it then fell to 99°, where it remained for a few days, and for the remainder of the time was practically normal. The first dressing was done on September 2d, when the wound was healed, except a small granulating area about half an inch square. The circular plaster was replaced and retained until September 22d, when the wound was entirely healed and some motion in all directions was found.

This patient was kept long in bed, as he had lost his left arm many years before and was unable to use crutches. He was thirty-two years old at the time of the accident, and was the driver of a beer-wagon. He had lost his arm some years previous from a compound fracture of the hand, which to his eyes was much more serious than the accident to his foot and his surprise and delight at retaining his leg was very great. He now walks without any support. When shown to the Society, he walked with both feet bare on the level floor with but a slight limp, but in going up or down stairs there is evident disability.

The second case was Mr. A. L. P., aged forty at the time of the accident, which occurred on April 23, 1888. When brought to the City Hospital on that date the articular end of the tibia projected more than two inches through a wound over the outer malleolus. The foot was turned inwards and upwards so that the exposed bone lay over the heel. The periosteum was stripped up from the tibia, and both malleoli broken off. The accident resulted from a fall of about six feet from a ladder that broke while he was upon it. He came down feet foremost on an inclined plank driveway.

Everything was made clean; the incision was enlarged upwards; and fragments, of which there were many small ones, were removed with forceps, fingers and irrigation. As the removal of the fragments seemed incomplete, an incision was made over the inner malleolus, and the fingers passed freely through the joint. The bones were then replaced, the periosteum adjusted and secured in place with a stitch or two of cat-gut, the skin carefully replaced and stitched with silk. No drainage-tubes were used, but a stitch or two omitted to allow easy exit for any discharge. Irrigation with corrosive-sublimate solution was freely done during the operation, and corrosive gauze dressing was applied. The whole was carefully enveloped in a plaster-of-Paris bandage.

The first dressing was done on May 7th, when there was slight external sloughing at the site of the original wound. There was afterwards slight suppuration at that point, but it was confined to the external portions of the original wound.

The patient was sent home on June 3d, and made a good recovery. When shown to the Society, there was motion at the joint in all directions, and the patient declared that the foot was as good as before the accident.

The principle point in the treatment of these cases — which were not unique, though extremely favorable examples of what may be done with compound dislocations at the present day — was the disinfection of the wound, but the immobility, as enforced by the plaster bandage, was of almost equal importance.

PEROXIDE OF HYDROGEN AS A DEODORIZER, IN CANCER OF THE UTERUS.

BY GEORGE W. KAAN, M.D.
Surgeon to Out-Patients, Free Hospital for Women, Boston.

THE value of peroxide of hydrogen in washing out sinuses and abscess cavities, has led me to use it recently as a vaginal injection in cancer of the uterus; and with gratifying results.

My cases have been few; but in each the distinctive cancerous odor was noticeable about the patient before the use of the peroxide of hydrogen, and absent afterwards. In one out-patient case the fetor was so pronounced, that the air of the room seemed saturated with it, the moment she entered. When I last saw her in making an examination no odor was perceptible a foot from the vulva, and only slightly so close to it. In this case she had used the injection the night before, and a cancerous mass as large as a man's fist, hung in the vagina, within two inches of the vulva. This case had had palliative treatment in the hospital, by curetting, Paquelin's cautery, and chloride of zinc applications. When she first came to me the disease had extended over the whole anterior vaginal wall; since then the peroxide of hydrogen has been used, and the anterior wall is clear. It seems to me that the injections have had some curative action.

Further observation, of course, is necessary; but bearing in mind what Sir Spencer Wells says of cancer and cancerous disease, that everything in relation to it is so important that nothing should be thought a trifle, and my material being limited, I venture to state the facts as they appear to me in this case.

Regardless, however, of any value it may have as a curative agent, its use as a deodorizer, and this without substituting another odor for the cancerous one, makes it of inestimable worth in adding to the comfort of the patient, where palliative treatment alone is all that remains.

The method of using has been to take about an ounce of the peroxide of hydrogen and an equal quantity of water, warmed by being placed in a pan of hot water, and injected through a soft rubber catheter, so that the injection shall be sure to reach the back part of the vagina. Such an injection once or twice a day has been sufficient.

Medical Progress.

RECENT PROGRESS IN PUBLIC HYGIENE.

BY S. W. ABBOTT, M.D.

(Concluded from No. 13, page 313.)

CHEMICAL AND BACTERIOLOGICAL INVESTIGATION OF THE SYSTEM OF SEWAGE TREATMENT AT POTSDAM.⁵

It is pointed out in the introduction that the object to be attained in the purification of sewage-water is the destruction of all the infectious matter contained therein. It is also necessary to effect such changes that the liquid after treatment may no longer be liable to putrefaction. The success of any process in accomplishing these results must be tested by chemical and bacteriological analyses. The chemical investigations should in the main be relied upon for the de-

⁵ B. Proskauer and Dr. Nocht: Zeitschrift für Hygiene, vol. x, 1891, p. 311.

termination, quantitatively, of the amount of putrescible organic matters present in the sewage. The best methods of conducting the analyses by the computation of (1) the loss on combustion; (2) the amount of permanganate potash needed to oxidize the organic matters; and (3) the total amount of nitrogen present, are described. The great differences in the results obtained in the examination and treatment of fresh sewage, and of sewage that is already partially putrid, are discussed. In addition to the above-mentioned facts it was deemed advisable, in the case of the Potsdam inquiry, to ascertain the total amount of lime and chlorine present in each sample before and after treatment. By reference to a diagram the arrangement of the works at Potsdam is described: They consist of a siphon-well constructed to hold 8.5 cubic metres of raw sewage, a deep well to hold 28.5 cubic metres, clarifying chamber, conical in form, with the clarifying cylinder dipping into it, the latter being 2.75 metres in diameter, inclined at an angle of sixty degrees, and rising to a height of 6.5 metres above the top of the conical vessel into which it dips. The mode of working the apparatus by means of a partial vacuum created in the upper part of the cylinder is explained. The authors state that the preparation employed for the treatment of the sewage is a secret in the hands of the firm, but the composition of the reagents was disclosed to them. The only active disinfectant is quicklime, which in the form of milk of lime, constitutes about one-fifth of the mixture. The quantity of the precipitants used is not varied in accordance with the strength of the sewage. It was found necessary to take samples of the sewage under treatment in seven different places. The results are set forth in tables. It is stated that the sewage was of a highly concentrated character, more in the nature of the contents of a cesspool than like ordinary town sewage. In order to give an idea of its composition, the sewage is compared with that of Dortmund, Essen, Berlin, and of the Schwartzkopff works, the last-named being practically pail-stuff, yielding a residue on evaporation of 2,408 milligrammes per litre. The Potsdam sewage contained in one trial a residue of 2,271.5 milligrammes per litre, and showed a loss on combustion of 819 milligrammes per litre.

The working of the process is contrasted with the corresponding figures obtained on the treatment of the sewage of Dortmund and Essen in a further table, from which it follows that at Potsdam the residue on evaporation in the effluent was reduced from 2,271.5 milligrammes to 1,844.5 milligrammes, the loss on combustion from 819 milligrammes to 443.5 milligrammes, the oxygen required as tested by permanganate of potash from 975 milligrammes to 546.5 milligrammes, and the total nitrogen from 262.3 milligrammes per litre to 169 milligrammes; these reductions being respectively equivalent to 19, 46, 44, and 36%. The amount of ammonia was increased by the process, owing no doubt to the decomposing action of the lime; and still better results were obtained towards the close of the treatment. The clarification, the removal of the matters in suspension, is stated to have been completely successful; not so, however, the results, as respects the matters in solution, owing in all probability to the extremely concentrated nature of the liquid. The chief remaining point to be ascertained was, whether the effluent, after its discharge

into the river Havel, was diluted to such an extent as to be prevented from subsequent putrefaction, and whether it was likely to have any deleterious effect upon the river-water.

Analyses are given to show the influence of the sewage admixture upon the composition of the river-water, and the authors affirm that it may be assumed from these that the dilution which takes place is such as to remove all danger of injury to the river.

The bacteriological examinations of the results of the process are shown in a series of tables, and from these it would seem that the amount of precipitants employed is insufficient to destroy all germs in the sludge and in the effluent, and that it would be necessary to make use of five times the present amount of quicklime to effectually sterilize the effluent.

ON THE SUCCESS ATTAINED BY VARIOUS SYSTEMS OF CLARIFYING SEWAGE-WATER AT FRANKFORT-ON-THE-MAIN.⁶

The experiments here recorded have been carried out during the past three years, at the Frankfort works, under the supervision of a Commission consisting of Dr. Spies, Mr. Lindley, Dr. Libbertz and the author. Certain of the results obtained have been already published, and an account of the works is there given. In all, eight series of experiments have been conducted, with five different systems of clarification. The various processes investigated were as follows:

- (a) Precipitation with sulphate of alumina and lime. Series I to III.
- (b) Precipitation with lime alone. Series IV.
- (c) Simple deposition, without chemicals. Series V.
- (d) Precipitation with sulphate of iron and lime. Series VI and VII.
- (e) Precipitation with phosphoric acid and lime. Series VIII.

The volume of sewage dealt with was about 30,000 cubic metres (6,600,000 gallons) per diem, and upwards of one thousand complete and comprehensive analyses were carried out. The results of the different series of experiments are set forth in eight tables. A second set of tables gives comparative analyses of the sewage-water and the effluent. In its mean composition the Frankfort sewage, though considerable fluctuations were observed, does not differ materially from that of other towns, London, Paris, Dantzig, Berlin and Breslau, with which it is contrasted in a special table. By means of a set of graphic diagrams are shown the results of the various purification processes, as evidenced by the character of the effluent as compared with the raw sewage, and the author sums up the general effect of the different modes of treatment. In all cases the suspended matters were far more efficiently dealt with than those in solution, and the appearance of the sewage-water, as tested by the eye alone, was greatly improved.

Passing on to the comparative value of each of the various processes as tested by the elimination of injurious constituents, numerous tables are given to show the amounts of suspended and dissolved impurities removed by each different system, and the effect produced by the various precipitants is discussed in detail.

In dealing with the amount of organic matter pres-

⁶ Dr. B. Lepius: *Vierteljahrsschrift für öff. Gesundheitspflege*, 1891, p. 230.

ent, special consideration is given to the phosphoric acid treatment, and a graphic diagram is appended to show the proportion of the phosphates removed at each different stage of the process, and carried off in the effluent.

From this it appears that though all the added phosphoric acid is expended in enriching the sludge, the amount of phosphoric acid present in the deposit from untreated sewage is nearly twice as great as is that in the sludge from the phosphate process. The figures in milligrammes per litre are as follows :

PHOSPHORIC ACID ORIGINALLY PRESENT.	PHOSPHORIC ACID AFTER TREATMENT.
(1) In raw sewage	67.4
(2) Added to secure precipitate	17.6
Total,	85.0
(1) In deposit in sand chamber	29.4
(2) In sludge	38.2
(3) In effluent	38.2
Total,	85.0

Hence, instead of securing a sludge valuable for agriculture, more than twice the quantity of the phosphoric acid employed for the precipitation is carried away in the effluent, namely, 38.2 milligrammes per litre, of which about half is in suspension, and half in solution. The author points out that from this aspect it would be better not to treat the sewage with phosphate of lime at all, but to clarify it by simple deposition, and then to add the phosphate to the sludge. In conclusion, it is stated that the experiments have demonstrated that the effect of chemical precipitation is not so greatly superior to the purification obtained by simple deposition in tanks, as to warrant the adoption of any of the above processes in preference to simple mechanical treatment. This, of course, does not hold good for sewage treatment generally, but it applies only to the conditions prevalent in the present works. It is proved, however, that in every case where tanks approaching the dimensions of those at Frankfort are available, more especially where the length of the tanks is equally great, it is possible to obtain, by purely mechanical means, results comparing favorably with the clarification attained elsewhere in tanks of smaller size only by means of chemical treatment, and therefore at a greater cost.

THE SCHWARZKOPFF SYSTEM OF SEWAGE-TREATMENT (BERLIN).⁷

The Berlin University Hygienic Institute having been requested to report on the Schwarzkopff process, to decide upon the extent to which the offensive constituents of fecal matters were eliminated by this system of treatment, the necessary bacteriological researches were entrusted to Dr. Plagge and Dr. Petri, under the superintendence of Dr. Noch; and the author was instructed to undertake the chemical investigations, and to report generally upon the experiments. The factory where the system is in use contained a set of water-closets, dry-closets and urinals, resorted to daily by about seven hundred work-people. The cesspit receives also the liquids from the urinals, which are flushed with water. The fecal matters are raised from the cesspit into a mixing tank close alongside, where they are pulped by mechanical means and mixed with chemicals which consist of : (1) milk of lime; (2) solution of sulphate of magnesia; (3) solution of crude superphosphate; (4) solution of chloride of magnesium. These substances are added separately, in tanks provided with stirring apparatus, and they are

apportioned by small metal cups attached to an endless band. After this treatment the mixture passes along an open channel into one or the other of a set of three depositing tanks, where the solids subside, and a tolerably clear liquid is decanted off and passed through a peat-filter. The sludge is also run on to a layer of peat to drain, and when all the liquid has been strained away it is converted into poudrette manure in a special apparatus at a temperature of 70° centigrade. The clear liquid from the filters is allowed to flow into the sewers. Eleven different samples were examined in order to complete the inquiry; namely, the fecal matters from each description of closet, the mixture of excreta in the tank before and after the addition of the chemicals, the supernatant fluid and the sludge from the depositing tanks, the peat and filtered liquid, the sludge and the liquid draining from the same, and the poudrette.

The author describes the mode of taking the samples, and the way in which the chemical analyses were conducted. The results are set forth in a tabulated form. The nature of the action of the precipitants, and the relative quantities of each substance employed are also inquired into. Three different sets of experiments were carried out, for reasons which are explained. A corresponding series of bacteriological investigations of the products obtained at each different stage of the process was conducted in the institute, and the number of germs present, which range from 150,000,000 per cubic centimetre in the fecal matters in the dry-closet to 20,000 in the unused peat, are shown in the table. Each of the three sets of observations are described in detail, together with certain side issues, which arose out of the inquiry; namely, the disinfecting action of each of the different kinds of chemicals, and the extent to which the clarified effluent is liable to undergo further putrefaction.

The general results of the investigation are summed up in a series of eleven conclusions, from which it follows that the process is capable of completely removing all suspended matters; but it produces but little effect upon the soluble ingredients, especially the nitrogenous substances and the ammonia. The chemical action is almost entirely due to the added lime. The treatment has a certain disinfecting action upon the sewage, and leads to a most marked reduction of the micro-organisms in the effluent: the sludge, on the contrary, remains in this respect but little affected. Other conclusions have reference to the liability of the effluent to putrefy, and to the imperfect degree of disinfection attained in the case of the poudrette. It is laid down that the effluent should not, without further treatment, be passed into the sewers, and the peat-filtration process is declared to be a disadvantage rather than otherwise.

THE POLLUTION OF THE RIVER ISAR AT MUNICH.⁸

In the course of an inquiry as to the sewerage of Munich, it was desirable to determine the effect of sewage pollution upon the river. Dr. von Widenmayer and Professor von Pettenkofer found that the amount of fecal matters discharged into the Isar produces little permanent pollution, and that it would be possible to adopt a water-carriage system of sewerage for Munich, without the interposition of depositing tanks or filtering beds. It is a fact that the river is

⁷ B. Proskauer: *Zeitschrift für Hygiene*, x, 1891.

⁸ Prof. M. von Pettenkofer: *Deutsche Bauzeitung*, February 18, 1891.

much more free from pollution when it is low than when it is high. It is shown that the 280,000 inhabitants of Munich could only raise the organic matter in one litre of the water of the Isar, at the abnormally low level of a discharge of only 40 cubic metres a second, by seven milligrammes. It is also shown that the solid residue can have nothing to do with excremental pollution, and Professor Pettenkofer asserts that he retreats from his previously expressed opinion that the sewage of Munich would have an injurious effect upon the Isar, and he believes that no injurious results will ensue from the discharge of the raw sewage into the river. He undertakes to prove on a future occasion that the bacteriological investigations do not support the theories of the opponents of the water-carriage system.

SEWERAGE OF MUNICH.⁹

The question as to the sewerage and sewage-disposal of Munich, which has been so much debated, has been finally settled in favor of the water-carriage system, and the scheme only awaits the Government sanction to be put in force. Under the plan adopted, though provision is made for the ultimate employment of filter-beds or tanks, if such should prove necessary, it is proposed to discharge the raw sewage into the Isar, with a tank near the outfall for the retention of floating impurities.

The author reviews a series of publications relating to this subject, and sums up his observations in the following conclusions:

(1) The investigations hitherto conducted into the self-purifying powers of rivers do not warrant any finite verdict respecting the admissibility of the direct introduction of the Munich sewage into the Isar, since too little is yet known of the life-habits of bacteria, more especially of those which are pathogenic.

(2) But the investigations have rendered it evident that, owing to the favorable local conditions which here exist, an experiment may be carried out on a large scale without exposing the towns situated on the River Isar to any material danger.

(3) In the present case this experiment can, if necessary, readily be abandoned, as the site of the sewage outfall renders it possible at once to resort to sewage irrigation.

ORAL COMMUNICATIONS.

TREMOR OF PARALYSIS AGITANS.

DR. MORTON PRINCE: I have here a case which I would like to show, and which is to me one of considerable interest. It is interesting from several points of view. One is that of the diagnosis. This man has, as you see, a curious tremor of the right hand. The character of the tremor is such that, at first sight, if he had been an older man, it might possibly have been mistaken for *paralysis agitans*. It is a case of "tremor

of *paralysis agitans*" following hemiplegia; and I say that, although there is no hemiplegia at the present time. These motor disturbances following hemiplegia are very common, and this particular kind is very well recognized, but in my experience it is comparatively rare. You will notice that the tremor persists while the hand is at rest and that he can control it by strong muscular effort. Volitional action does not increase it. Although I have seen many cases of hemiplegia, I have seen very few cases of this particular kind of tremor. The leg is also affected, so that at times, especially when in a constrained position, the knee will oscillate backwards and forwards. I say it is a case of hemiplegic tremor, although there is apparently no hemiplegia present. The knee-jerks are not increased. The superficial reflexes are not diminished on the right side, and yet I think it is or was a case of hemiplegia, partially from the history and partially from other symptoms still present. If he smiles the left side of his face moves before the right side. When he was first attacked the mouth was pulled to the left. This paralysis has disappeared, but still there is a tendency of the left side of the face to smile first. The right leg, when the patellar tendon is struck, kicks a little quicker than the left leg. Another peculiarity of the case is this: he insists that this tremor come on immediately after a "drunk"; that he waked up in the morning and found his right arm and hand in the same condition that it is now. He is very positive that there was no paralysis at that time, but at the same time I think there probably was some weakness. But the fact that this tremor should have come on in the course of a night, so to speak, is, I think, rather unusual and extraordinary.

A practical question has arisen in connection with this, and one on which I should be glad to receive suggestions; namely, the location of the lesion. Is the lesion in one of the deeper nuclei of the brains, the optic thalamus, or is it cortical? Now, in those cases that have hitherto been reported, lesions have been found in both these situations; although the majority have been in the optic thalamus; but there is a case on record where there was atrophy of the motor convolutions, and to the naked eye no lesion whatsoever in the optic thalamus could be detected. The evidence would seem to show that it is possible that it may be in either of these situations, although I am inclined to believe that the internal capsule cannot be involved in this case. If it is in the optic thalamus, it does not involve the internal capsule.

When I was in London last summer, I saw a case in Mr. Horsley's ward which had been operated on by him. He had removed a portion of the cortex. The patient was in bed at the time, and I do not know what the further result of the case was, but it was evidently considered that the lesion was in the cortex. If there is warrant in thinking that, this case would seem to hold out a certain promise of relief from operation. The patient himself says that the right hand is at present of very little use to him. He says he would be willing to take a certain amount of paralysis if he could regain control of the muscles. The question arises whether there is any likelihood of being able to relieve such a case as this by operation on the cortex. The motion persists during sleep, I think.

TUMOR OF CÆCUM CAUSING INTUSSUSCEPTION.

DR. M. H. RICHARDSON: I have a very rare speci-

⁹ A. Frank: *Gesundheits Ingenieur*, 1891, p. 281.

men which I removed from the cecum a few days ago. It is a lipoma which grew from the internal surface of the cecum by a broad base. As will be seen, the tumor is so large that it nearly fills the normal ascending colon. The upper part of the tumor became grasped by the muscular fibres of the intestinal wall and the whole was forced along dragging the caput cæci behind. In this way an intussusception was started which soon became extreme and required surgical interference.

The patient, C. P., a man of fifty-two years of age, had been in good health, although not robust. At the age of twelve, he had had what was called a bilious colic, and at one time, while young, there was a prolapse of the rectum, upon the surface of which there was said to be a small tumor.

Ten days before I was called to see this man he was taken with what was thought to be the grippe. After a week of slight illness, he was seized with violent pain in the lower part of the abdomen. He had taken a pill of rhubarb the day before and had had a good movement of the bowels at six o'clock Monday morning. During the day his stools, which were rather frequent, began to contain blood. The pain was controlled by morphia. His general condition improved during Monday night and Tuesday morning, although the pain was at times severe. The bloody stools also continued accompanied by occasional attacks of hiccough, but no vomiting.

I first saw him at South Hanover in consultation with Dr. MacMillan, the attending physician, on Tuesday afternoon. At that time his symptoms had improved so much that he expressed himself as feeling well enough to get up and go to his business. By physical examination nothing whatever could be discovered except a fulness in the left hypochondrium, suggesting a distended coil of intestine. It seemed at that time possible that there might be some acute obstruction, but the man's condition was so good as to make operative interference seem needlessome. During the night, and the following day, there was no passage from the bowels except a fluid which was odorless and darkly tinged with blood.

On the next day, Wednesday, Dr. R. H. Fitz saw the case in consultation and advised, on the whole, a laparotomy, on the ground that the man's chances seemed better than to try longer palliative treatment. His diagnosis was intussusception or a twist. On opening the abdomen, bloody serum escaped. A mass was found resembling a kidney at the beginning of the sigmoid flexure. Exploring farther with the hand, the distended and tense coils of the large intestine could be made out. The incision was enlarged and it was found that there was an intussusception starting at the ileo-caecal valve. The invaginated bowel had advanced as far as the sigmoid flexure. The mesenteric attachment of the small intestine was so tens as to suggest the ring-pillars of strangulated hernia. After about forty minutes' effort, during which the patient's condition continued to be remarkably good, the invagination was reduced. This was accomplished only with the greatest difficulty and not till I had about concluded to give up all efforts at reduction and to make an artificial anus. It was accomplished finally by pressing back the invaginated portion by a sort of milking process. When the cecum was delivered it was found to contain some unusual mass. I opened the bowel by longitudinal incision and found a pear-

shaped tumor, broadly pediculated, attached to the mucous surface of the cecum below and to the right of the ileo-caecal valve. It was large enough to entirely fill the cavity of the cecum. The base of the tumor bled freely and required the application of continuous silk suture. The cecum was closed by the interrupted Lambert stitch. Everything was replaced and the line of suture protected by iodoform gauze.

Immediately after the operation the patient's condition became alarming, and it was only after prolonged efforts on the part of Dr. MacMillan that he rallied. On the following morning his condition was very good indeed. There was no vomiting, and the hiccough, which had been very persistent before the operation, had disappeared. I saw him again the following night and found his general condition reassuring except that his pulse was rapid. During the night he failed and died. There was no autopsy.

The tumor, examined by Drs. Fitz and Whitney after removal, was found to be a polyoid lipoma.

DR. C. L. SCUDDER read a paper on

THE MANAGEMENT OF COMPOUND DISLOCATIONS OF THE ANKLE-JOINT.¹

DR. ABNER POST showed

TWO CASES OF COMPOUND FRACTURE AND DISLOCATION AT THE ANKLE-JOINT,²

which occurred, respectively, a year and a half and four years ago.

The first patient, who had lost a portion of the astragalus, walked about the level floor without perceptible limp, but showed considerable disability in going up and down the steps of the hall.

The second case was one in which the tibia had projected through a wound over the inner malleolus. The accident occurred four years previous, and the patient was forty years old at the time. The patient demonstrated the movement at the ankle-joint in all directions, and said that he could see no difference between the two feet.

DR. A. L. MASON read a paper entitled

NOTES ON TYPHOID FROM 670 CASES AT THE BOSTON CITY HOSPITAL IN 1890 AND 1891.³

DR. GEO. B. SHATTUCK: It is true that figures in themselves are apt to be dry; but if they show us that we have made a decided progress from the past, and if they point out how we may make progress in the future with reference to practical results in the improvement of treatment of a disease which is so constant as typhoid fever, and which is with us always, as one may literally say in our large cities now, then figures are not dry. I think that none of us have found that Dr. Mason's paper was dry. On the contrary, it was very interesting and instructive. As well as I remember, Dr. Upham's series of cases (1864-1870), which I tabulated for the City Hospital, gave mortality of something like fourteen per cent, and even if we make no reductions whatever from the cases reported by Dr. Mason, that shows that we have at least kept pace with the tendency to improvement in the death-rate from this disease, which he says, and rightly, is to be found all over the world; and I think we not only have kept pace with it, but more than that. Of course, the interesting practical point upon which

¹ See page 334 of the Journal.

² These cases are reported more fully on page 335 of the Journal.

³ See page 339 of the Journal.

these figures have a bearing is that of the treatment of typhoid fever by Brand's method, whether it should be adopted by us or not. I think that Dr. Mason's paper is a much more reasonable and rational paper and one which certainly, individually I may say, wins my confidence more than that of a great many utterances which have been made in regard to this subject. It seems to me there is nothing in regard to which the proverbial fallacy of statistics may be so applicable as that of any one system of treatment to a disease like typhoid fever, and I think we must take all the statistics with reference to Brand's method with a great deal of caution. Now, if it can be shown that that method or any other will produce a diminution in the death-rate of this disease of two per cent. or more, then it is our duty to adopt the method, whatever the inconvenience and the cost may be. At the same time, it seems to me that it is not injudicious that we should perhaps allow other hospitals and other cities to prove that for us in this country. Certainly the material which we have to deal with, its outside surroundings, the time of admission to the hospital, and our facilities for applying the method,—all these factors differ very much from those which obtain abroad; and it is therefore necessary that the method should be tested especially for us here, and that being the case, it is, it seems to me, as I said, not injudicious that we should allow others to test it for us if they are willing to do so. In New York at Bellevue, in Philadelphia at the German Hospital and elsewhere, they seem disposed to try it. Of course, there are two questions with reference to the adoption of that method. One is the question of therapeutics; the other is the question of hospital administration. If there are only a certain number of reliable attendants who can be secured for any given hospital service, and if there is only a certain amount of money disposable for a hospital service, then I must frankly say that if it is a question between being deprived of either liberality in the way of nourishment and stimulants and other therapeutic measures and of good nursing, — if we have to choose between this and the application of the cold-water treatment according to Brand's method, — I should certainly prefer to have the first mentioned rather than the second. If the hospital facilities and the hospital funds and the hospital administration will permit of both, and it is satisfactorily proved for us in this country that the Brand method will reduce the mortality in our hospital cases by two per cent., then it seems to me that we must have it, and if it is proved that the mortality can be reduced by two per cent., the profession is in such a position and the public is in such a position, that they can demand from municipalities and boards of trustees that sufficient provisions should be made for all necessities as they arise under those circumstances.

If we deduct, as Dr. Mason suggests, the cases which are inevitably fatal, which come in late and die early after admission, and deduct the cases giving a large percentage from intestinal complications such as perforation and hemorrhage — and the ratio at the City Hospital from perforation was a very large one — of course, it reduces the mortality very much indeed, a mortality which is already favorable. I do not think to-day it is claimed by impartial observers with reference to Brand's treatment that his method does reduce these two important and constant factors of hemorrhage and perforation. There is one other thing to be said about it, that those who advocate his

method began by claiming that it was successful on account of combating the hyperpyrexia. Then it was claimed it was successful on account of some mysterious and yet unexplained influence upon the nervous centres. What precisely that action is, has not so far been explained; but all the advocates, Brand himself and all the advocates of his method, constantly reiterate that, in order to have it successful, and in order to have a fair test of the method, it should be applied from the very early stages of the disease, and that is where he has his advantage in dealing with the army cases, not simply that they are young and vigorous, but also he is able to take them from the beginning. Well, that we never can do in our municipal hospitals. The patients come in late, or if they do not come in late, they come in, as Dr. Mason suggests, because they are particularly severe cases. Now, according to the claims of the advocates of this method, a very large percentage of our cases are not suitable subjects for that method; and if the application of the method is unsuccessful in our cases, then the answer is that they were not taken early enough. Then there is a great number of the cases taken very early in the very first days of their symptoms, in regard to which the diagnosis cannot possibly be a positive one, and never would be a positive one if they are rapidly cured. I entirely agree with what Dr. Mason has said in regard to the small value of conclusions drawn from a few cases, and have but very little confidence in intestinal antisepsis.

DR. F. H. WILLIAMS: I have been very much interested in Dr. Mason's paper. Dr. Shattuck has discussed it in its broader features, and there hardly remains anything for me to say except to speak of one or two details. I am very glad to be able to confirm Dr. Mason's observations in regard to the use of hydronaphthalin. It seems to me the intestinal symptoms are decidedly milder, there is less diarrhea, less distension of the abdomen, and the patients are rather more comfortable with hydronaphthalin than without it. With the hydronaphthalin I used a special food through the co-operation of Dr. Rowe, with whom I arranged to use evaporated milk, that is, milk prepared in a way which enables one to give it to a patient in a fresher and better condition than one usually can do. That was used in the typhoid cases during the two months of the service I had last summer. I have not observed a great deal of difference between the hydronaphthalin with and without the evaporated milk. The number of cases, however, was not large enough to base an opinion on.

DR. C. P. PUTNAM: With regard to the source of the contagion, do not the records show where the patient had been a short time previous to entrance, or were the statements only taken from his residence?

DR. MASON: The statement I made was only with reference to the residence of the fatal cases. There was not time to investigate the whole series, so that I cannot answer that question. There was but one fatal case that came from a distant town. The great majority had lived in the city.

DR. GEO. B. SHATTUCK: Since Dr. McCollom read his paper some weeks ago I have questioned my patients pretty carefully as to whether, though residents of Boston, they went to picnics outside, and especially to one dangerous locality, and I have found that only two or three had been to such picnics.

DR. MASON: When I was in Germany twenty years

ago, this matter of cold baths interested me, and it was then that this second edition of Brand was published. Other works were written by Ziemssen, Bartals and Liebermeister. I found that the results varied much in different cities. There was a great difference between the results in Berlin and Vienna, where the method had been tried on a comparatively small scale but without reduction in the mortality; still it has always seemed to me a rational procedure. We recognize the desirability of cold water, of hydrotherapeutics; and I think that if we are going to bathe at all, we might as well use the easiest and most efficient method. It certainly is less trouble for ward attendants to put the patient into the tub-bath and let him lie there than to sponge him fifteen or twenty minutes.

DR. G. W. GAY reported

THREE CASES OF OESOPHAGOTOMY.⁴

DR. RICHARDSON: I would like to know whether in these very interesting cases Dr. Gay made any efforts to detach the foreign body and remove it by the mouth. I think that reasonable attempts should be made in this direction, unless there is some very good reason for not doing so. A few years ago a man came to me with a plate of teeth which had been impacted in his oesophagus eleven months. I made careful observations as to its situation and distance from the incisors. I found that the plate was about opposite the transverse portion of the arch of the aorta, and could probably be reached easily by external oesophagotomy. In testing the firmness of the contraction by means of the coin probang, the plate was detached and removed with the greatest ease. I should therefore think it worth while in all similar cases to make some attempt at removal by the mouth.

There is some danger in the use of the coin probang, especially in attempting to detach plates of teeth. In the first case of the kind which came under my observation, attempts had been made to detach the plate by means of this instrument. The probang got caught in the plate in such a manner that it was impossible either to remove the plate or detach the instrument. The plate had been impacted nearly a year and had become so firmly imbedded that the end of the probang broke off without producing any sensible change in the position of the plate. I believe it is a good plan to make such efforts, however, unless the foreign body has sharp points, or has been very long imbedded. In the latter case, as I have already stated, it seems to me worth while to make gentle attempts. But it must be borne in mind in the use of an instrument like the coin probang, that if it is once fast to the foreign body it may be impossible to detach it, as in the case already referred to; then something must give way — either the instrument, the foreign body, or the part in which it is imbedded. If the foreign body is impacted at the common place — the beginning of the oesophagus — there is less danger of serious injury to the surrounding parts than where it lies deep within the thorax. In some portions of the thorax, and, in fact, in all portions of its course below the aorta, the oesophagus is in very close contact with the heart or with some portion of the aorta itself. It is obvious that violent efforts at removal are very dangerous indeed, and that sudden death may take place during the course of these manipulations. In such cases it is certainly better to follow the plan of Dr. Gay, and to

remove the foreign body by opening the oesophagus, and by intelligent manipulations, than to make any efforts at detachment through the mouth. Even when no attempts have been made to remove foreign bodies by the mouth, numerous cases have resulted in ulceration into the aorta, posterior mediastinum or pleural cavity. In doubtful cases it certainly seems better to perform external oesophagotomy or gastrostomy. External oesophagotomy is one of the most beautiful operations that we have, and now that so much better results follow methods of aseptic surgery, we are justified in making attempts at removal by intelligent dissection and demonstration of the seat and position of the foreign body. I have never observed any bad results from the impaction of foreign bodies in the oesophagus, but such is not the usual experience. Where urgent symptoms exist, as in the cases previously reported by Dr. Gay and Dr. Cheever, I believe that immediate operative interference is imperative.

DR. GAY: The little girl was well in three weeks, and the man lived two months with comparative relief. Towards the end of life we did tracheotomy to relieve the dyspnoea from the pressure of the growth. It did some little good, but not very much.

NEW YORK NEUROLOGICAL SOCIETY.

MEETING of February 2, 1892, the President DR. L. G. GRAY, in the Chair.

PACHYMEMENINGITIS AND MYELITIS.

DR. MARY PUTNAM JACOBI read an account of a case of this condition which was at first supposed to be due to a Pott's disease, but where a solid tumor had developed against the spine during the last weeks of life, and was diagnosed as sarcoma. The case was compared with one related by Dr. Gee in the St. Bartholomew Hospital report, and close resemblances pointed out between them. In Dr. Gee's case the sarcomatous nature of the disease was demonstrated by an autopsy which could not be obtained in the case under discussion.

DR. C. A. HERTER thought it unfortunate that no autopsy had been made in the case reported by Dr. Jacobi as the diagnosis seemed open to a good deal of speculation. There was apparently no justification for the assumption that two lesions existed and a single one would explain the symptoms. This lesion may have been one of sarcoma or tubercular disease, and it would be difficult to determine which; the existence of malignant disease was probably out of the question.

DR. W. H. THOMSON disagreed with the last speaker. The chief point of interest was in the fact that there may have been two distinct lesions in the cord, presenting in their symptoms the contrast in the nature of the lesions. It was well known that in the case of tumors pressing upon the cord there was present as a symptom local pain, especially on movement of the parts. Transverse myelitis there would present this kind of pain, and unless accompanied by distinct meningitis there would be no irritation of nerve roots. Therefore, according to description, there might have been two conditions of the cord occurring in the same patient. The symptoms developing afterwards in the legs were the sequelae of transverse myelitis. Finally, the effect of

⁴ See page 332 of the Journal.

the presence of a tumor invading and spreading into the tissues was simply pressure at that point.

DR. B. SACHS doubted if in the majority of cases there was myelitis associated with the presence of a tumor, though in a tuberculous case these sometimes occurred. Tubercular myelitis was distinguished by being more destructive to the substance of the cord than other forms.

DR. JACOBI said that the reason for supposing that there was a second lesion differing from the original one was the persistence of the epigastric reflexes. It was presumed that there was a tumor of the cord beginning in the first dorsal vertebra, causing a pachymeningitis at that point, followed by a meningitis.

THE SURGICAL TREATMENT OF EPILEPSY,

by DR. JOSEPH PRICE, of Philadelphia.

Epilepsy was defined as an apyreptic nervous affection, characterized by seizures of loss of consciousness with tonic or clonic convulsions. Its history from a therapeutic standpoint was one that taxed the efforts of supreme superstition and defied the sources of scientific medication. Its treatment had been one of trial and disappointment, for it still remained one of the greatest opprobria of medicine. Its attacks were visited upon both sexes, hysterical epilepsy for the most part being confined to females. This latter class were attacked when a marriageable age was reached. Debauchery had frequently led to it.

Young widows were prone to attacks, and its origin, outside of physical causes, might be traced to amorous songs and certain stimulants, such as chocolate and coffee. For its cure various suggestions had been made, among other things that of resorting to venery. It had, however, been abundantly proven that excessive lust had produced epilepsy, and was no doubt yet to be recognized as a great factor in its causation. That it was transmissible did not admit of dispute, any more that it was caused by traumatism. Operative interference in the traumatic cases, for the removal of the cause was both logical and often successful. The operation of clitoridectomy had brought Baker Brown into disrepute, and yet we had to-day no less a person than Lawson Tait boldly expressing the opinion that here was doubtless a place for the operation. The belief that a moral element must be reached in addition to the physical interference was no doubt justified by the facts. One table that the author had consulted gave as high as 73.7% of cases cured of masturbation, by clitoridectomy.

This surely made it not presumptive in its claims for recognition. Epilepsy in women appeared to be more fatal than in men. The acquired epileptic habit was more fatal than the congenital. In the congenital it was two to one, and the acquired three to four, fatalities in women, to one in man. As to the inheritance of the disease, it was sufficient to note that among epileptics marriage should be discouraged. The history of eunuchism as a preventive of epileptic propagation and also the edicts forbidding their marriage were of interest to the student of law as well as to the theologian and physician.

In the treatment of epilepsy proper there was no doubt that surgery must form an important factor in the hope of cure, whether done for direct traumatic results or for the removal of reflex causes. In entering upon the consideration of the removal of the appendages in women for the cure of epilepsy it was unneces-

sary to take up in detail the history of castration as practised upon the male for the same purpose. Suffice to say that the history of this operation, both from a priestly standpoint and from a carnal or musical standpoint was often instructive and oftener horrifying. The mortality was often simply terrible, while the practice of mutilating children to preserve their voices for song, marked an era of refined religious cruelty scarcely conceivable. So far as the surgery of the disease was concerned, in a general way operation had the best of the argument. Out of 71 cases treated medically, and out of a second series of 71 treated surgically, statistics showed that of the surgical treatment all were at least benefited, while the medical series, a great proportion showed no effect at all from treatment, and in others the conditions were aggravated. In a general surgical way then, if operation was beneficial when it could be directly traced to the ovaries or their diseases, logical deduction would seem to indicate that beneficial results might at least be hoped for. So far as unsexing an epileptic was concerned, the author did not understand how or why there was reason to feel compunction at such a suggestion. He could hardly question the protective value to society not only of forbidding epileptics to marry, but of rendering them unable to procreate. A wise legislation would of course be needed, to prevent abuse, but the essential right of society to protect itself ought not to be questioned.

Going aside from the actually demonstrable disease, what was to be done in the presence of epilepsy where disease was doubtful?

If we had an unmarried woman in whom every menstrual period, from the initiation of her puberty to the time that she came under the physician's care, was marked by an epileptic seizure, who at other times was entirely free from attacks and showed no tendency to fall into them, who recovered as soon as the period was over and who had no other demonstrable disease, or probable cause of seizures than her monthly irritation, it seemed there was little doubt that operation was justifiable. Unless we could thus pin down the seizures to definite time and cause, the author held that it was wrong to burden surgery with a class of cases that could only fail to detract from its good name, while it did no possible good to the individual. If ovarian disease was found to be the cause of the epileptic seizures it was of no use to do a partial removal and expect relief or cure. The effect obtained might be due to either one or two causes; first to the removal of an irritable or diseased organ whose presence stirred up the reflexes into a commotion, or the relief might be due to the excitation by operation of a different epilepto-genic zone. Charcot had laid down as a principle that irritation of one epileptic zone might be relieved by irritation or pressure upon another. Assuming it as a fact that the disease was often a reflex manifestation of a local trouble, it followed that in those diseases in which deposits were found as a result of systemic affection, resort should be had to recognized remedies, and the chances for effecting a cure were equal with those of surgical cases where operative interference was resorted to.

DR. H. J. BOLDT, in opening the discussion of Dr. Price's paper, thought that some nervous diseases might be due to menstrual disorders, but they were not numerous. The removal of adnexa was one of the gravest operations in surgery, both in its medical and

medico-legal aspects. It was most important to select cases. When absolute pathological conditions were present, and treatment had been carried on unsuccessfully by all the methods known to the profession, and when the gross lesion could be discovered to be present in the adnexa, then operation was perhaps justifiable, and good results might accrue. If the epileptic attacks were restricted to the menstrual period, and it was concluded that the prime cause lay in the adnexa, then operation might be resorted to, but little else but bad results was to be expected.

DR. G. M. HAMMOND thought that two points should be borne in mind, the establishment of the epileptic habit, and the influence of pathological conditions of the uterus and ovaries in producing epilepsy. The fact that operations performed on the brain for the relief of epilepsy when there existed a well-defined lesion were not in the majority of cases followed by cure of the seizures was well known now. The habit persisted, and many of the cases so operated upon were reported cured too soon. The condition was in fact only abated or dormant for a more or less limited period. As to the influence of abnormalities of the genital apparatus in the production of epilepsy, it seemed to the speaker that those of the uterus were more potent than those of the ovaries. Lacerations, malpositions and inflammations of the uterus were more likely to cause epileptic seizures than irritation of the ovaries. At a time when gynaecologists were removing ovaries by the bushel, the speaker had sought to inform himself of some of the results by writing to a number of asylums. The questions put were as to the cases of melancholia in which operation had been done. He had received a stock of reports. The consensus of opinion was to the effect that epilepsy and insanity had not been relieved by removal of the ovaries. As to the effect of ovariotomy in producing insanity, he had seen four or five cases of epilepsy and hystero-epilepsy come on in a few days after ovariotomy was performed. Others had met with the same experience. While he had seen some cases of insanity and melancholia recover after relief from uterine irritation, he had never seen such result follow ovariotomy.

DR. BUCKMEISTER said it was hardly fair to call epilepsy a disease. It was a collection of symptoms which had no anatomical basis. It was influenced by irritation of all kinds, and naturally those produced in the reproductive organs would be of the most marked character, though observers were not agreed upon the exact role which these organs played in this respect. The previous speaker was probably correct in assuming that more irritation could arise from injuries of the uterus than from lesions in the tubes or ovaries. Evidence was so strong that no good was accomplished by ovariotomy in the conditions under consideration that the operation was to be condemned.

DR. W. M. POLK said his experience of the results of operations for the cure of hystero-epilepsy was limited to three cases and was not such as to embolden him to continue the procedure. Two of the patients had become insane, and the third one was in a distressing condition of nervous irritability. Epilepsy was still really a fruitful field for investigation. It must be remembered that eighty per cent. of women were stated to be hysterical.

A large amount of epilepsy was known to be due to peripheral irritation, and there was no reason why the

ovaries should not set up some of this. If they did this, they should be taken out.

DR. SACHS had seen a number of cases in which operation had been done, and with no effect upon the epilepsy. It was a mistake to remove ovaries because the patient had epilepsy at the menstrual period. If it could be proven that the person had no congenital epilepsy, and that the first attack came on with menstruation and had occurred constantly since, but only at the menstrual period, there might be some fair reason to remove some of the sexual organs. Because a woman was an epileptic and had sensitive organs which could be removed, was a ridiculous argument in favor of the removal.

DR. L. WEBER did not take the view that the irritation following lacerations of the uterus was a cause of epilepsy. In a large experience of twenty-eight years he had never seen more than two cases in which the epileptic condition had been thus induced unless there was a history of hysterical or epileptoid taint before the age of puberty. He believed that true epilepsy acquired from lesions of the genital organs was a rare condition. He would only give his consent to operation interference on very narrow grounds, and where there was a fair hope that by removal of the ovary the condition could be cured.

DR. BUCKMEISTER explained that he did not mean that injuries to the uterus following parturition were active in producing epilepsy, but that of all lesions to the reproductive organs these were most likely to act as irritants, and were, therefore, quite likely to result in the nervous condition under discussion.

THE PRESIDENT said that all neurologists were agreed that what was called the epileptic state was nothing more than a symptom indicating intra-cranial disturbance, spinal or peripheral nerve irritation, or inflammation of the visceral nerves. The most frequent source of the symptom lay in intra-cranial disorders. Spinal epilepsy was rare as was also that arising from peripheral irritation. How important a part the abdominal nervous system played was not quite known. But the most uncertain of all was the influence of the female organs in producing the epileptic symptom. At any rate there was not a single reputable record of the cure of epilepsy; not one that would stand the test of examination. To report relief for a few months, or even a few years, was to report nothing; and this was all that had been done. Almost every therapeutic or surgical measure had done good, but there was nothing more in the way of cure reported by modern effort than could be found chronicled by Escarol in 1828.

DR. PRICE closed the discussion by reiterating his opinion that permanent benefit was possible in properly selected cases.

ANCIENT HINDU VACCINATION.—At a meeting of the Epidemiological Society (*Lancet*, February 29, 1892), Dr. Pringle quoted a remarkable passage from an ancient Hindu work, which showed that true vaccination was known and practised in India centuries before the birth of Jenner: "The small-pox produced from the udder of the cow will be of the same mild nature as the original disease . . . the pock should be of a good color, filled with a clear liquid, and surrounded by a circle of red. . . . There will be only a slight fever of one, two or three days, but no fear need be entertained of small-pox so long as life endures."

Recent Literature.

A Manual of Practical Hygiene. By E. A. PARKES, M.D., F.R.S. Eighth edition, pp. 769. Edited by J. LANE MOTTER, M.A., M.D. Philadelphia: P. Blakiston, Son & Co. 1891.

There is no more progressive department of the science of medicine than that which relates to public hygiene, a fact which is shown in the demand for frequent revisions of practical standard works upon the subject.

The editions of this excellent work which were issued after Dr. Parkes's death in 1876, were edited by Professor De Charmont, whose rich experience added great value to the work.

The present editor has brought the work down to date by the careful addition of new and important matter, and the omission of such as had become obsolete.

The arrangement of the contents has been slightly changed from that of the earlier editions, and the chapters are as follows: 1. Soils; 2. Water; 3. Removal of Excreta; 4. Air; 5. Ventilation; 6. Habitats; 7. Warning of Houses; 8. Food; 9. Quality, Choice and Cooking of Food; 10. Beverages and Condiments; 11. Exercise; 12. Clothing; 13. Individual Hygiene; 14. Disposal of the Dead; 15. Climate; 16. Meteorology; 17. Disinfection; 18. Prevention of Disease.

The second part is devoted to military hygiene, and the third part to chemical and microscopic examination.

Lessons in the Diagnosis and Treatment of Eye Diseases. By CASEY A. WOOD, M.D. With numerous wood cuts. 12mo, 154 pp. Detroit, Mich.: George S. Davis.

This little book is one of the leisure-hour series, and while it necessarily suffers from the attempt to put much into small space, nevertheless it is the best of the numerous small hand-books which have been issued in later years. For its purpose, as an aid to the general practitioner without taking too much time to "look the matter up," it will no doubt serve a useful purpose.

The Complete Medical Formulary and Physician's Vade-Mecum. Containing more than 2,500 prescriptions, also a special list of new drugs with their dosage, solubilities and therapeutic applications, together with a large number of other tables. Collected for the use of practitioners, by J. C. WILSON, A.M., M.D., Physician to the German Hospital, Philadelphia: J. B. Lippincott & Co. 1892.

This volume, as its name implies, is a collection of prescriptions arranged under the head of diseases. The prescriptions are taken from a large number of authorities, in all cases credit is given to the authority. There are also several tables containing useful information. Except for these the book may be said to be nothing but prescriptions, without any reading matter whatever. It is to be hoped that few practitioners would rely upon such a compilation to any extent. On the other hand, it might be useful to any physician as an occasional reference or inspiration. Although it is bound in the form of a book for the pocket, it would be found bulky to carry in anything smaller than an overcoat.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, APRIL 7, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE OBLIGATIONS OF MEDICINE TO PHYSIOLOGY, AND OF PHYSIOLOGY TO MEDICINE.

THE dependence of medicine, both as a science and an art, on physiology is everywhere recognized. Disease is but a disturbance of the normal conditions of the organism, and the aim of the physician must always be to restore the physiological integrity. If this proposition be sound, then medicine must advance *pari passu* with physiology. This will be found to be true of ages when physiology was unprogressive; medicine was at a standstill or pursuing empirical *ignes fatui*. Out of innumerable instances we will cite only one—the senseless infatuation for bleeding of a former generation. If bleeding as a routine therapeutic measure in the treatment of acute inflammatory affections has gone out of use, this is chiefly because it has been found opposed to the teachings of an enlightened physiology.

If physiology has made any progress in any age, such progress has been accomplished through experiment, and largely through experiments on animals. It is quite possible for a physiology to be founded on observation alone, but such a physiology could not get beyond a few simple rules respecting the conditions of function, or in any way satisfy human needs. The same may be said of "the medicine of observation"—to use an expression of Claude Bernard. Notwithstanding the large debt which we owe to clinical observation, which has laid the foundation of our knowledge of diseases, it is evident that its status and its progress lie wholly within the domain of empiricism.

These truths are sufficiently familiar to medical men, and the illustrations are abundant. Among those most often cited to prove the utility of vivisection are the discovery of the circulation of the blood in the seventeenth century, and the bacteriological discoveries of the present epoch; no one pretends that these discoveries and the consequences flowing therefrom, so important to medical and surgical therapeutics, could

ever have been brought about without vivisection. The opposition to vivisection has never come from medical men: if the anti-vivisectionist party has been able to attract to its ranks, here and there, a physician of some note, such support has been tendered from sentimental, political or other purely selfish consideration, rather than from any devotion to science or any principle of liberal humanitarianism.

The rank and file of the medical profession are united in approbation of the work of the experimental physiologists, and recognize the fact that too few, rather than too many, have the time, the means and the ability to engage in original researches whose practical outcome is helpful to science and beneficial to humanity. Physicians should be the educators of society in matters connected with the progress of medicine by experimentation, and if from time to time they have to acknowledge their remissness in this respect, they are ready to welcome the aid of lay writers, who, like the Rev. Lionel J. Wallace in the *Westminster Review* for March, 1892, have set forth the advantages accruing to mankind from vivisection.

It may not be that we are in any special danger from anti-vivisection legislation in this country, but cranks of the same nature abound here as have inflicted on Great Britain an obstructive enactment whose effects in stifling original investigation are keenly felt by our transatlantic *confrères*.

Rev. Dr. Wallace, in the *Review* aforesaid, begins with the twofold inquiry concerning vivisection; Is it useful? Is it moral? With regard to the first, he urges, with Darwin, that physiology can progress only by the aid of experiments on living animals. This is proved by contrasting the past with the present. Accounts of old-fashioned surgery read like a bad dream. Boiling pitch or oil, red-hot knives, corrosive sublimate used to stop the hemorrhages from wounds, and in four out of five cases used in vain, made the surgery of our forefathers horrible. If the luckless patient survived the actual operation and escaped bleeding to death, he very often succumbed to fever, or mortification ensuing on the violent means employed for his cure. Everything is now changed. During the insensibility induced by an anesthetic, the knife does its work swiftly and cleanly; the severed vessels are securely tied; the wound dressed antisepically, and the patient awakes as from a sleep. That this change has been mainly owing to knowledge acquired by vivisection. Mr. Wallace next shows. He goes back to the immortal discovery of Harvey, which never could have been demonstrated without vivisection, and he then appeals to the writings of Jean Louis Petit, of Ambrose Paré, of John Hunter, etc., who admit that by means of the help obtained from experiments on living animals, all their most momentous discoveries were made. "By carefully conducted amputations performed on dogs, the best method of tying the great vessels and preventing excessive hemorrhage were found; an experiment on the antlers of a stag suggested some of the resources of collateral circulation:

ligatures bound around the arteries of dogs confirmed the facts thus suggested. The successful accomplishment of a now not excessively rare operation, the excision of a part of the intestine, was rendered possible by an experiment on the living animal."

The writer next enters the domain of therapeutics, and shows how much we are indebted to experiments on animals for the knowledge which we now possess of the physiological and toxicological effects of strychnia, digitalis, chloral, aconite, straphanthus, and other drugs. That therapeutics has immensely benefited by this knowledge, no really sane person would deny.

It is in the domain of the nervous system that we now resort to vivisection. Mr. Wallace reviews the labors of Sir Charles Bell and of Claude Bernard, though he singularly enough omits all mention of Louget, Flourens, Magendie, Vulpian, Brown-Séquard and other French, besides numerous equally well known German, experimenters. After glancing at the practical outcome of those discoverer which have thrown a flood of light upon the functions of nearly every part of the nervous system, he takes up bacteriology with which present science is so much interested, and shows all the dependence of bacteriology on physiological experimentations. Into this subject we need not enter, as the readers of this JOURNAL are sufficiently familiar with these investigations and their results to medicine, surgery, and obstetrics from a prophylactic and curative point of view. He now takes up the charge of immorality.

Briefly summed up, the arguments of the anti-vivisectionists appear to amount to this: That even granting that occasionally some good results have been gained by means of vivisection, the pain inflicted is altogether out of proportion to the results achieved; that, however, no results can justify man in inflicting excruciating agony upon any living creature, for in so doing he outrages one of the highest moral laws; besides which the practice tends to debase the mind and harden the heart, and it is of far more importance that the mind shall be pure and the heart tender than that a curse should be found for any bodily disease.

To which the vivisectionists reply: We deny that the pain inflicted is out of proportion to the results achieved; on the contrary, we assert (and we challenge our opponents to impugn the assertion) that the pain is trifling in comparison with the benefits conferred. A minority must always suffer for the majority, and so far from outraging any ethical law by sacrificing a certain number of animals, we believe that we would be guilty of a serious moral wrong if we abstained from this sacrifice, since by our experiments we may give relief to millions of men and beasts. While to stand idly watching the ravages of disease, which, by certain measures we might prevent or diminish, would certainly suggest and induce a condition of callousness and mental degradation. We have no right to withhold from suffering humanity any good thing which it is possible to give it.

The writer of the *Review* article believes that a

great moral force in working on behalf of the physiologists. Suffering and death are on every side of them, and if, by any fair means, they can alleviate the one and retard the other, they have no right to neglect these means. They are, so far as their power extends, debtors to humanity, and they would act an immoral part if they declined to make any legitimate effort to discharge this debt. This the anti-vivisectionists will not see or will not acknowledge. They are not satisfied with merely denying the fairness of the means, but they deny the morality of the whole science, not perceiving that in so doing they place themselves in a serious dilemma. For none save the most bigoted would deny the lawfulness of putting an animal to death for some useful purpose. Few would refuse sanction to the infliction of a certain amount of pain if the object thus gained were good. The butcher is counted a respectable member of society though he puts many animals to death, and some of them by a method not essentially painless, because he kills them for food. If he were to slaughter them merely for amusement, or through sheer wantonness, he and his actions would at once become immoral. But if a single butcher were to do this, it would not lead any rational person to assert that the trade was an immoral one. The fact of one or a hundred physiologists experimenting through curiosity or from an entirely selfish love of knowledge does not render vivisection immoral, if it can be shown that the science in general tends to good. It is indeed conceivable that vivisection might develop into a something ethically wrong; but with the safeguards secured by the State, on the one hand, and on the other, by the fact that men of science are not, as a rule, necessarily brutal or wanton, and have some regard for virtue, concrete as well as abstract, this does not seem likely to be an immediate danger.

THE THIRTEENTH ANNUAL REPORT OF THE MASSACHUSETTS BOARD OF LUNACY AND CHARITY.

The reported number of insane under supervision of this Board is 5,944, an increase of 232 during the year 1891, to further swell the accumulation of inmates of our already long-overcrowded institutions for the insane. The aggregate number of persons admitted to the different State hospitals for the first time is 1,238 against 1,122 for the preceding year. Of this number 632 are patients suffering from the acute curable forms of insanity (exclusive of alcoholic cases) against 695 in 1890.

Some relief to these gloomy statistics is offered by an unusual increase of three per cent. in the number of reported recoveries at the lunatic hospitals over that of the preceding year. This is particularly encouraging as it is a gain not to be accounted for by any increase of new cases nor by the advent of any unusual number of habitual drunkards, of cases of toxic insanity, delirium tremens and the like, which so often swell lists of reported "cures." If this happens when

our hospitals are crowded as never before, the deduction must be either that proper accommodations and good care — such as the Board strongly advocates in the erection of the proposed chronic asylum at Medfield — will still further increase these figures, perhaps to those reported in England and Scotland, or that, as a few respected authorities would have us believe, recoveries among the insane are by no means necessarily the most frequent when their care is the best and the methods the most approved.

There is the usual depressing chapter — to which we annually recur — of reports on the condition of the town almshouses and the insane therein, who now number 806. Although there is some surface improvement in their care, the neglect of these unfortunates is practically the same as ever, and will so continue until the State adopts the plan of supporting all the dependent insane within her borders, a practice recently adopted in New York, and in vogue in several other States. To our mind the relief of these unfortunates will hardly be brought about, as the Board hopes, by the erection of the chronic asylum at Medfield, even in the event, which is by no means in the near future, of the rate of board becoming there "so low as to enable every town to board its insane there as cheaply as at home." Witness the large chronic asylum at Willard, in New York, with its low rate of board, which has long existed side by side with county almshouses, in which were large numbers of disgracefully-treated insane whose care that State has only just now undertaken.

There is, to be sure, every reason for alleviating the condition of the insane in the State hospitals by preventing overcrowding through new provisions for their care, but it should not be forgotten that their condition is even now one of great comfort beside that of the almshouse insane, and that efforts for the relief of both these classes should go hand-in-hand. No greater philanthropic endeavor could be instituted than immediate work in the line of exclusive State (as distinguished from town) care of the insane.

The boarding-out system for the insane is still classed as an experiment, although now in not unsuccessful operation (except as a relief to the numbers in the hospitals) for seven years. It is acknowledged that a few have been made happier thereby, some self-supporting, some well in mind and body, and that the system is well worth continuing. It is, however, thought to have reached its numerical limit — the number averaging 142 — and to have been an expensive undertaking. The former statement cannot yet, we believe, be confidently predicted, and the latter does not appear from the usual calculation of cost *per capita*, if made from the figures given. In fact, the cost compares very favorably with, and is, as a rule, less, than that incurred for the support of the same patients when in asylums.

Dr. Moulton, the former inspector, contributes a thoughtful and discriminating paper on "Lunacy Administration in Scotland," which we wish space would

allow us to comment upon at length. Much of it is devoted to a comparison of the boarding-out system in that country and at home. His views thereon are particularly valuable, owing to his practical experience in developing the system in Massachusetts. He is, on the whole, favorably inclined to such a provision; but although he touches upon the improved care received in the homes of such patients in this country, we miss the warm advocacy of the measure and of its development in this country which his former reports and other contributions would lead us to expect.

THE ANNUAL REPORT OF THE BOSTON CITY BOARD OF HEALTH.

THE annual report of the Board of Health for the year 1891 shows that the city is in good sanitary condition. The deaths during the year were 10,571, an excess of 390 deaths over the number of the previous year. This increase is in part accounted for by the unusually large number of deaths from cholera infantum during the summer months, which were marked by a continued higher temperature and an excess of humidity over 1890. The advent of the epidemic of influenza in December, and its influence on other diseases, increased the number of deaths during the latter month to 1,133, as against 850 for the same month of the previous year. The population is estimated at 459,062, and on this basis the death-rate for the calendar year is 23.02, an increase of .32 over the rate of the previous year. The deaths due to zymotic diseases show a smaller percentage of the total mortality than in any year since the Board was established, being about 15.27 of the total number of deaths. There were only 232 deaths from diphtheria, as against 401 the preceding year and an average of 426 for the ten previous years. There was a slight increase in the deaths from scarlet fever. There were fewer deaths from typhoid fever than the average, and the percentage to the number of cases reported shows that the disease was of a milder type than usual. One thousand and three hundred and fifty-two deaths were reported as due to consumption of the lungs, 1,149 to "inflammation of the lungs," 1,071 to pneumonia, 597 to cholera infantum, and 494 to "heart disease, unclassified." Three thousand one hundred and fourteen deaths were due to diseases of respiration, and 3,608 were children under five years of age. There were 5,712 cases of contagious disease reported to the Board, as against 4,370 in 1890, but the deaths from these diseases fell from 617 in 1890 to 471. There were 1,327 cases of scarlet fever with 64 deaths; 2,588 cases of measles with 21 deaths; 966 cases of typhoid fever with 154 deaths.

Concerning influenza, the report says that the occurrence of this disease every fifteen or twenty years, its apparent disappearance at the end of a year, and its recurrence at the end of two years are extremely interesting facts. The second epidemic, through which the city has just passed, although not so general as

the epidemic of two years ago, has had, in proportion to its extent, much greater influence on the death-rate from acute pulmonary diseases. The effect of the first epidemic, however, on the death-rate from chronic pulmonary diseases was much more marked than that of the second. It may be safely stated that, directly or indirectly, this last epidemic of influenza has increased the mortality-rate of Boston from 21.28, the estimated rate per thousand for 1891, to 23.02, the actual rate for the same year.

The effect of deaths from consumption on the death-rate of Boston is not fully appreciated by the general public. The percentage of deaths from this cause is larger in this city than in many of the cities either in this country or in Europe. In addition to the infectious nature of this disease, crowded and overheated halls, workshops and dwellings,^{out} important factors in causing its prevalence.

The cases of typhoid fever are carefully tabulated and studied, and the statistics, carefully compiled, make it evident that neither the water-supply, nor made land, nor imperfect drainage, can be considered responsible for the comparative prevalence of typhoid fever in Boston, but that the frequency of this disease must be attributed to other causes than those over which the Board of Health has control.

For more than a year the Board has endeavored to inaugurate a system of medical inspection for the schools by which the spread of contagious diseases would, it believes, be diminished and many other dangers of school-life avoided. An appropriation of \$5,000 for this purpose was transferred to another department before the system could be organized, and it will be necessary to wait until another appropriation can be obtained.

In his report the physician to the Board states that 43 cases, reported as small-pox, were examined, but that in no instance was small-pox found to exist. This has been the first year since 1879 in which there has not been a single case in the city for a period of twelve months. With regard to diphtheria and scarlet fever the fact brought out clearly in his report a year ago is again mentioned, that with the opening of the school year the number of cases steadily rises, and that it is by far the least frequent during the months when the schools are closed.

The report of the physician at Quarantine shows that 52 patients were treated in the Quarantine Hospital, of which number 32 were cases of measles and 8 were detained for observation. Six hundred and thirteen vessels were boarded and 35,577 immigrants inspected. No case of contagious disease existing at the time of arrival in Quarantine had escaped notice.

MEDICAL NOTES.

MORE TYPHUS CASES IN NEW YORK.—Three new cases of typhus fever have been discovered by the health authorities in New York, and the sufferers were removed to North Brothers Island.

JEWISH IMMIGRATION.—The recent attempts to regulate the flood of immigration into the United States has been the cause of anxiety in England, lest some of the Russian Jews should turn in that direction. In the House of Commons a member asked the Government whether it intended to introduce a bill limiting or prohibiting their admission into the United Kingdom. Mr. Balfour, in reply, stated that at present there was nothing to justify such a bill. The expectation that a large number of Jews would come to England was based upon the belief that the United States would be closed against them, but inquiry showed that there was little reason to fear such a catastrophe. The fact that Austria and Germany have closed their frontiers against these immigrants makes the position of England still more safe.

AN OUTBREAK OF SMALL-POX IN LONDON.—During the past week a large number of cases of small-pox have been reported in London. Whereas during the four months previous there were only five cases, last week there were forty patients under charge of one of the local Boards of Health. The northeast and eastern districts are especially affected.

NEW MEDICAL PERIODICALS.—The *Iowa Medical and Surgical Reporter*, a new monthly medical journal, appeared for the first time with the March issue. It is published in Des Moines, Iowa, and is edited by John W. Overton, M.D. The *Archives Cliniques de Bordeaux*, a monthly journal, under the editorial charge of M. le Dr. W. Dubreuilh appeared in Bordeaux in January. The *National Medical Review*, a monthly journal, edited by Chas. H. Stowell, M.D., to be devoted to current medical literature, appeared in March.

NEW ENGLAND.

MEDICAL INSPECTOR OF IMMIGRANTS IN BOSTON.—Dr. Fairfax Irwin, surgeon in the Marine Hospital service, has been detailed as medical inspector of immigrants at the port of Boston.

MORTALITY FOR THE WEEK IN BOSTON.—The death-rate for Boston for the week remains high. The number of deaths reported has been 240, making the death-rate 27.2. The deaths from consumption were 27, pneumonia 31, bronchitis 13. The number of persons over sixty years of age was 51.

MASSACHUSETTS LEGISLATURE.—The Committee on Public Charitable Institutions have reported leave to withdraw on the petition of the Carney Hospital for a State appropriation of \$10,000. The Committee on Agriculture have reported a bill to prevent the spread of tuberculosis by more thorough inspection of cattle.

NEW YORK.

EXECUTION BY ELECTRICITY.—The eighth electrical execution in the State took place at Sing Sing prison on March 28th, and the efficiency of the method in causing death in a prompt and painless manner can now be regarded as positively assured. In most of the executions some slight variations were

made in the application of the current, with a view, probably, of determining the most satisfactory details of procedure in such cases.

UNIVERSITY OF THE CITY OF NEW YORK.—The fifty-first Annual Commencement of the Medical Department of the University of the City of New York was held at the Metropolitan Opera House on March 29th. The first Faculty prize for general proficiency at the final examinations was awarded to S. C. Minor, who was also the valedictorian of the class. The address to the graduates, who numbered one hundred and sixty-two, was delivered by the Rev. George Alexander, D.D.

A TOY BALLOON IN THE THROAT.—At a coroner's inquest the other day, a novel cause of death was brought to light. A little girl, eleven years old, was playing in the street with a penny toy balloon, and during a sudden inspiration, this was drawn into the upper air-passages. Death from asphyxia resulted before medical aid could be summoned, and at the autopsy the balloon was found lodged in the throat.

REPORT OF THE COMMITTEE ON THE CONDITION OF THE INSANE.—The advisory committee appointed by the Mayor to examine into the condition of the insane under the care of the city, and report on the advisability of transferring this class of dependents to the charge of the State, as the municipal authorities have the option of doing under the provisions of the State Care Act, on March 22d handed in their report, and in it they advise that this change be not effected. In the prosecution of its labors, the committee visited and thoroughly inspected all of the city's institutions for the insane, both on the Islands and at Central Islip, Long Island, and afterwards visited the State Hospitals for the Insane at Binghamton and other places.

While the state of affairs at the farm at Central Islip was, on the whole, very satisfactory, that at the asylums on Blackwell's, Ward's and Hart's Islands, was found to be the reverse. "The condition of these insane poor," says the report, "is pitiable. Their accommodations are a reproach to humanity. Overcrowding exists in every building of every department, and their wretched existence is rendered still more intolerable by the absence of comfortable surroundings, of proper accommodations of every kind, and by insufficient protection, in the case of many of the smaller buildings, from the inclemency of the weather. There is also the danger of fire, which in the inflammable wooden buildings would be certain to result in large loss of life." The State care of the insane at Binghamton and Willard, except in the matter of buildings and the absence of overcrowding, and perhaps that a better quality of meat was supplied to the inmates, was not found better than that of the city; while the cost of maintenance was considerably greater.

Having advised that the city's insane be not turned over to the State, the committee offers certain recom-

mendations. The first of these is that the appropriation for supplies be made more definite to each institution separately, and that the *per capita* allowance be increased at least fifty cents a week. "The insane should be removed from the neighborhood of the convicts and paupers," the report continues. "They should be given all the comforts possible, and those who take care of them should be fairly dealt with. The lot of these attendants is not a pleasant one. Their pay should be adequate, and their quarters pleasant. Meat should be of a better quality. Every straw bed should be burned up at once, and wire mattresses substituted without delay." It is also recommended that the pay of the General Medical Superintendent be increased, and that he be given full power to appoint and remove his subordinates. The committee then recommends that the care of the city's insane be confined to a separate department and that this class be provided for wholly on Ward's Island and at Central Islip, where the accommodations should be properly enlarged for the purpose; the buildings on Hart's and Blackwell's Islands being needed for paupers and criminals. It is also urged that application be at once made to the Legislature for permission for the city to purchase that part of Ward's Island which it does not already own; that the city ask to be relieved from the payment of State taxes for the care of the State's insane; and, lastly, that the Legislature be asked to authorize an issue of bonds to the amount of \$1,500,000, for the purchase of property at Ward's Island and Central Islip, and for the erection of new buildings for the insane at both places.

Miscellany.

EXTRAORDINARY MUTILATIONS FROM A RAILWAY ACCIDENT.

MRS. HOMER R. BALDWIN has brought suit for \$250,000 against the New York Central and Hudson River Railroad Company on account of injuries received in the accident on the road which occurred near Hastings on Christmas Eve last; and, in view of the frightful mutilations she has received and the terrible amount of suffering involved, it is probable that a jury will award her the sum asked, or, at all events, a large proportion of it, especially as she announces that she will devote all the money received to the founding of a charitable institution for women.

This is undoubtedly one of the most remarkable cases on record. In the accident she received a fracture at the right elbow, both hands were mangled, and she was scalded in the most shocking manner about the chest, neck, head and face, including the mouth and upper air-passages, by escaping steam. It was thought at first that she could not possibly survive more than a few hours, but her endurance and tenacity of life were astonishing. She was treated for a number of weeks at the St. John's Riverside Hospital, at Yonkers, and afterwards removed to a hotel in that city. On January 1st, her right hand and the fingers of the left hand were amputated, and her condition

was so critical at the time, that the operations were performed without the use of an anesthetic. In the mean time both ears had sloughed off, and the sloughing away of the scalp laid bare a large surface of cranial bone. After a time skin-grafting was commenced on an extensive scale, and proved successful on the face and neck, though not to a satisfactory extent on the scalp. In the latter part of February a destructive inflammatory process commenced in both eyes, and this proved so disastrous that total blindness resulted, and it finally became necessary to excise both eyeballs. This was done on March 19th, by Dr. P. A. Callan, of New York, and at the same time a number of dead bones were removed from the left hand by Dr. Emil Schopen, the regular attendant in the case. It had been the intention also to scrape away a considerable amount of necroscopic tissue from the exposed skull, but as the patient showed signs of sinking, this was postponed until a later time.

Throughout the entire history of the case Mrs. Baldwin, though never for a moment free from pain, unless when asleep or under the influence of narcotics, has shown the most extraordinary fortitude and cheerfulness, and since the operations just mentioned her general condition has improved to a considerable extent, though her wasted body still weighs only about sixty pounds.

SUGGESTIONS FOR THE REGULATION OF DAIRY FARMS.

In a paper on "Cow's Milk in relation to Human Health and Disease," Dr. H. E. Armstrong,¹ Medical Officer of Health at Newcastle, commends the system of milk-supply and distribution in operation at Copenhagen, and offers the following suggestions for adoption in England:

- (1) That all conditions relating to the production, storage, and distribution of milk should be under State control and regulation.
- (2) That every cow with tuberculosis (proved or reasonably suspected) on a dairy farm should be slaughtered and the owner compensated.
- (3) That all milk by the consumption of which there is risk of the spread of any infectious disease to human beings should be at once destroyed, and, where no blame respecting such risk attaches to the owner, that he should be compensated.
- (4) That the sanitary authorities of towns should have power to license and control the sale of milk sent into their districts from farms outside, and to prevent the sale of such milk, unless satisfied as to the sanitary conditions under which it is produced, stored, or distributed.
- (5) That, in outbreaks of infectious disease associated with milk-supply, the sanitary authority should have power to demand from the retailer the name and address of the producer of the milk.
- (6) That in outbreaks of infectious disease in any district, due to milk sent from another district, the sanitary authority of the district in which the disease breaks out should have power, without delay, to inspect the dairy, and, if necessary, prohibit by their officers the sale of the milk.
- (7) That the sanitary authorities of rural districts from which milk is sent for sale into urban districts

¹ The Practitioner, March, 1892.

should be to some extent responsible to such urban districts for the sanitary condition of the dairy farms on which such milk is produced; and that they should inform such urban authorities of any infectious disease or other condition at such dairy farms whereby the wholesomeness of the milk is likely to be affected injuriously.

(8) That rural sanitary authorities should be required to provide hospital accommodation for the isolation of cases of infectious disease occurring among dairy operatives.

CASTRATION AS A PUNISHMENT FOR CRIME.

At the last meeting of the New York Society for Medical Jurisprudence, Dr. William A. Hammond, of Washington, read a humorous paper entitled, "A New Substitute for Capital Punishment and Means for Preventing the Propagation of Criminals." The substitute was castration, and the following are extracts from the paper:

"A man places greater value on his generative powers than on his life. As a French writer has said, 'the dignity of a man resides in his testicles.'

"The author has several times put the question to criminals under sentence of death, and they all said they would rather hang than be deprived of their testicles.

"Castration would have the effect of making the criminal of some use to society. A dead man is of no use to society, and a man in prison is almost as bad. There are many occupations that would be open to him; he could occupy any position in which boldness or originality are not essential. Possibly he might make a good clergyman. He would not make a soldier, or a sailor, or a policeman, but he could edit a mild newspaper or make an efficient member of the legislative body. The value of eunuchs as singers has long been known. They would make excellent dry-nurses and safe type-writers.

"The scope of this paper was restricted to the male sex. Women have become so accustomed to removal of the ovaries, and these organs are so much less essential to womanhood than the testicles are to manhood, that it might be necessary to substitute imprisonment for life in their case."

METEOROLOGICAL RECORD.

For the week ending March 26, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:

Baro-meter	Thermometer.		Relative humidity.		Direction of wind.		Velocity of wind.		Weath'r.		Rainfall in inches.

Deaths reported 3,162: under five years of age 1,161; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 427; acute lung diseases 667; consumption 355; diphtheria and croup 174; scarlet fever 74; diarrhoeal diseases 39; typhoid fever 35; measles 21; cerebro-spinal meningitis 21; whooping-cough 21; erysipelas 18; malarial fever 7; puerperal fever 7; typhus fever 7. From typhoid fever Philadelphia 12, New York 4, Cleveland 3, St. Louis 1, Boston 1, Pittsburgh 1, Worcester 1, Lowell 2, Cincinnati, Milwaukee 1, Waukesha 1, Charleston, Cambridge and New Bedford 1 each. From measles New York 9, Brooklyn 3, Philadelphia and Pittsburgh 2 each, Boston and Washington 1 each. From cerebro-spinal meningitis New York 9, Brooklyn 4, Washington 2, Worcester, Fall River, Lynn, Lawrence, Springfield and Gloucester 1 each. From whooping cough Pittsburgh 6, New York 3, Brooklyn 3, Philadelphia and Washington 2 each, Boston, Cleveland and Charleston 1 each. From erysipelas New York 7, Brooklyn 4, St. Louis 3 each, Boston 2, Cleveland, Philadelphia and Washington 1 each. From malarial fever New York 4, Philadelphia 2, Brooklyn 1. From puerperal fever Milwaukee 3, Boston 2, Pittsburgh and Nashville 1 each.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 26, 1862, TO APRIL 1, 1862.

The leave of absence granted CAPTAIN MARSHALL W. WOOD, assistant surgeon, U. S. A., is extended one month.

CAPTAIN C. N. B. MACAULAY, assistant surgeon, U. S. A., will report for temporary duty at U. S. Military Academy, West Point, N. Y., during the absence of CAPTAIN HENRY S. KILBOURNE, assistant surgeon, U. S. A., as member of the Army Medical Board, New York City, N. Y., and on return of that officer will rejoin his proper station.

FIRST-LIEUT. FRANK T. MERIWETHER, assistant surgeon, U. S. A., ordered for temporary duty at Madison Barracks, N. Y., during the absence of CAPTAIN HENRY S. TURRILL, assistant surgeon, as member of Army Medical Board, New York City, and on return of that officer will rejoin station.

FIRST-LIEUT FRANCIS A. WINTER, assistant surgeon, U. S. A. (recently appointed) will proceed from St. Louis, Mo., to Jefferson.

erson Barracks, Mo., and report to the commanding officer of that station for duty.

MAJOR JOHN VAN R. HOFF, surgeon, ordered to St. Louis, Mo., to represent the medical department of the army at the meeting of the Association of Surgeons of the National Guard to be held in that city, April 19 to 21, 1892.

The suspension of the operation of Par. 2, S. O. 13, January 16th, A. G. O., relating to CAPTAIN AARON H. APPEL, and FIRST-LIEUT. JULIAN M. CABELL, assistant surgeons, is removed.

Leave of absence for one month, on surgeon's certificate of disability, is granted CAPTAIN EDWIN F. GARDNER, assistant surgeon, U. S. A.

The leave of absence granted CAPTAIN R. W. JOHNSON, assistant surgeon, U. S. A., for seven days, is hereby extended fourteen days.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 2, 1892.

D. O. LEWIS, surgeon, from Naval Hospital, Washington, and to Naval Hospital, Mare Island, Cal.

T. A. BERRYHILL, passed assistant surgeon, from the U. S. S. "Pensacola" and to the U. S. S. "Ranger."

MERRILL W. BARNUM commissioned an assistant surgeon in the Navy from March 15, 1892.

W. G. FARWELL, surgeon, granted leave of absence for six months with permission to leave the United States.

GEORGE W. WOODS, medical inspector, from the U. S. S. "Pensacola" and to the Naval Hospital at Mare Island, Cal.

N. L. BATES, medical director, detached from Naval Hospital, Mare Island, Cal., and ordered home.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE FOUR WEEKS ENDING MARCH 26, 1892.

BAILIACHE, F. H., surgeon. To inspect unserviceable property at Port Townsend, Wash., March 9, 1892. Detailed as member of Board for physical examination, officer Revenue Marine Service. March 26, 1892.

PURVANCE, GEORGE, surgeon. Ordered to Washington for temporary duty. March 5, 1892.

AUSTIN, H. W., surgeon. To inspect Service at New Orleans, Savannah and Charleston, and the Gulf and South Atlantic Quarantine Stations. March 3, 1892.

IRWIN, FAIRFAX, surgeon. Detailed as medical inspector of immigrants, port of Boston, Mass. March 3, 1892.

CARMICHAEL, D. A., passed assistant surgeon. To inspect the San Francisco Quarantine Station. March 7, 1892.

WHITE, J. H., passed assistant surgeon. Ordered to South Atlantic Quarantine for temporary duty. March 26, 1892.

KINNOON, J. J., passed assistant surgeon. To proceed to New York on special duty. March 7, 1892.

FERRY, T. B., passed assistant surgeon. Granted leave of absence for thirty days. March 1 and 14, 1892.

GUTIERAS, G. M., assistant surgeon. Ordered to examination for promotion. March 23, 1892.

BROWN, B. W., assistant surgeon. Assigned to temporary duty at San Francisco Quarantine. March 14, 1892.

EAGER, J. M., assistant surgeon. Granted leave of absence for thirty days. March 1, 1892.

DECKER, C. E., assistant surgeon. Detailed as recorder, Board for physical examination, officer Revenue Marine Service. March 26, 1892.

PROMOTION.

COBB, J. O., passed assistant surgeon. Commissioned by the president as passed assistant surgeon. March 23, 1892.

AMERICAN ACADEMY OF MEDICINE.

PRELIMINARY PROGRAMME.

The following topics are promised for discussion at the Seventeenth Annual Meeting of the American Academy of Medicine, at the Cadillac Hotel, Detroit, Mich., on Saturday, June 4, and Monday, June 6, 1892.

(1) "Essentials and Non-essentials in Medical Education," the Address of the retiring President, Dr. P. S. Conner, of Cincinnati.

(2) "The Value of the General Preparatory Training afforded by the College as compared with the Special Preparatory Work suggested by the Medical School in the Preliminary Education of the Physician," a paper by Dr. T. F. Moses, of Urbana, O.

(3) "Does a Classical Course enable a Student to Shorten the Period of Professional Study?" a paper by Dr. V. C. Vaughan, of Ann Arbor, Mich.

(4) "The Value of a Collegiate Degree as an Evidence of Fitness for the Study of Medicine," a paper by Dr. L. H. Menter, of Chicago.

(5) "The Value of Academical Training Preparatory to the Study of Medicine," a symposium by Drs. H. B. Atlys, of Philadelphia, W. D. Bidwell, of Washington, and Elbert Wing, of Chicago.

(6) "The Newer Medical Education in the United States," a symposium by Drs. W. J. Herdman, of Ann Arbor, Charles Jewett, of Brooklyn, and Elbert Wing, of Chicago.

(7) "The Newer Basis of State Supervision of the Practice of Medicine," by Peter H. Millard, of St. Paul.

Some other papers are partially prepared and the usual reports may be expected from the committees.

Members of the profession are cordially invited to be present at the sessions of the Academy.

ANNUAL MEETING OF THE ASSOCIATION OF MILITARY SURGEONS OF THE NATIONAL GUARD OF THE UNITED STATES.

The second annual meeting of the Association of Military Surgeons of the National Guard of the United States, will be held in St. Louis, Mo., April 19, 20, and 21, 1892.

The railroads have granted one and a third rates. Papers will be read and discussed by regular Army and Navy, and Guard medical officers.

For any information as to meeting, etc., address,

COL. E. CHANCELLOR, 515 Olive Street, St. Louis, Mo.
Surg.-Gen. N. SENN, W. N. G. President.
Lieut. and Asst. Surg. RALPH CHANDLER, Corres. Sec'y.

DELEGATES TO AMERICAN MEDICAL ASSOCIATION.

Members of the Mississippi Valley Medical Association wishing to go as delegates to the American Medical Association at Detroit, will please send names to

DR. E. S. MCKEE, Secretary, 57 W. 7th Street, Cincinnati.

SOCIETY NOTICES.

SURGICAL SECTION OF THE BUFFALO DISTRICT MEDICAL SOCIETY. — There will be a meeting of this Section at 19 Boylston Place, on Wednesday evening, May 4, 1892, at 8 o'clock.

DR. S. J. MIXTER, "Median Abdominal Section for Removal of Tumor of the Kidney; Recovery."

DR. H. W. CUSHING, "A Case of Nephrectomy; Recovery."

DR. JOHN L. MORSE, "Tracheotomy with Delayed Removal of the Tube."

DR. C. L. SCUDER, "Diphtheria; Tracheotomy, Caretting the Trachea; Recovery."

CHARLES L. SCUDER, M.D., Secretary, 94 Charles Street.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held on Monday, May 1, 1892, at the Medical Library, 19 Boylston Place, at 8 o'clock p.m.

DR. S. J. MIXTER, "Aneurism of External Iliac, Laparotomy and Ligation of Common Iliac; Death."

DR. J. B. AYER, "Recuporative Power in Advanced Age."

DR. F. H. WILLIAMS, "Early Local Treatment in Diphtheria." Election of new members.

G. G. SEARS, M.D., Secretary.

ERRATUM.

On page 316, Vol. CXCVI, twenty-fifth line from the bottom, first column, for *faculty* read *fraternity*.

RECENT DEATHS.

SIR WILLIAM BOWMAN, Bart., M.D., consulting surgeon to the Royal London Ophthalmic Hospital, died in London, March 20th, aged seventy-five years. He was the author of several works on the eye. He received the honorary degree of M.D. from Dublin University in 1857, of LL.D. from Cambridge in 1880, and Edinburgh in 1881. He was made a baronet in 1884. He was first president of the Ophthalmological Society of the United Kingdom, and was an honorary member of many foreign societies.

BOOKS AND PAMPHLETS RECEIVED.

Announcement of the Twenty-ninth Annual Course of Lectures of the Medical Department of the University of California, with Catalogue of Students and Graduates. 1892.

Original Articles.

NITRITES: THEIR THERAPEUTIC ACTION AND SCOPE IN MEDICAL PRACTICE.

BY KENELM WINSLOW, M.D., NEWTON, MASS.

THE comparatively recent introduction of the nitrites as therapeutic agencies, and their growing popularity, may serve as an excuse for presenting a paper, the object of which is to point out briefly the value of the nitrites, more especially nitro-glycerine, in certain affections in which they have proved serviceable and to show the rationale of their curative effect in each instance.

The writer must, however, first acknowledge his indebtedness to the following gentlemen for their kindness in assisting him by communications with reference to their experience with nitro-glycerine in practice, doses employed, method of using and views as to its action in the various diseases in which they had employed it, namely, Drs. Francis P. Kinnicutt and H. B. Millard, of New York; Drs. Weir Mitchell, H. C. Wood and Hobart Amory Hare, of Philadelphia; Drs. Robert T. Edes, Francis Minot, Frederick L. Knight, H. F. Vickery and Vincent Y. Bowditch, of Boston, and to Dr. Mary Putnam Jacobi, of New York.

The preparations in common use representing the nitrite group are spirits aetheris, nitro-, potassii nitras, sodii nitris, amyl nitris and nitro-glycerine.

Spirits of nitre, although a useful preparation as a stimulant, diaphoretic and diuretic, is often useless as a nitrite. The United States Pharmacopoeia article should contain four per cent. of ethyl nitrite, but it is said authoritatively that the official process called for in making it will only produce a preparation containing three per cent. of ethyl nitrite at best.

In a report¹ containing the result of recent analyses of 68 samples of nitrous ether; seven contained mere traces of ethyl nitrite, 47 were so far below the standard as to be valueless, and there was so much difference between the strongest and the weakest that a teaspoonful of the former was equivalent to a pint of the latter. Frequent exposure to the air, preservation in warm places and errors in preparation explain, for the most part, these deficiencies.

It is doubtful how far the therapeutic effect of nitrate of potash depends upon its action as one of the nitrite group. As a cardiac sedative, renal stimulant and diuretic it does not differ much from the other salts of potassium. When burned, in the form of nitre paper, its fumes contain the nitrite of potassium, which consequently represents the action of this class. In the blood it is uncertain whether it acts as a nitrate or not. Therefore nitre cannot be looked upon as a satisfactory representative of the nitrites.

Nitrite of sodium is not distinguishable from the other nitrites in action except that it is slower, more permanent and not so reliable in its effect on the economy.

Nitrite of amyl and nitro-glycerine are similar in kind of action, but differ in degree. Whereas the action of the first in diminishing vascular tension is observed by means of the sphygmograph² to occur within one minute and to last for two to four minutes, with variations from ten to thirty minutes, the action of the second is indicated within six to seven minutes,

is most marked for half an hour, and sometimes an hour longer, although varying somewhat with different people. Anemic persons, or those with weak circulation, may be affected much more easily and for a longer time. Good nitrous ether lowers tension for from forty-five to sixty minutes.

This gives a comparative idea of the duration of action of these representatives of the nitrites. It will be noted, from what has gone before, that nitrite of amyl or nitro-glycerine are the most reliable preparations, and the latter the more permanent of the two.

Without digressing too much to speak of the physical and chemical properties of nitro-glycerine, we may say that it is a nitrate of glycerol, also called glenoine. Its formula is $C_3H_5(NO_3)_3$. It is decomposed by the alkaline blood and two-thirds of its nitric acid is reduced to nitrous acid, and with the alkali forms a nitrite of potassium or sodium, while the remaining third is not reduced and forms a nitrate in the blood. Nitro-glycerine is more powerful than the other nitrites because it is absorbed undecomposed, setting free nascent nitrous acid in the blood. The one per cent. alcoholic solution is the preparation usually employed and as strong a solution as ten per cent. is safe as far as any danger of explosion is concerned. It has been perhaps wisely suggested that in writing prescriptions the synonym glenoine be used, it not having so formidable or suggestive a sound as nitro-glycerine to patients, indicative of violent disturbing consequences.

The action of nitro-glycerine will be taken as a type. Gienoine dilates the arterioles all over the body by relaxing the walls of the vessels. This action is no doubt peripheral, but whether due to impression on the vaso-motor ganglia or muscular fibres is uncertain. The heart beats more quickly in consequence, as the vascular resistance is lessened and because a diminished blood-pressure depresses the vagus centre and often stimulates the accelerator centres. The arterioles being dilated in the heart as elsewhere, increase its blood-supply, nutrition and force. Nitro-glycerine is more of a vasodilator than a cardiac stimulant, that is, it increases the rapidity of the blood-current by dilating the vessels rather than by increasing the motive force *a tergo*. There is much evidence for believing, however, that in small doses nitro-glycerine usually stimulates the heart. It is shown to some degree physiologically and also clinically, and it would seem as if this action had not been duly appreciated until recently. It is now claimed that nitro-glycerine is better than alcohol in all emergencies, as it acts with much more rapidity, is tasteless, the dose is infinitesimal, and it may be dropped on the tongue and absorbed when swallowing is impossible during unconsciousness. It is also asserted that one minim of glenoine is equivalent to an ounce of brandy.

Lauder-Bruntton has found that the general blood-pressure is raised by small doses of nitrite of amyl notwithstanding the vascular dilatation; and Dr. Robert T. Edes writes me that, "There seems to be good reason to suppose that nitro-glycerine also stimulates the heart directly, that is, quickens the pulse by its action on the cardiac ganglia, as well as simply taking off blood-pressure." Digitalis and nitro-glycerine are said to be antagonistic in all respects, save that they both increase the force of the heart.³ Digitalis slows the heart and increases blood-tension; nitro-glycerine accelerates it and diminishes blood-pressure.

¹ Druggists Circular, August, 1891.

² D. J. Leech, M.D.: British Medical Journal, November 28, 1885.

³ J. B. Burroughs, M.D.: London Lancet, June 22, 1884.

Digitalis is therefore indicated in the case of a rapid heart which is weak from the lack of rest periods; nitro-glycerine is to be used with a slow heart where the diastole is too prolonged and weakness occurs, not from too little rest, but, on the other hand, from stagnation of the blood-current. So that digitalis is particularly applicable with a frequent pulse of low tension, nitro-glycerine with an infrequent pulse of high tension.

In either case the abnormal pulse is caused to become nearer the normal state in character and frequency. Where frequency, however, is due to weakness of innervation, nitro-glycerine, like alcohol or other stimulants, may not increase but rather diminish rapidity of the cardiac pulsations.

Nervous System. — Nitro-glycerine lessens reflex action by its influence on the spinal cord. It depresses especially the motor centres, and to a less degree the activity of the motor nerves.

Muscles. — Gleoine lowers the functional activity of muscular tissue in large doses, and nitrite of amyl locally applied to the muscles of a frog causes them soon to lose their power of contractility and to become paralyzed. Nitrates relieve spasm of muscular tissue wherever it occurs, owing to their depressing action on motor nerves and muscular tissue.

Blood. — In poisoning by nitro-glycerine, and nitrates generally, the oxidizing function of the blood is interfered with and hæmic respiration is diminished by the conversion of the oxy-hemoglobin into meth-hemoglobin. This latter is not so readily de-oxidized but still yields up its oxygen to reducing agents, so that it has been suggested that when the venosity of the blood becomes great, lethal poisoning is prevented by the unoxidized products of tissue waste becoming reducing agents and again restoring internal respiration.

Urine. — Nitro-glycerine augments the amount of urine, increasing the local blood-pressure within the glomeruli by dilating the afferent vessels of the renal artery which supply them.

THERAPEUTICS IN DISEASES OF THE RESPIRATORY ORGANS.

Nitro-glycerine has proven very efficacious in the treatment of acute lobar pneumonia. The theory of its action is based upon its power of dilating arterioles generally and thus relieving the load put upon the right heart due to the pulmonary obstruction. In this way dyspnoea may be averted. The result is somewhat similar to that of venesection without its weakening effect. It is "bleeding a patient into his own blood-vessels." How much of a stimulating effect on the heart nitro-glycerine has, it is difficult to say, but I have certainly not known of its depressing the heart in these cases. It may be used to advantage in combination with such agents as alcohol, ammonia, strychnine or atropine.

Dr. Andrew H. Smith⁴ says: "Again and again I have seen a patient with pneumonia somnolent or even comatose, with face gray, the lips livid, respiration superficial and fifty to sixty per minute, and the chest everywhere full of moist riles; but nevertheless rescued from this apparently hopeless condition by minims doses of a one per cent. solution of nitro-glycerine administered every fifteen or thirty minutes." Dr. Frederic I. Knight, of Boston, writes me that he has

often seen relief of dyspnoea in acute pneumonia from the use of nitro-glycerine.

Prof. T. R. Frazer⁵ has given a practical demonstration of the therapeutic action of nitro-glycerine in chronic bronchitis. It was a case of four months' duration, with snoring, whistling and cooing riles heard all over the chest. One minim of the one per cent. solution of nitro-glycerine caused the riles to immediately disappear, showing that the physical signs could not have been due to either congestion or exudation within the bronchial tubes, for this agent could have diminished neither; but had been the result of spasm.

An asthmatic patient, under my care, subject to repeated attacks of acute bronchitis, was more relieved by nitro-glycerine than by any other single remedy after the pharmacopeal resources had been wellnigh exhausted. This was an old hospital patient who had long been the object of some such treatment as was pursued by a sea captain, who came to a friend of mine for consultation.⁶ A nautical prescriber was at a loss as to what he ~~should~~ do, for having begun treatment in the northeast corner of his medicine chest, and having tried every remedy in turn with a praiseworthy lack of therapeutic prejudice, he had conscientiously worked around into the southwest corner of said chest, declaring with justifiable astonishment, he could detect no change in his patient notwithstanding.

The acute attacks in my case were followed usually by asthmatic seizures, which lasted for a considerable period. Therefore it is not improbable that the spasmodic element existed during the bronchitis, and the useful effect of nitro-glycerine was thus more apparent, although its action in equalizing the circulation may have been an important factor beside. One minim of the centesimal solution of gleoine, administered in three doses at intervals of fifteen minutes, effectively cut short the asthmatic attacks, although in another case it had to be discontinued on account of the fulness in the head it produced.

Asthma is very commonly treated successfully with nitro-glycerine or nitrite of amyl by inhalation.

Dr. Hobart Amory Hare was kind enough to write as follows: "I have found nitro-glycerine very useful in the treatment of asthma, and have never seen any untoward effects produced by it in this disease, while I have found nitrite of amyl to be of value when used for the purpose of stopping an attack. I have seen one or two instances in which serious cardiac embarrassment seemed to be produced by it, and I believe, under the circumstances, the heart was already so distended with blood that the action of nitrite of amyl simply increased the cardiac difficulty. How drugs do good in asthma is a matter which is not positively decided. Their depressing effect on the nervous system, combined with the vaso-motor changes which they produce, probably explain their beneficial influence."

Dr. Hare's explanation refers to the relief of spasm and equalization of the circulation.

The writer in his service in the Carney Hospital, as interne, where there is always a large number of phthisical patients, observed that minims doses of nitro-glycerine gave more relief in the dyspnoea of advanced cases than alcoholic stimulants or any other one remedy. Nitro-glycerine may accomplish this by acting as a cardiac as well as a vascular stimulant. In emphysema with dilatation of the right heart and venous engorgement owing to pulmonary obstruction, ni-

⁴ American Journal of Medical Sciences, November, 1890.

⁵ London Lancet, July 9, 1887.

tro-glycerine is likewise useful, and cases could be cited where it has been employed with considerable benefit.

In acute pulmonary oedema nitro-glycerine acts favorably, especially as a vascular stimulant, thus distributing the blood more freely about the body, and relieving the right heart. Dr. A. Alexander Smith⁶ relies upon nitro-glycerine ($\frac{1}{10}$ gr.) given every two hours with strychnine ($\frac{1}{10}$ gr.) subcutaneously. In addition to this, he uses two doses of atropine ($\frac{1}{10}$ gr.) two hours apart at the outset, as respiratory and cardiac stimulants. Nitro-glycerine is recommended by Ringer for hiccup, and by Bartholow for whooping-cough and laryngismus stridulus.

The antispasmodic action of the nitrites would account for any beneficial effect occurring in its use in the treatment of these maladies.

Cardiac Affections.—It is needless to dwell on the usefulness of nitro-glycerine in the treatment of angina.

I am indebted to Dr. Francis Minot, of Boston, for the following communication to me on this subject. He writes: "I think nitro-glycerine is more efficient in angina than nitrite of amyl. I give nitro-glycerine in doses of from one to four drops of the one per cent. solution, repeating it when required. I have never found any injurious effects from it, even when continued for months. It succeeds better than any remedy I have ever employed in angina and orthopnoea from cardiac disease."

Dr. Francis P. Kinnicutt, of New York, in reply to my queries on the subject, tells me he relies largely on nitro-glycerine in the treatment of arterio-sclerosis, with or without renal complications, and that it is especially useful in the mental hebetude accompanying this affection. He gives six to eight doses of one minim each during the twenty-four hours, for long periods.

In the angio-neuroses generally, particularly where there is an irregular distribution of the blood, with pallor of the skin and mucous membranes, or with small rigid arteries, it is indicated (as in migraine), but is to be avoided when the face is congested.

In all these cases the relief of spasm and equalization of the circulation is the true explanation of the effect of nitro-glycerine.

In almost every instance where severe dyspnoea or orthopnoea occurs during cardiac disease I believe nitro-glycerine stands at the head of therapeutic agencies in affording relief. Where there is loss of compensation and passive congestion of the internal organs, it takes the load off the heart and aids in distributing the blood about the body in its proper channels.

The writer has had a case with cardiac disease where the orthopnoea was so great that the patient had not been able to lie down for weeks for a minute at a time, yet was made absolutely comfortable, in this respect, by minim doses of nitro-glycerine given at four-hour intervals. In the interim digitalis or strophanthus was used.

Although digitalis antagonizes to some extent the effect of nitro-glycerine on the vessels, they both stimulate the heart and the combination has been employed with apparent benefit where the pulse was frequent and irregular in heart lesions with dyspnoea. Alcoholic and ammoniacal preparations, atropine and strichnia are not open to the same objection, and therefore are more appropriate as heart stimulants.

* New York Medical Record, December 19, 1891.

It has been urged that in aortic regurgitation the prolonged diastole produced by digitalis militates against its use, by allowing more blood to leak back again into the ventricle during the long rest period than is pumped out by the more complete and forcible contraction under digitalis. Here the cardiac stimulants just mentioned, together with strophanthus, may be employed with advantage as is illustrated by a case reported by S. Solis Cohen.⁷

It has always been found advisable as a precaution, to have nitro-glycerine at hand in cardiac cases, even if not regularly in use, to avert attacks of dyspnoea or angina. The writer has a case in mind with aortic stenosis and good compensation usually, but where syncope often occurred on exertion. These attacks were completely relieved by nitro-glycerine. As a heart stimulant, pure and simple, apart from its power to increase the vascular flow by dilatation of the arterioles, nitro-glycerine is more potent than is generally held. It is a substitute for alcohol, although much more rapid and transient in its effect. It is doubtful whether subcutaneous administration is more speedy in its effects than when given by the mouth.

In typhoid, complicated with bronchitis or pneumonia, it has been employed with good results as a stimulant and to alleviate dyspnoea. It is recommended in collapse.

In poisoning by various agents there is undeniable evidence of its life-saving properties on record. In chloroform narcosis, it stimulates the heart and dilates the cerebral vessels. In the syncope and collapse following cocaine poisoning it speedily aids recovery through its cardiac and vascular stimulating powers.⁸

Following toxic doses of opium, nitro-glycerine has been used successfully to stimulate the heart, where the respiration was sustained, and other cardiac stimulants had proved of no avail.⁹ Nitro-glycerine has also proved efficacious in poisoning by illuminating gas, probably stimulating the heart and countering the effect of the gas on the vagus centres.

Renal Diseases.—Nitro-glycerine reduces arterial tension and relieves headache, dyspnoea and convulsions of uremic conditions in chronic Bright's disease. Not only this, but it increases the amount of urine and diminishes correspondingly the quantity of albumen.

The uremic symptoms usually depend upon, or are at any rate associated with, increased arterial tension, and relief follows lowering of blood pressure by nitro-glycerine. It is useful in interstitial as well as chronic parenchymatous nephritis. Dr. Kinnicutt advises beginning with one two-hundredth of a grain of nitro-glycerine in alcoholic solution, to test the patient's susceptibility, and then, if it is well borne, continuing it in one-minim doses of the one per cent. solution each hour till relief of uremic symptoms occurs or inefficiency of the treatment is demonstrated.

In urgent cases of renal dyspnoea of uremia it may be given in one-minim doses at intervals of fifteen minutes for two or three times and afterward at one-half-hour intervals. Then, to avert critical attacks, maintain lowered blood-tension and prolong life, it may be employed for years in one-minim doses from four to six times daily.

Dr. Kinnicutt points out that it increases the amount of urine notwithstanding it diminishes general blood-

⁷ Philadelphia Hospital Records, vol. 1, 1890.

⁸ Central. f. d. gesammte Therap. Schilling, February, 1886.

⁹ I. Burroughs, M.D. London Lancet, June 29, 1890.

pressure. Dr. H. B. Millard, in his work on Bright's disease, shows that according to the experiments of Goll, Stokvis and Overbeck¹⁰, increased secretion of urine follows *pari passu* an increase of blood-tension, whereas the quantity of albumen depends upon rapidity of the blood-current. Diminished rapidity favors albuminuria. As nitro-glycerine stimulates the heart and dilates the vessels, it is easily seen how increased rapidity of vascular flow is brought about, but it is not so clear how the blood-pressure is heightened. Dr. Millard advances the theory that there is a local vaso-motor spasm which is relieved, or that the renal ganglia are stimulated.

Brunton¹¹ believes that the local pressure in the malpighian glomeruli is increased physiologically by nitrates through their action in dilating the afferent branches of the renal artery supplying the malpighian tufts. This theory would reconcile the apparent anomaly of a drug, which generally lowers blood-pressure, increasing the quantity of urine. On the other hand, Dr. Millard reports a case of polyuria, with a hard and tense pulse, passing daily, for three weeks, twenty-four quarts of urine. The sulphate of iron (gr. iii, t. i. d.) brought about a reduction of this quantity to twelve quarts. Subsequently the use of gencloine (one minim of the centesimal solution four times daily) was followed by a diminution of the amount to six quarts per diem. This result may have been due to the fact that lessening of the general tension was the more important factor in the case than increase of local tension, but the therapeutic rationale in such conditions must still be considered *sub judice*.

Dr. J. H. Burroughs¹² thinks benefit is derived from the use of nitro-glycerine in acute nephritis, by its relieving renal congestion in dilating vessels elsewhere. He relates the history of a case where there was coma, with feeble pulse of 100, becoming a mere thread, which was given one-minim doses of nitro-glycerine every fifteen minutes for one hour and then every hour for four hours. The pulse was at this latter period 100, but full, the skin dripping and the kidneys had secreted a pint of urine.

I may be permitted in closing this section to append two extracts from letters kindly sent me relative to the matter in hand.

Dr. Francis P. Kinnicutt, of New York, writes that, "In all cases of renal disease, with high arterial tension, and also in other diseases where this condition has obtained, I have been convinced by a rather large clinical experience, both in hospital and private practice, that the effect of nitro-glycerine in ameliorating this condition is more positive than that obtained by other means."

Dr. Mary Putnam Jacobi, of New York, says, "I use nitro-glycerine in renal cirrhosis or in the high tension pulse of lithæmia, without demonstrable renal lesion, and with great benefit as to the various symptoms accompanying the condition."

Nervous Affections.—Epilepsy is one of the maladies more commonly treated with nitrates.

Dr. H. A. Hale, in his communication to the writer on the subject, says, "Nitrite of amyl whenever used has proved itself invaluable in the prevention of epileptic attacks which were preceded by a sufficiently prolonged aura to permit the patient using the drug."

¹⁰ Vide Charcot: *Leçons sur l'Albuminurie*.

¹¹ Practitioner, vol. xxii, April and May, 1884.

¹² Ibid.

Dr. Mary Putnam Jacobi writes me, "According to Crichton Browne's suggestion in averting an approaching epileptic attack, I consider the nitrite of amyl invaluable and order patients liable to epileptic fits to always have the drug in readiness. In my cases, where the disease was not invertebrate, I have seen the attacks greatly diminished in frequency by its use."

Osler¹³ has found only a temporary improvement in most cases where nitrite of amyl was used continuously as an ameliorating agent. He recommends five minims t. i. d., increasing the dose up to eight minims where bromides fail.

The writer's experience has been very limited in this field and not particularly favorable in the use of nitrates as prophylactic agents in epilepsy, as his cases have been apparently "invertebrate" ones. The nitrite of amyl is a better preparation for use as a prophylactic agent, given in the form of five-minim glass capsules; to be broken in the handkerchief and inhaled as soon as a premonition of the attack is perceived. It acts favorably in counteracting vaso-motor spasm of the cerebral vessels which is supposed to occur in the seizures.

Migraine, which is accompanied by a somewhat similar pathological condition, may be benefited by nitro-glycerine, especially where the face is pale.

Dr. H. F. Vickery, of Boston, writes me he has stopped a sick-headache with vomiting immediately, by inhalation of nitrite of amyl and also states that a dose of nitro-glycerine, once repeated, cured a case of violent intercostal neuralgia. He believes that nitro-glycerine has a certain sedative effect on the sensory nerves, in curing neuralgia, apart from its action in relieving spasms and in dilating vessels. It has been recommended by Bartholow in gastralgia for the same reason and also in hepatic colic, reflex vomiting and tetanus, for its power in combating spasmoid conditions. Ringer speaks of its value in sea-sickness.

The nitrates are serviceable in spasmoid dysmenorrhœa. F. W. Kindle¹⁴ advises the use of nitro-glycerine in dysmenorrhœa and the sickness of pregnancy, and reports a case of severe after-pains with a firmly contracted uterus and no clots, cured as if by magic. Hiccough is another spasmoid affection in which nitro-glycerine is remedial. The cold stage of ague, in which there is a vaso-motor spasm of the peripheral vessels, is relieved by nitrates.

We may summarize the therapeutical indications for the employment of nitrates as follows: (1) To dilate the peripheral arterioles and equalize the circulation in internal congestions; (2) To stimulate the heart; (3) To relieve spasm of vascular, nervous or muscular origin; (4) To increase the quantity of urine and diminish the amount of albumen; (5) Possibly to relieve pain.

POISONING BY NITRITES.

Many interesting cases, which practically represent the effects of toxic doses of nitro-glycerine, have been reported by Thomas Darlington, M.D.¹⁵. They occurred in workmen overcome by dynamite fumes (volatilized nitro-glycerine) during the construction of the Croton aqueduct. The symptoms presented were: flushing of the face, succeeded by pallor, nausea and

¹³ American Journal of Nervous and Mental Diseases, vol. xii, No. 1.

¹⁴ London Lancet, March 19, 1887.

¹⁵ New York Medical Record, p. 681, 1890.

frequently vomiting, trembling sensations, throbbing of the temples, fulness of the head, as if it would burst, followed by intense headache persisting for twenty-four hours. The heart's action was increased and the pulse was full, round and compressible. None of the cases were fatal. The treatment consisted of cold applied to the head, ergotin and atropine subcutaneously, inhalations of ammonia and spirits of aromatic ammonia by mouth. Intense headache is sometimes produced in patients by nitro-glycerine in ordinary doses and precludes its use. Such an unfortunate result cannot be predetermined, as far as we know, although it is more likely to occur in cases treated for dysmenorrhea.

Dr. H. F. Vickery reports to the writer a case where nitro-glycerine ($\text{gr. } \frac{1}{10}$) given by mouth to an adult caused within a minute the most frightful dyspnea, pallor and cold extremities. There could be felt no radial pulsations. Alcoholic stimulation gave speedy relief. This exemplifies the rather common occurrence that the toxic effect of many drugs is opposed diametrically to their physiological action in medicinal doses. The depressing effect of overdoses of the nitrites on the heart, together with their paralyzing action on the red blood-corpuscles, interfering with the normal hemic respiration, leads to syncope, dyspnea and collapse.

Dr. Kolipinski¹⁰ reports a case where a delicate woman took two drachms of the centesimal solution of nitro-glycerine. She became semi-conscious, her extremities were cold, face pale, she had gastric distress and vomited. Her pulse was strong and regular. She made a good recovery, the only treatment being a mustard foot-bath. The treatment consists in stimulating the heart and respiration and in contracting the blood-vessels. Alcoholic or ammoniacal stimulants may be used and ergotin, atropin and strychnine injected subcutaneously together with cold applications to the head.

Although symptoms of poisoning have been many times reported following the administration of ordinary therapeutic doses of the nitrites, we have yet to learn of any case proving fatal.

NOTES ON TYPHOID FROM 676 CASES ADMITTED TO THE BOSTON CITY HOSPITAL IN 1890 AND 1891.¹¹

BY A. L. MASON, M.D.

(Concluded from No. 14, page 332.)

TABLE I.
COMPLICATING CAUSES OF DEATH.

	Recovered.	Died.	Total.
Phthisis	4	3	7
Pneumonia	28	6	34
Pleurisy	8	3	11
Bronchitis (severe)	72	2	74

Epididymitis	2	Purpura	1
Erysipelas	3	Scarlet fever	1
Furunculosis	2	Tonsillitis	7
Insanity	2	Tubercular peritonitis	1
Jaundice	1	Ulcer of leg	1
Neuritis	21		

CASES NOT AMENABLE TO TREATMENT.

In estimating the probable effects of treatment certain classes of cases may be excluded as having little bearing upon the question of therapeutics. Such cases are moribund at entrance; cases of intestinal perforation and hemorrhage, and those fatal through delirium tremens, phthisis, chronic Bright's disease, chronic endocarditis or syphilis. Pregnancy must also be included as exposing females to an additional danger.

Therefore I have tabulated the following fatal cases on which the treatment would have had little influence, namely :

Moribund at entrance	15
Perforations of bowel (9)	7
Intestinal hemorrhage (34)	13 ^a
Phthisis	3
Chronic nephritis	2
Endocarditis (chronic)	2
Endocarditis with pneumonia	1
Pregnancy with pneumonia	1
Abortion with septicemia and perforation	1
Delirious tremens	2
Delirium tremens with intestinal hemorrhage	2
Delirium tremens with chronic Bright's	1
Total	56

The case of abortion with perforation and two cases of delirium tremens with hemorrhage are entered twice. This leaves us 23 fatal cases in which the acute renal, circulatory and respiratory disturbances, diarrhea and other conditions were probably due to pyrexial exhaustion. Of these, however, four had lobular pneumonia, of whom two entered on the fifth day of the fever and died on the eleventh and twelfth days, respectively. The pregnant woman with pneumonia, alluded to above, is not included. She entered on the fourth day and died on the eleventh day of the typhoid, in the sixth month of pregnancy.

One case only of fatal lobular pneumonia is recorded. He entered on the fourteenth and died on the thirty-fifth day. This complication is usually a late one.

One case died as mentioned above with acute aortic endocarditis, one with acute pleuritis, pericarditis and nephritis, and one with parotitis; and after defervescence, two from embolism of the pulmonary artery, and two from extensive thrombosis of the iliac and femoral veins.

The 15 autopsies are entered below. They were performed by Dr. Gannett and Dr. Mallory.

AUTOPSIES.

Perforations (5).

CASE 1. Man, thirty-three. Entered on 7th day. Died on 21st. Perforation one-third inch in diameter at junction of cecum and ileum. Another, ten inches further up ileum, one and one-half inch long and one-

^a Two cases had perforation, and one had fatal hemorrhage soon after entrance, and are included among the moribund.

half inch in diameter apparently confined to a Peyer's patch. Typhoidal enteritis. Acute fibrinous peritonitis.

CASE II. Man, nineteen. Entered on 21st day. Died on 27th. Perforation of ileum a little above ileo-caecal valve. Typhoidal ulceration of two or three Peyer's patches in ileum. Acute fibrinous peritonitis.

CASE III. Female, twenty-nine. Entered on 29th day. Died on 54th. Perforation in cecum corresponding to ulcer on mucous surface. Fifteen to twenty typhoid ulcers in cecum and a few in lower ileum. Acute peritonitis.

CASE IV. Female, twenty-six. Entered on 8th day. Died in relapse on 42d day. Perforation through Peyer's patch in lower ileum. Few typhoid ulcers in colon and lower part of ileum. Acute general peritonitis. Acute fibrinous pleurisy. Cloudy swelling of kidneys. Chronic mitral endocarditis with stenosis and insufficiency.

CASE V. Man, fifty-three. Entered on 28th day. Died on 31st. Perforation two and one-half feet above cæcum, large enough to admit lead pencil. Typhoidal ulceration of Peyer's patches. Acute purulent peritonitis.

Hemorrhages (4).

CASE I. Female, twenty-one. Entered on 7th day. Died on 19th. Large intestine full of dark fluid blood. Typhoidal enteritis. Acute aortic endocarditis.

CASE II. Man, twenty-four. Entered on 14th day. Died on 32d. Partly digested blood throughout small and large intestines. Typhoidal ulceration of Peyer's patches in lower ileum and in colon. Cloudy swelling of liver and mesenteric glands. Edema of lungs.

CASE III. Male, twenty-five. Entered on 8th day. Died on 18th. Typhoid ulcerations in lower three feet of ileum. Granular degeneration of liver and kidneys. Emphysema of lungs.

CASE IV. Male, nineteen. No history. Typhoidal enteritis. Haemorrhagic infarction of spleen.

Pneumonia (3).

CASE I. Male. Acute fibrinous pneumonia at both bases. Typhoid ulcerations in lower ileum.

CASE II. Female, twenty-five. Entered on 5th day. Died on 12th. Acute pneumonia. Acute fibrinous pleurisy. Granular degeneration of kidneys and liver. Typhoid ulcerations in first four feet above cæcum.

CASE III. Male, twenty. Entered on 6th day. Died on 21st. Acute fibrinous pericarditis. Acute fibrinous pleurisy. Acute parenchymatous nephritis. Hypostatic pneumonia. Cloudy swelling of heart and liver. Typhoidal enteritis.

Pulmonary Embolism (2).

CASE I. Male. No history. Embolism of pulmonary arteries. Haemorrhagic infarction of lung. Thrombosis of common iliac and internal iliac veins. Acute septic pleurisy. A nodule of septic necrosis of spleen with extension through diaphragm. Cloudy swelling of heart and kidneys. Injection of vessels of brain. Typhoid ulcerations in lower ileum.

CASE II. Male, twenty-eight. Entered on 16th day. Died on 43d. Embolism of pulmonary artery. Thrombosis of right external iliac and both femoral veins. Injection of lungs, kidneys and liver. Typhoid ulcerations in lower six inches of ileum.

Exhaustion and Pyrexia (1).

CASE I. Female, twenty-one. Entered on 5th day.

Died on 11th. Cloudy swelling of heart, kidneys and liver. Typhoidal ulcerations in colon and lower ileum.

THERAPEUTICS.

Brand had collected, two years ago, 20,000 cases of typhoid fever treated by his plan, chiefly in Germany and in Lyons, with a mortality of about 7.5%. Most of the physicians who had tried it reported a considerably lower death-rate, this sometimes falling, in small series of cases and under favorable circumstances, to two or three per cent., or even to zero. It is to be noticed, however, that such results usually came from hospitals where many children and young persons were treated, and from the army hospitals in Germany where healthy young soldiers compose the material. Under these conditions many of the causes of a high mortality are eliminated.

In Paris, last year a committee was appointed to report to the Société Médicale des Hôpitaux as to the mortality from typhoid fever in the Paris hospitals and the influence of treatment. This report⁹ was on the whole favorable to Brand's method. It shows that under various modes of treatment, chiefly expectant, the mortality from 1866 to 1881 was 21.5%. From 1882 to 1888 it was 14.1%; in 1889, 13.5%.

Twenty-one reports from various *chefs de service* show 916 cases with 114 deaths, 12.44%, under different kinds of treatment.

In 1888 and 1889, 1,063 cases treated symptomatically showed 133 deaths, 12.51%; whereas, in 323 cases treated by baths, 32 died, or 9.9%.

Jaccoud, with the use of tonics, cold lotions and antipyretics, lost in sixteen years, 71 cases out of 655, or 10.8%.

Bouchard at the Hôpital Lariboisière, since 1884, with baths gradually cooled, intestinal antisepsis, quinine, etc., had a mortality of 11.16% in 421 cases, instead of 21% as before.

In this country, since the cases of Drs. Edes and Stedman at the City Hospital, reported about fifteen years ago, the system of Brand has not been brought before the profession in a practical manner until recently, when Dr. James C. Wilson, in Philadelphia, Dr. Baruch, in New York, and other physicians have reported a few cases. Dr. Wilson, at the German Hospital in Philadelphia, treated 66 cases without a death.

Under the use of prolonged tepid baths, Riess, in 900 cases, had a mortality of 7% to 8%; and under simple expectancy with four or five litres of drinking water daily, Debove, at the Hôpital Andral, of 9.2%.

Dr. James Barr, of Liverpool, England, reports¹⁰ twelve cases of severe typhoid treated successfully by prolonged immersion in a tank filled with water at a temperature of 90° to 98° F. Patients were kept in the tank constantly for periods varying from six to thirty-one days. The inconveniences of such a method are obvious but the results appear to have been very good.

At the City Hospital latterly cold sponging and affusions have been applied very thoroughly, at frequent intervals day and night if necessary, the water being cooled with ice during the warmer months and sponging of the whole surface being continued long enough to lower the temperature materially. As 100 typhoids, more or less, are in the wards for many

⁹ Gazette Médicale des Hôpitaux, July 10, 1890.

¹⁰ Lancet, March 20, 1890.

weeks continuously, this involves more labor probably than the administration of full baths, and the discomfort to the patient is quite as great. The effect upon the pyrexial symptoms, however, has been manifest.

It seems, then, that hydro-therapeutic measures in some form or other have received the general approval of the medical profession and the only question is as to the best methods. I think that the full bath of Brand is the most efficient and convenient.

Antipyretic Drugs. — The rapid disfavor into which these drugs have fallen owing to their depressing influence in unsuitable cases has, I think, led to their too general abandonment. Phenacetine, especially, in three, five or ten grain doses often proves valuable in allaying fever and modifying the nervous symptoms. Phenocoll, a newer compound, has been used in a few cases with similar effect.

Laxatives in the first week fulfil a rational indication and of these I think the salines are preferable.

Internal Antiseptics by the use of minute doses of calomel, salol in five-grain doses several times daily, naphthaline, salicylate of bismuth and naphthol, has been attempted in a more or less systematic manner at the City Hospital. Of these agents hydro-naphthol in doses of from two to four grains every two hours has appeared to have influence in modifying diarrhea and the offensive character of the stools. But it is doubtful whether the infecting germs and poisonous alkaloids can be effectually neutralized in this way by any harmless agent.

Hydro-naphthol. — Between May 9, 1891, and January 1, 1892, 103 cases of typhoid were admitted to the second medical service, 83 males and 20 females; 48 had diarrhoea, 55 had not; 45 were treated with hydro-naphthol, 58 were treated without hydro-naphthol. Of the former series two died; of the latter series seven died. None of those who used hydro-naphthol had hemorrhage from the bowels, while three of the others had. In 27 patients diarrhea diminished or ceased while using this drug, often after a few days, sometimes not for two weeks. Relapse took place in six patients who were treated without hydro-naphthol and in four who took this drug.

About 30 patients without regard to the presence or absence of diarrhoea were treated from the time of admission continuously with hydro-naphthol, at first, every two hours, later every four or six hours until convalescence was well established, in the hope of preventing relapse. Two of these patients had relapses, nevertheless, and one died with symptoms of perforation of the bowel. No ill-effects attributable to the drug itself were noticed in any case. These facts were tabulated by Dr. Benjamin Tenney, house-physician, who watched all the cases.

Stimulants. — Too early use of stimulants as well as their over-use, is to be guarded against. But with the large number of alcoholic subjects who come under treatment it is often difficult to decide how far it is prudent to withhold their accustomed stimulus. A weak heart and rapid pulse should be the guides, in spite of nervous symptoms which may supervene. As in pneumonia, delirium tremens often comes on in typhoid patients several days after admission.

In general, careful attention to the digestion and to the eliminating organs, a free supply of drinking-water, correct estimation of danger-signals, and prompt application of such measures as each case may demand are of more importance in the management of this

complicated malady than any systematic method, however brilliant its results may appear to be.

But we cannot escape the fact that the mortality from typhoid fever has diminished all the world over during the last twenty-five years, and that Brand's system of bathing is thought by a large number of the best observers to be an important factor in this reduction.

CONCLUSIONS.

(1) That in the Boston City Hospital the mortality in typhoid fever from patients admitted moribund and with grave complication is 4%.

(2) That at least 3% more die from intestinal perforation and hemorrhage.

(3) That little diminution in the mortality from these causes can be expected under any mode of treatment.

(4) That the mortality from renal, pulmonary and circulatory disturbances, from diarrhea and pyrexial exhaustion, is about 3.5%.

(5) That, excluding deaths from intestinal perforation and hemorrhage, the mortality among females is 3.4% greater than among males.

(6) That a diminution of 2% in the general mortality might be expected from the systematic use of cold baths, the reduction being largely in females.

(7) That favorable results followed the trial of intestinal antiseptics, but that relapses were not prevented thereby, and that a much wider experience is necessary to determine their value.

CASES OF LAPAROTOMY PRESENTING FEATURES OF UNUSUAL INTEREST.¹

BY CHARLES P. STRONG, M.D.

Assistant Surgeon, Free Hospital for Women, Physician to Out-patients, Massachusetts General Hospital, etc.

MANY of the operations performed by me during the last eight years, involving opening of the abdomen for various reasons, have been reported; but there remain others, presenting certain points of interest, which have not been reported. I wish to emphasize and illustrate by some cases the following points:

The difficulties of diagnosis of abdominal growths.

Results of removal of the uterine appendages in their influence upon menstrual disorders associated with reflex symptoms.

Change, as of senile atrophy, rapidly following the removal of diseased ovaries.

Certain unexplained results; for example, decrease in tumors with subsidence of symptoms following laparotomies, which are but little more than exploratory incisions.

The difficulties of diagnosis of abdominal growths.

Mrs. L. S., thirty-eight. Married six years. One miscarriage at six months, five years ago, since which time menstruation has been more abundant.

Examination under ether December 10, 1889. The patient had previously to this time been under treatment in the out-patient department for hemorrhages, very constant and very profuse, confining her to bed for two weeks at a time. During the past three months these hemorrhages had been almost without cessation. She entered with a diagnosis of submucous fibroid. A mass the size of a pigeon's egg, firmly con-

¹ Read before the Obstetrical Society of Boston, February 13, 1892.

nected to the uterus, was found on the left. In the median line was felt a mass extending up to the umbilicus, the pubic outline of this induration ill-defined. The fundus of the uterus could not be mapped out. On the right side was a firm, movable mass about the size of the kidney, at the level of the umbilicus. The depth of the uterus was four and one-half inches. The curette brought away, through an os that readily admitted two fingers, considerable masses of tissue, which Dr. W. F. Whitney pronounced hyperplastic uterine mucous membrane. The diagnosis of fibroid was apparently confirmed by this examination, in so far as it was possible to make any diagnosis.

The hemorrhage not being checked by the curetting, the patient was operated upon, and the following condition found: The left tube convoluted and twisted upon itself, and glued to the uterus, its cavity distended with puriform secretion, formed the mass on the left. On the right, the whole broad ligament spread over the intestines like the omentum, and was attached at the level of the umbilicus. The right tube was very much enlarged, holding about four to six ounces of puriform material. This kidney-shaped mass, which felt like a pediculated fibroid, the omentum and the apron-like broad ligament were firmly adherent throughout their extent, and the intestines were also matted together by both chronic and recent adhesions. The case was one of double purulent salpingitis and pelvic peritonitis.

Results of removal of the uterine appendages in their influence upon menstrual disorders; reflex symptoms.

Mrs. H. N. T., thirty-two. Mother of three children. Questionable miscarriage a year and one-half ago, at two months. Seen in June. Always been well previously until March, when it was supposed that she had an attack of malaria, as she had chills and fever. These were accompanied by very little pain on the right side. In bed about half the time. In May a swelling was noticed on the right side; coincident with the appearance of this swelling, there was pain in the right leg along the course of the sciatic nerve, and pain which shot up along the course of the right ureter. The pain was so excessive as to demand frequent and large doses of morphia. Patient much emaciated; general condition very poor; occasionally a high temperature; most of the time the temperature very slightly elevated above normal. Depth of uterus between three and three and one-half inches. No catamenia since March, that is, three months. Had previously been entirely regular.

Under ether there could be felt an enlarged tube on the left side. On the right side there could be felt adhesions; and in the median line a mass about the size of the fetal head at term — elastic, not distinctly fluctuating, not separated from the uterus, lying toward the right side, and on the anterior surface of the uterus. This tumor had increased somewhat in size since it was first discovered, but not rapidly. The diagnosis was between a uterine fibroid and salpingitis, with the preference rather in favor of the former from the relation of the mass to the uterine body. I operated the first of August, and found the mass overlying the uterus to be a tubo-ovarian abscess, densely adherent to the surrounding tissues. The ovary contained a cyst the size of a man's fist, into which the thickened tube opened freely; this cyst was filled with somewhat offensive pus. In consequence of the manipula-

tions necessary to free it from its adhesions, tears were made into the rectum and into the tube, so that the pus escaped freely into the cavity of the rectum and the abdominal cavity. The rectal tear was stitched up by a continuous suture of fine silk. The left tube was also freed from its adhesions and removed; it was enlarged to the size of the little finger and contained pus. The abdominal cavity was washed out and the patient made a perfect convalescence.

In this case it was impossible to say that the tumor felt before the operation was not fibroid. Its location, the symptoms caused by its presence, were all indicative of fibroid rather than salpingitis. The estimated contents of the two tubes was a pint in the right side, a half a pint in the left.

I operated during December, 1890, upon three cases to bring about cessation of the menstrual flow, and involution of the genital uterine organs.

Miss G. C., school-teacher. Bed-ridden for two years; intense dysmenorrhea; probably from the history, membranous dysmenorrhea. Had been dilated, curetted, galvanized, undergone the rest cure, and, in fact, had every treatment that could be suggested, without relief. Removed both tubes and ovaries, which were reported by Dr. Whitney to show increase of cicatricial tissue in the ovaries; tubes slightly catarrhal. The patient has entirely recovered. Superintended and performed a housekeeper's work on a large farm where there were many boarders last summer, and is self-supporting in every way, and entirely free from abdominal pain at the present time.

Miss S. B. Associated with the dysmenorrhea was intolerable backache and pain in the side. She had been attendant at the out-patient department for nearly four years pretty constantly. Uterus was retroflexed and strongly adherent. By one or two etherizations and manipulations the adhesions were broken up, and the uterus replaced; but it never stayed long in its position. The shortening of the round ligament kept it in place six months; then it went backward, due to the traction of the unruptured adhesions, uniting the uterus and rectum. Both broad ligaments were shortened and thickened. The laparotomy showed that the reason for the falling backward of the uterus was not due to the stretching of the round ligaments, but to the fact that they had each ruptured at the uterine attachment, permitting the fundus to go backward. The patient is now very well; not strong as she will be, but gaining constantly. Her weight has increased from ninety-five to one hundred and fifteen pounds.

Miss K., thirty years of age. Always had dysmenorrhea, which, during the past few years, has steadily increased, rendering her unable to perform her duties as nurse. Headache nearly constant, pain over each ovarian region, nausea. The inter-menstrual periods too short to permit complete recovery of strength. Previous treatment very thorough, including rest, galvanism, drainage of uterus.

Both Fallopian tubes and ovaries removed. Report, December, 1890: "The microscopical examination showed evidence of a former catarrhal salpingitis with cicatricial contraction in both tubes and ovaries." Convalescence uneventful. Since the operation the patient has performed her duties as nurse, and gained flesh and strength, suffers from no reflex phenomena and considers herself entirely well.

These three cases represent the favorable results

which may be accomplished by this treatment; but, as I have always taken occasion to state, I never would advise removal of the uterine appendages to overcome symptoms on any account, unless these symptoms were acutely threatening, without first having the patient pass through preliminary palliative treatment of suitable duration and character.

Change, as of senile atrophy, rapidly following the removal of diseased ovaries.

Mrs. L. Was referred to me last December for operation, having a large rectocele and lacerated and sub-involved uterus. On examination, I found in addition to these lesions, an ovarian cyst upon either side, which I removed by laparotomy, and which proved to be dermoid, and occupied, so far as could be determined, the entire structure of the ovary, consequently these must have formed rapidly, as her child was only eighteen months old at this time. She made a perfectly uninterrupted recovery, and was to report six months later for the plastic operation first advised. At that time there were such marked changes of atrophy occurring, that I deemed it best to wait until further time had elapsed to see if this operation could be avoided.

January, 1892, one year from the operation, I found atrophy of the uterus and the vagina, and a senile-vaginitis with its tendency toward adhesive inflammation, as marked as though she had normally passed the climacteric ten years.

Certain unexplained results; for example, decrease in tumors with subsidence of symptoms following laparotomies, which were but little more than exploratory incisions.

Miss M. S., twenty; single; school-girl.

December 9, 1890. Previous history and family history both good. Three months ago had pain in both ovaries and lumbar region, coincidental with a profuse, greenish discharge from the vagina; frequent and painful micturition. The menstrual history is of interest. Before this, for a number of years, she had been regular, flow lasting four days, and requiring six to eight towels. The first menstruation after this pain began lasted but one day and she used but one towel. The second appeared two weeks late, and then was brought on by medicine which her medical attendant gave her. The third was similarly late, but had appeared without the use of medicine or treatment.

The pains at first lasted about an hour, occurring only two or three times daily, without abdominal tenderness on pressure. These pains grew steadily worse, both in frequency and severity. Ten weeks ago these attacks were followed by fever, intense pain and abdominal soreness, necessitating confinement to bed, with indefinite, but large doses of morphia; a temperature varying from 102° to 104° , and very considerable bladder irritability.

I first saw the patient December 9, 1890. She had then been in bed ten weeks, and was more or less completely narcotized. Her temperature was 102° , abdomen very sore, slightly enlarged. The following day, under ether, I found by examination, that there was atresia of the vagina about two inches within the vulva, through which I could not insert an ordinary sound. Combined rectal and abdominal dilatation showed a mass upon either side of the pelvis, dense, elastic, non-fluctuating, indistinct in its outlines, but

extending, apparently, across the whole pelvis. I made a diagnosis of salpingitis and peritoneal adhesions. There was no vaginal discharge of moment, so that I restored the vagina, by curetting and dilating, to its normal dimensions. The posterior cul-de-sac was lacking, the cervix terminating abruptly the upper end of the vagina.

Rest in bed, and the employment of hot douches produced little effect upon the temperature, which continued fluctuating daily between 100° and 102° , with regularity. The patient's general condition seemed quite good, with this exception.

I operated January 2d. Through an incision of two inches it was found that the omentum was glued everywhere to the surface of the abdominal walls. The perineum was much thickened, and everywhere there were light, fresh adhesions which were easily separated. Deflecting the omentum upward and backward, there occurred a discharge of six to eight ounces of clear, serous fluid. There was no evidence of any cyst having been opened, but everywhere, as the finger was swept about, it encountered matted masses of intestines, which in part were easily separated, and the intestines of which were filled with fluid of encysted peritonitis. This line of pelvic peritonitis terminated sharply at the brim of the pelvis, above which were all the intestines except the rectum and some few matted and adherent coils of the smaller intestine.

The adhesions which bound these parts together were, as a rule, well organized and very strong. Many of them existed as long bands, notably one or two which seemed to stretch entirely from one side to the other of the pelvis like a piece of twine. These long bands were, as a rule, about as large as a lead pencil. The largest cavity that was opened, contained perhaps, about six ounces of serum. Multitudes of smaller cysts contained amounts varying from a few drops to an ounce or two.

There were two especially distinct masses to which the tubes could be traced, and which probably contained the ovaries, but an attempt to dissect these out to remove them, showed that the ureter on either side was also implicated in these masses, consequently, I terminated the operation by breaking down all the adhesions possible, by sponging out and rupturing all the cysts, and by replacing, as far as possible, the intestines in their normal position. Convalescence was uninterrupted. Pain ceased from the time of the operation; temperature fell to normal, and remained there. Examination under ether, one month after the operation, showed that there was present two distinct masses; one on the right, about the size of a pigeon's egg, and one on the left, about the size of a hen's egg. The patient has reported from time to time, is perfectly well, going to school again, and menstruation has resumed its normal course.

Miss M., nineteen. Referred to me by Dr. Marion. Gives history of having passed through two severe attacks of pelvic inflammation, accompanied by high fever. It was supposed at that time that she had salpingitis. The last attack had been about two months before I saw her. There was a firm, dense, resisting mass to be felt, filling the left side of the pelvis, crowding the uterus to the right, very tender. The exploratory incision showed this to be a fibroid growth beneath the front of the broad ligament; its seat of attachment to the uterus occupying about two-thirds of

the lateral surface of that organ; non-pediculated intramural. The broad ligament and uterus were so matted together, as the result of previous peritoneal attacks, that it seemed unwise to attempt the enucleation of the fibroid. The patient made a good recovery from the exploratory incision, has been able to resume her work, has declared that there is a noticeable decrease in the size of the mass, and that she is entirely free from pain, unless after very prolonged exercise, when she finds that the left side tires more easily than any other part. Exactly what local change, if any, has taken place here beyond that of freeing the adhesions, I am unable to say, but certainly the patient has practically received great benefit.

PURULENT OPHTHALMIA NEONATORUM AS A CAUSE OF BLINDNESS.¹

BY FREDERICK E. CHENEY, M.D.

Instructor in Ophthalmoscopy, Harvard Medical School; Assistant Surgeon, Massachusetts Charitable Eye and Ear Infirmary.

THE term, purulent ophthalmia neonatorum, is used in preference to ophthalmia neonatorum in this paper, for the reason that the latter seems to me objectionable, including as it does all inflammation of the conjunctiva occurring in the new-born. A very large proportion of these cases are extremely mild in character; they recover rapidly with the use of "borax and camphor," or some other mild collyrium, and stand in the same relation, as regards importance, to the purulent variety, that simple catarrhal conjunctivitis in the adult, does to gonorrhœal ophthalmia. If purulent ophthalmia neonatorum could be more generally applied to the disease so much discussed and written about as a cause of blindness it would undoubtedly save much confusion. The character of this affection is so well-known that more than a brief mention of its symptoms and appearances is unnecessary. It usually begins within three or four days after birth, — occasionally as late as the seventh or eighth. At first, the discharge is thin and watery, but it soon becomes thick, yellow, and copious. The conjunctiva is greatly injected, the lids are considerably swollen, and if they be everted, the palpebral conjunctiva will be found infiltrated and thickened, with an intensely red, velvety look, and will bleed easily on slight irritation. We have, in fact, a purulent inflammation of the conjunctiva caused by infection from some morbid vaginal secretion, and which to all appearances, differs from gonorrhœal ophthalmia only as regards its lesser intensity. By an unfavorable termination of the disease, we understand that a secondary inflammation of the cornea has taken place, which has resulted in an impairment, or entire loss, of sight. It is but natural that the gravity of the affection should be more fully realized by the oculist, who is continually seeing the unfortunate results, than by the other members of the profession who, perhaps, see but one or two such cases in a lifetime. Statistics as to the cause of blindness, from various asylums are, however, so nearly uniform in the per cent. attributed to this disease, that there can be no question of exaggeration as to its importance. For example, the asylums of Switzerland, give 26.02% to this cause, of Germany, 25.83%, of Hungary, 20.47%, while in this country, the New York State Asylum, at Batavia, gives

19.5% (Howe), the Philadelphia Blind Asylum, 20% (Harlem), and the Perkins' Institution for the Blind, with the Kindergarten at Jamaica Plain, 18.6% (Derby).

In an article entitled "Legislation for the Prevention of Blindness," Dr. Howe, of Buffalo, writes concerning this disease as follows: "There is a perfect unanimity of opinion that when these cases are seen at the very outset, the eye can be saved in almost every instance with little or no injury, while, on the other hand, ulceration and perforation often occur when the children are neglected until the disease is far advanced."

If it is a fact, and I believe it is, that purulent ophthalmia neonatorum terminates favorably in almost every instance, when recognized and properly treated from the beginning, neglect or ignorance is accountable for about one-fifth of all the cases of blindness occurring in early life. For obvious reasons, the affection is most prevalent among that class of patients who are the least able to comprehend its serious nature, and who, consequently, often fail in obtaining proper medical advice until it is too late to be of any value. In a hope of rectifying, in a measure, this unfortunate state of affairs, at the recommendation of Dr. Howe, made in a paper read before the New York State Medical Society, February 18, 1886, on "Purulent Conjunctivitis of Infancy and Blindness," the following law, headed "An Act for the Prevention of Blindness," was adopted by the New York legislature:

SECTION 1. Should any midwife or nurse having charge of an infant in this State notice that one or both eyes of such infant are reddened or inflamed at any time within two weeks after its birth, it shall be the duty of such midwife or nurse so having charge of such infant, to report the fact in writing within six hours to the health officer or some equally qualified practitioner of medicine of the city, town or district in which the parent of the child reside.

SECT. 2. Any failure to comply with the provisions of this act shall be punishable by a fine, not to exceed one hundred dollars, or imprisonment not to exceed six months or both.

SECT. 3. This act shall take effect on the first day of September, eighteen hundred and ninety.

This law has been in force for so short a time, that it is impossible to arrive at any definite conclusions as to the amount of good it is capable of accomplishing. If the per cent. of blindness from this cause can, however, be decreased in the least degree by the adoption of such laws, other States should not be slow in following the lead taken by New York in this matter. In Boston, the employment of midwives is, I understand, a very much less common practice than formerly, since the establishment of the "Out-Patient Department" in connection with the Lying-in Hospital. In other parts of this State it is probably still considerably practised, and if an act for the "prevention of blindness" should be adopted by the legislature of Massachusetts and properly enforced, some good would undoubtedly result.

The nurse and midwife cannot, however, be held accountable for every unfortunate case. The physician is, in many instances, directly responsible in that precautions are not taken for the prevention of the disease, or it is not properly treated when found to exist. The result of bad treatment in diseases of the eye is apt to be more apparent, both to the physician and patient, than are errors of equal gravity in other situa-

¹ Read by invitation before the Obstetrical Society of Boston, February 13, 1892.

tions; and it is probably for this reason that the study of ophthalmology is more neglected by the general practitioner than are the other special branches of medicine, it being thought unnecessary to give much attention to a subject, whose practice is regarded both by the profession and laity, as best confined principally to the hands of the specialist. There are, however, a certain class of cases, and first among them purulent ophthalmia neonatorum, that may be properly considered in the light of emergency cases, and which every practitioner should be as well qualified to treat as he is pneumonia, dysentery, scarlet fever and the various other troubles that are usually considered as falling more within his province. The physician is or near the city can, if he choose, transfer the responsibility of these cases to the oculist, but in the country he must take entire charge, and will be held accountable for any unfortunate result. It is of the first importance, therefore, that the value of prophylactic measures, and the necessity of a thorough and intelligent treatment of the disease, should be more generally recognized by members of the profession. The large number of outpatients that come under the supervision of the Boston Lying-in Hospital, offers, it seems to me, an exceptional opportunity for the practical illustration of the points in question; and if certain regulations could be introduced and systematically carried out, I am confident that results published at the end of five years would emphasize their importance, in this vicinity at least, as no other method would be capable of doing. The custom of washing the vagina before and during labor, as practised in this institution, is certainly to be commended; and if, in addition, a single drop of a two per cent. solution of nitrate of silver could be dropped into the eyes, after they have been thoroughly cleaned, as recommended by Credé, the chances of this disease making its appearance would be still further lessened. A moderate amount of irritation is usually produced by this procedure, the eyes being red and watery for two or three days. If, however, but one or two drops have been used, nothing more serious is to be looked for. Dr. Noyes, in his text-book on "Diseases of the Eye," expresses the opinion that a one per cent. solution can be employed with equally good results, and in the hands of the inexperienced it would probably be safer to use it. If, in spite of these precautions, a purulent inflammation develops, the child might be referred at once to the Massachusetts Charitable Eye and Ear Infirmary, or some other institution, where a record could be kept of the case, as to the severity of the inflammation, condition of the eyes at time of discharge, etc., and made use of later, if desirable. It would not be difficult to arrange some such system and it would undoubtedly produce satisfactory results, not only in directly preventing a few cases of blindness, but also in impressing upon the minds of future practitioners, the fact that purulent ophthalmia neonatorum is a serious trouble and one that must not be neglected.

There is very little difference of opinion as to the value of nitrate of silver in the treatment of this disease, and if this agent is properly used, in connection, of course, with thorough cleanliness, that is, in keeping the eye as free as possible from the purulent discharge, the results will be almost invariably satisfactory. Its daily application in a one or two per cent. solution to the palpebral conjunctiva, as long as the lids remain infiltrated, and there is the least purulent discharge, seems to me of the utmost importance. It

is not at all unusual to meet with cases where this treatment has been discontinued too early, and the inflammation again becomes decidedly active in consequence. It is certainly a safer plan to continue its use for a few days after the discharge has entirely ceased.

Clinical Department.

TWO CASES OF PREGNANCY AND LABOR AT TERM, FOLLOWING THE ALEXANDER-ADAMS OPERATION.

BY F. W. JOHNSON, M.D.,

Visiting Gynecologist, Carney Hospital; Visiting Gynecologist, St. Elizabeth's Hospital.

CASE I. J. K., married, thirty years of age, mother of two children, was sent to me by Dr. J. J. McCann, September, 1889.

Since last confinement, five years ago, has aborted four times; at seven, five, seven, and three months respectively. Last abortion occurred in June, 1889. At this time there was excessive flowing, but no history of inflammatory trouble. Dated her trouble from the third abortion, which occurred Christmas, 1888. As in June, there was excessive flowing, but no symptoms of inflammatory trouble. Menstruates every twenty-five days. Flows three to four days. Flows but little. No dysmenorrhoea. Complained of sagging and dragging down, and leucorrhœa. She was one of those fat, fleshy neuroasthenics so well described by Dr. Mitchell.

Diagnosis: Ruptured perineum; retroflexion; bilateral laceration of the cervix; left ovary prolapsed and adherent beside the uterus at the base of the left broad ligament. This diagnosis was verified, under ether, by Dr. Conant and myself.

After using the packing for a few weeks the uterus became perfectly movable, but a pessary could not be worn owing to the so-called "thickening" at the base of the left broad ligament, which "thickening" I have always found to be due to a prolapsed ovary or tube, or both, and not in any way caused by a thickening in the broad ligament.

In a very large experience with examinations under ether, both through the rectum and with the fingers inside the abdominal cavity, I have never found any alteration in any way, shape or manner in either broad ligament that would suggest a previous attack of inflammation in the cellular tissue. Except in cases of sepsis following an abortion or labor, pelvic cellulitis is rare.

The sagging and dragging down still continuing she was advised to have the lacerated cervix repaired, and to have the round ligaments shortened to correct the retroflexion.

February 21, 1890. Operation. Dr. W. M. Conant assisted. Both the operation on the cervix and the Alexander-Adams were a success, and relief was obtained from all pelvic symptoms. I saw her every month or two, and she remained perfectly well as far as the contents of the pelvis were concerned. November, 1890, she became pregnant, and was delivered August, 1891.

In answer to several questions, Dr. McCann, who attended her, wrote the following concerning the case: "There was one thing peculiar about the pregnancy.

She carried the child much higher than ever before. Had much better health and less sickness during the nine months. These three facts are in strong contrast with similar conditions in every previous conception."

Length of labor? "About one and three-fourths hours."

Sex and weight of child? "Boy: nine and one-half pounds."

Character of labor? "She had good pains, better than ever before."

Puerperium? "She remained in bed fourteen days. She flowed a good deal—not post-partum haemorrhage—but during her stay in bed she lost considerable blood, although there was good and permanent contraction of uterus. She was weak on getting up, but nothing of interest occurred. She nursed the baby."

What is the condition and position of the uterus? "The womb seems a little heavy, but in normal position. It does not seem lower or dependent, yet she passes a considerable yellowish discharge."

October 29, 1891. Examined at my office. Uterus in perfect position. Cavity measured two and one-half inches. No discharge from vagina or cervix.

CASE II. M. McG., married, twenty-seven years of age, was sent to me by Dr. J. J. McCann, December 29, 1890. She complained of pain in the back and in the left ovarian region. Every month for the past year, midway between each menstrual period, suffers from nausea and vomiting. Menstruation began at sixteen; regular every four weeks. Flows moderately for three days. Some dysmenorrhœa for the first two days of the flow. No children. No abortions. General health good. She sought relief for sterility.

Diagnosis: Retroversion with adhesions; left ovary prolapsed; chronic endometritis.

January 21, 1891. Operation. Dr. Conant assisted. Cervix dilated for drainage. Round ligaments shortened. Ligaments fastened with silk-worm-gut. Incision closed with silk.

January 27th. Superficial abscess on the right side.

January 29th. Small superficial abscess on the left side.

February 21st. Uterus in perfect position, except that it was drawn over towards the right side. The right ligament was probably so shortened that during healing it drew the uterus away from the left side. Discharged well.

March 7, 1892. Reported at my office. Menstruated for the last time March 25, 1891. Confined December 28, 1891.

During the third and fourth months there was some morning sickness, "about every other morning." During the last two months of pregnancy she had considerable pain in the right side with bearing-down. In labor seven hours. Staid in bed fourteen days. There was a bloody discharge from the vagina for four weeks after confinement.

The child was a female, and weighed about five pounds. Examination found the uterus in the same position that it was when she went home, February 21, 1891. The left ovary could not be found. Since the operation there had been complete relief of all backache and of the pain in the left ovarian region. There was present endometritis.

A MORAL CITY.—A Chicago paper states that a manufacturing chemist of that city recently received an order for five million aphrodisiac pills.

Medical Progress.

RECENT PROGRESS IN GYNECOLOGY.

BY F. H. DAVENPORT, M.D.

PROLAPSE OF THE FEMALE URETHRA.

KLEINWÄCHTER¹ has found in the literature of the subject the records of nearly a hundred cases. As a result of a careful study of the cases, he has come to the following conclusions:

(1) Urethral prolapse is by no means so rare an occurrence as has been generally supposed.

(2) The cause of the prolapse is as yet not fully understood; this much is sure, however, that the age of the patient plays the most important part.

(3) Children are most frequently affected, probably as a result of the peculiar typographical anatomical relations of the bladder and urethra.

(4) Next to children, but much less often, women who have passed the menopause are affected. This is probably the result of senile involution.

(5) Women in the height of sexual activity are most rarely the subject of this affection, in spite of the fact that they are apparently most exposed to those injurious influences which might cause prolapse.

(6) Prolapse of the urethra is of varying importance according to the place where the separation of the mucosa from its underlying structure begins, and in consequence calls for different operative measures.

(8) The separation of the mucosa in the lower part of the urethra with consequent prolapse requires only a simple operation, the removing with knife or scissors of the prolapsed mucous membrane and uniting the cut edges.

(8) If the mucosa becomes separated higher up in the urethra and later is crowded down, this is not a simple prolapse but an inversion of the mucous membrane with prolapse. Such a condition requires the opening of the urethra and the removal of a portion of the separated mucous membrane with subsequent suturing of the wound.

(9) If the prolapsed mucous membrane is removed regardless of the form of prolapse present, much damage may be done.

(10) Ligating the prolapsed part is entirely contrary to the principles of antiseptic surgery.

DRAINING AFTER ABDOMINAL SECTION.

Dr. R. B. Hall² makes a strong plea for drainage after abdominal section. He claims that in the majority of fatal cases of laparotomy, the cause is sepsis from the absorption of septic fluids in the peritoneum. For this reason he would keep the peritoneum drained until the fluid removed is straw-colored. It has been his practice to do this in every case, simple or complicated, removing the tubes if it is found unnecessary, in from eight to ten hours. He has never had bad results, either in the way of its being a source of septic infection, or a cause of hernia, or from the omentum being caught in the perforations, and he says he has saved the lives of several patients by putting in a drainage-tube when it was apparently not indicated.

DRAINAGE OF THE UTERUS.

Dr. W. M. Polk³ describes a method of draining

¹ Zeit. für Geb. und Gyn., Band xxii, Heft 1.

² Medical Record, December 12, 1891.

³ New York Journal of Gynecology and Obstetrics, February, 1892.

the uterus for chronic endometritis and metritis, not only when these conditions exist independently of salpingitis or other forms of perimetritis, but also when they are associated with such disorders. His conclusions are based on the results in forty cases that he has operated on.

He refers to the fear which has prevailed of invading the uterine cavity, especially if there is disease of the appendages, and claims that there is no ground for such fear if scrupulous cleanliness is observed, and the escape of infecting material is provided for.

His method is to thoroughly disinfect the genital tract, dilate the cervix, introduce the cervical speculum, which should have an anterior diameter of about five-sixteenths of an inch, irrigate the interior of the uterus with bichloride, curette, and then pack the cavity with gauze. This may be left in until the sixth day. As a rule, only one packing is needed, but if a second is desirable, it can be done without anesthesia at the time of the withdrawal of the first.

The results gained are depletion of the uterus, reduction in size in cases of sub-involution, cessation of endometrial discharge and the diminution in size of peri-uterine masses. There is very little febrile action following this procedure.

TEDELENBURG POSTURE FOR GYNECOLOGICAL EXAMINATION.

Stroynowski⁴ recommends this position not only in abdominal operations where a clear view of the pelvis is desirable, but also in simple gynecological examinations where the pathological condition of the pelvic organs is difficult to make out. In one case where there was considerable free fluid in the peritoneal cavity and it was of importance to determine the relations of the appendages to the uterus, this position, which allowed the fluid to gravitate towards the diaphragm, enabled the author to make a satisfactory examination. He finds that in all difficult cases it makes the exploration easier.

VAGINAL OÖPHORECTOMY.

Dr. H. T. Byford⁵ makes a plea for the more frequent employment of vaginal oöphorectomy for the removal of diseases of ovaries, and small ovarian tumors. In sixty-two cases of vaginal section he has had but one death, twenty-seven being vaginal hysterectomies, one of which died, and thirty-five vaginal oöphorectomies with no death. He prefers it in suitable cases, if for no other reason, because it avoids the danger of hernia. He gives the history of a case which presented more than the ordinary difficulties, including extensive adhesions, a right ovary buried in solid adhesions, and persistent hemorrhage requiring a Mikulicz drainage, all of which difficulties were easily met, and the patient did well.

He claims that where the trouble is low down in the pelvis, an exploratory incision through the vagina will be more satisfactory, and less of an operative procedure than an abdominal section. Usually the vagina can be rapidly dilated sufficient for the manipulation, even in the case of virgins who have passed the menopause. In only one case was perineal incision necessary.

As regards reaching the diseased parts, if the uterus is retroverted or the cervix can be pulled forward and the fundus easily pushed down into the cul-de-sac of

Douglas, Dr. Byford is confident the ovaries can be also pulled down into the vaginal opening. If the cervix is back and the fundus forward, he prefers the ventral incision. The same principles apply to the danger of wounding adherent intestines. If the structures are low down in the pelvis, there is not much likelihood of extensive adhesions to the bowel; if high up, such adhesions are more likely to occur, and they had better be approached by the abdominal route.

HYDRASTININ IN HEMORRHAGE FROM THE UTERUS.

Abel,⁶ as a result of the trial of this drug, first recommended about two years ago by Falk, in cases of meno- and metrorrhagia, considers it a valuable addition to our means of controlling hemorrhage. He found it efficacious in cases of primary bleeding in endometritis and myomata, and in secondary hemorrhage from disease of the appendages, as parametritis, tubal cysts, and tubo-ovarian tumors; also in cases of so-called ovarian or congestive hemorrhage, where no disease is found. Abel always uses it subcutaneously, and for the details of the method as regards dosage and frequency in the varying conditions present, the reader is referred to the original article. Three cases of bleeding during pregnancy were checked, and the drug showed no tendency to produce abortion.

The author considers it the best means we have of controlling hemorrhage from the uterus. Its good results show themselves only after prolonged use, hence it is of no avail in acute hemorrhages. The cause of the bleeding must be clearly made out first before the drug can be intelligently used. If used in proper cases it will often render curetting unnecessary.

ELECTRICITY IN THE TREATMENT OF MYOMATA.

The question of the value of electricity in the treatment of myomata of the uterus is again discussed in a paper by A. Martin and Mackenrodt,⁷ of Berlin. As material on which to base their conclusions, the authors have made use both of the cases which have come to them originally for treatment and in which the Apostoli method was employed, and also those where electricity had been used elsewhere, and owing to farther trouble had sought relief. In all, there were sixty-six cases, of which thirty-six were treated in the hospital; sixteen who had been treated elsewhere came for operation, and fourteen came for advice and occasional observation, but not for treatment. The last cases were rightly included as they gave valuable indications as to the final results. All were treated strictly according to Apostoli.

Of the thirty-six patients treated originally at the hospital, twenty were suffering from myomata of small size, and in all these a symptomatic improvement was noticeable as regards hemorrhage, pain and the general condition in the first-half year. In no case was there either a disappearance of the tumor, or an undoubtedly lessening in size. Of the twenty, eight were over forty-five years of age, and the coming on of the menopause contributed to the good result. Of the remaining twelve, the majority showed later a return of the flowing and pain, and were treated preferably in other ways.

The second class of cases, of which there were sixteen, so far from showing improvement, were on the contrary made worse, and three died.

⁴ *Cent. für Gyn., January 10, 1891.*

⁵ *American Journal of Obstetrics, March, 1892.*

⁶ *Berl. Klin. Woeh., January 18, 1892.*

⁷ *Deutsche. Med. Woeh., January 14, 1892.*

By a comparison of these results with those of other operators who look with favor on this method of treatment, it is seen that while the proportion of those made worse is less with them, yet in no case has the tumor disappeared, and the improvement has been lasting only when the patients are treated near the time of, or after, the menopause. The authors, therefore, consider electro-therapy as merely one of the various palliative measures for the treatment of these cases, and when the bad results and deaths are taken into consideration as a decidedly dangerous one.

Looking the whole subject over in the light of these cases treated by electricity, and of three hundred and fifty-six cases of myomata which have come to operation in Martin's clinic, the writers come to the following conclusions:

They regard the electrical treatment of myomata as an inappropriate procedure, which causes the patient pain and loss of time, results in symptomatic improvement in only a third of the cases, and makes the patient's condition worse in more than a third; they, therefore, advise against its employment.

In the case of fibroids which cause none or only slight symptoms, they employ no local treatment. If serious disturbances occur they advise operation, the character of the operation depending upon the nature of the case.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

MEETING, February 13, 1892.

DR. F. E. CHENET read, by invitation, a paper on PURULENT OPHTHALMIA NEONATORUM AS A CAUSE OF BLINDNESS.¹

DR. C. E. STEDMAN said he had seen no case of ophthalmia for a long time until last summer, when he had a severe case which for a long time resisted treatment. He was particularly surprised at the occurrence of this case, for the most careful antiseptic precautions had been taken and the trained nurse was one of the best.

DR. MCCOLLUM said that he had had a few cases of ophthalmia neonatorum at the Chardon Street Home, and he had used nitrate of silver and zinc in the treatment, but he considered frequent washing and strict cleanliness to be the most important measure.

DR. WM. INGALLS, out of a large number of obstetrical cases seen in private practice, had had but two or three cases of ophthalmia, and they had all recovered. He believed that his freedom from this trouble was due to the fact that he always made a practice of wiping the babies' eyes immediately the head was delivered.

DR. A. D. SINCLAIR had had but one case of ophthalmia neonatorum where the eye was lost, and that was in a wretched case in Edinburgh where the treatment of cleanliness was not properly carried out. He felt sure, however, that he would have lost other cases if he had not always insisted on very frequent washing of the affected eyes.

DR. WITTINGTON referred to an instructive case of ophthalmia which occurred in his practice a year ago,

and the only case he had had. The patient was first seen three days before delivery, and a pessary that had been worn nineteen months was removed from the vagina. Frequent antiseptic douches were given to combat the resulting vaginitis, but even with the greatest care the child had a violent conjunctivitis which lasted a month but left no injury. He treated the case with water and with a solution of alum.

DR. GAVIN said that most physicians were not provided with a retractor for the eyelids such as the reader referred to, and he had found that one could easily be extemporized from a hair-pin bent at right angles. In the few cases of ophthalmia that had occurred in his practice he had used alum in the strength of ten or fifteen grains to the ounce.

DR. CLEMENT spoke of three cases that he had seen, which made good recoveries. The treatment consisted of frequent cleansing and the use of a bichloride of mercury solution in the strength of 1-5000, which seemed to do more good than anything else.

DR. DUNBAR saw a case a year ago, the cause of which he was at a loss to discover, until he found that another practitioner was treating the father for gonorrhoea.

DR. GERRY referred to two cases of ophthalmia, the first of which was of a severe nature, no doubt of gonorrhœal origin. The mother had cystitis and the father had a persistent rheumatism of a gonorrhœal character, although the latter disease was denied by the man. He succeeded in saving the eyes, using a weak solution of corrosive sublimate and also a solution of nitrate of silver which accomplished what the corrosive solution did not. In the second case, of mild nature, the mother an intelligent woman and a reader of "Babyhood," evidently thought that he had done wrong in not washing out the vagina before labor.

DR. J. STEDMAN insisted on the importance of wiping the eyes with a clean napkin as soon as the head is delivered.

DR. C. W. TOWNSEND said that the reader had suggested the advisability of the routine use of nitrate of silver after delivery in the clinic of the out-patient department of the Lying-in Hospital. Nearly a thousand cases were attended during the last year, counting in the two hundred in the obstetrical department of the Boston Dispensary. Out of those, although nitrate of silver is not used at birth, but very few cases of ophthalmia are seen, and these, as a rule, respond readily to treatment by washing with water and the use of nitrate of silver, and he could not recall a single case where the eyes had been lost. Under these circumstances he questioned very much whether it would be advisable to use nitrate of silver as a routine practice at birth, especially as the ignorant mothers would object and would attribute any conjunctivitis due to the introduction of dirt to this treatment. In the hospital, before the days of antisepsis, ophthalmia was very common. The routine use of nitrate of silver at birth almost did away with the trouble, but it was found that with antisepsis during labor and careful washing of the eyes at birth, as good results could be obtained.

DR. EDWARD REYNOLDS would object to the use of nitrate of silver in every case, for he believed that the slight serous discharge occasioned by it would cause much anxiety to the parents.

DR. G. J. BLAKE had formerly seen a good many cases of ophthalmia in the hands of the midwives. Frequent washing and the use of nitrate of silver had

¹ See page 362 of the Journal.

been his treatment. He remembered the objection of a prominent occultist that the solution might stain the tissues.

DR. CHENEY, in closing, said that undoubtedly cases could be cured without the use of nitrate of silver, although he believed that this treatment was the most successful. The disease had, as in a case spoken of by Dr. Green, developed as late as the eighth day, although contracted at birth.

DR. C. P. STRONG reported

CASES OF LAPAROTOMY PRESENTING FEATURES OF UNUSUAL INTEREST.²

DR. DAVENPORT said that he considered the question of the advisability of the removal of the appendages for symptoms alone as the most important one suggested by the paper. While it is true that a reaction has set in against the indiscriminate operating of a few years ago, yet the best surgeons would probably not refuse to operate in certain cases, even though no appreciable pathological change were present. His own opinion was that, where severe symptoms were present, which were either connected with the pelvic organs or were associated with the menstrual epoch, and other appropriate measures had been tried for their relief without success, that then an exploratory incision was justified. This was the more so, since the most careful examination in competent hands, under ether, may fail to recognize the existing conditions.

In the few cases which he had operated on for symptoms, he could not say that any had been made worse. One or two cases, however, had not improved, but in this way, that though the particular symptoms for which the laparotomy was performed, were relieved, yet other perhaps quite as troublesome ones took their place. One case of persistent menorrhagia with intense pain, which had resisted all treatment for years, was relieved of the flowing, but now suffers from constant pain below the scar, in the bladder and rectum, and cannot do any more work than she could before. He does not consider it justifiable to operate where the symptoms are those of neurasthenia, without special reference to the pelvic organs; but, under the conditions described above, it is the surgeon's duty to give the patient the chance of an operation.

DR. F. B. HARRINGTON believed that certain carefully selected neurasthenic cases could be relieved by ovariotomy. There are other neurasthenic cases, however, where this operation would be of no value, for if a local trouble is relieved at one point, it is sure to recur at another. As an illustration of the sort of cases that could be relieved, he referred to one who had been bed-ridden for three or four years. The tubes and ovaries were removed, and the patient is now well and about. The tubes were found dark and congested, and the ovaries contained some cysts.

DR. G. W. GAY said: One of the early subjects of this operation has been a patient of mine for many years. She is highly neurotic, so much so, that a neuralgia in some part of her body has come to be her natural condition. The removal of the left ovary had not the least effect upon the pain, from which she had suffered for years, and from which she continued to suffer for about three years after the operation. This patient, like many other neurotics, gets along much more comfortably without medicine and medical treatment, than she ever did with them, for the reason,

I presume, that her attention is not so constantly directed to herself.

Several cases of oophorectomy for neuralgia have come to my personal knowledge, in which no relief followed the operation. Under these circumstances it is fair to conclude, that the cause of the pain was not local in its character, but had to do with the general nervous system. Too often pain, distress and all sorts of suffering seem to be the fate of these unfortunate women, however they may be treated.

I have not yet arrived at such a stage of development, as to have no respect for the peritoneum. Such a doctrine is hardly safe for the youngest members of the profession, despite the fact that a few surgeons have done scores of laparotomies without a fatality. The operation in the hands of most surgeons is not free from danger.

For these two reasons then, unless some organic change could be detected, I should hesitate a long time before removing the ovaries for simple neuralgia.

DR. BOWLES agreed with Dr. Harrington that ovariotomy should not be performed in some cases of neurasthenia as nothing was accomplished, although in others carefully selected it was of value. In one case he had seen from time to time, the ovaries had been removed, but the neurasthenic symptoms remained as bad as ever. She was a uterine crank.

In another case he was asked as to the advisability of doing an operation. He was unable to find any disease on examination, which was followed by an hysterical attack of pain and fever, and he declined to operate. She was taken to a hospital for neurasthenics which took fire and she has been better ever since.

Another case where there had been much pain and a small tumor was found, he had operated on a few days ago and removed a small dermoid cyst. A good many years ago while making autopsies he was surprised at the frequency of small cysts of the ovary or tuberculated extremity of the tubes, perhaps as many as one in five, where there had been no symptoms, the patient being under observation at the City Hospital. They may therefore exist without causing any harm, and they should only be removed when there were symptoms referable to them.

DR. G. HAVEN spoke of two cases where ovariotomy gave relief from severe neurasthenic symptoms. The first case had had severe pain at each menstrual period keeping her in bed most of the time. She had been treated in institutions and outside without any relief. As a last resort he performed ovariotomy two years ago, finding only a small cyst in one ovary. She made a good convalescence, has been much relieved and able to do a certain amount of work. The second case had been suffering much pain for seven years, spent a good part of the time in bed and at various institutions, treatment being of no avail. A short time ago he removed the tubes and ovaries, which were reported to be slightly thickened and edematous by Dr. Mallory. Since then she has felt and slept much better and three or four days ago walked half a mile.

DR. C. P. STRONG, in conclusion, said, he did not wish to be understood to be an advocate of ovariotomy except in carefully chosen cases. Of a very large number of cases seen in his hospital services, in only a small proportion would this operation be thought of and in those only after thorough treatment for a year by galvanism, etc. If after that time there is no improvement it seems to be our duty to consider the

² See page 359 of the Journal.

operation especially in the case of those who work and cannot afford to lie idle. He would advocate conservatism first and then be prepared to do something rather than to fold our hands and do nothing.

DR. E. J. FORSTER showed a hair-pin which a patient had introduced into the uterus for purposes of abortion. He had introduced a sponge tent to dilate the cervix in order to remove the pin, and on taking out the tent, the hair-pin shot out onto the floor. It had been there four weeks.

DR. F. H. DAVENPORT showed some pus tubes he had removed that morning. The patient was first seen a year ago and the probable diagnosis of purulent salpingitis made at that time. She refused operation and gained twenty-three pounds under treatment. Lately she began to have pain with an increase in size of the tubes and an escape of pus into the peritoneal cavity and he operated at once.

NEW YORK COUNTY MEDICAL ASSOCIATION.

STATED MEETING, MARCH 21, 1892.

THE President, DR. S. B. W. MCLEOD, in the Chair.

DR. J. LEWIS SMITH read a paper on

RECENT INVESTIGATIONS RELATING TO THE PREVENTION OF DIPHTHERIA AND SCARLET FEVER.

The germ of scarlet fever, he said, though its precise character had not as yet been demonstrated, surpassed that of every other disease with the exception of small-pox in its tenacity to objects, its portability and its activity and virulence. Having given instances illustrating these points, he said that in cities, there was reason to believe that the contagion was often conveyed by means of books which children, ill with scarlet fever, handled. The most recent investigations tended to show that the disease was controlled, and its spread prevented in a marked degree by the frequent antiseptic treatment of the fauces from the commencement of the attack. The secretions from the faecal surface and the faecal surface itself contained numerous microbes, of which the streptococcus was far the most abundant, and was presumably an active agent in producing the inflammation. This streptococcus, as Professor Hutinal, of Paris, had claimed, was apparently identical with that which occurs in suppuration processes, the Rosenbach pyogenic streptococcus. Since these dangerous microbes were located primarily upon the faecal, nasal and post-nasal surfaces, the early and repeated use of germicidal applications was now considered of the first importance, and this consideration undoubtedly enlarged the scope of prophylaxis.

As regards diphtheria, it was now almost universally acknowledged that the Klebs-Loeffler bacillus was the specific germ of the disease, and Brieger and Fraenkel had demonstrated in diphtheria a virulent toxine which was believed to be elaborated by this microbe, which recent investigations had shown to be of itself comparatively innocuous. These observers also showed that slight variations in the chemical composition of the toxine named destroyed its virulence. It was true that the fact, that sometimes on the mucous membranes of perfectly healthy individuals a benign bacillus was discovered which as regards appearance and behavior was not distinguishable from the Klebs-

Loeffler bacillus, tended to militate against the efficiency of the latter in the production of diphtheria; but this was now explained by the hypothesis that the benign bacillus in question was simply the Klebs-Loeffler bacillus deprived of its virulence. As confirming this supposition, it might be mentioned that the benign bacillus was sometimes found in those who had recently recovered from diphtheria. While scarlatins and other diseases were capable of producing pseudo-membranous exudations, Dr. Smith believed that no case should be designated as true diphtheria unless it was produced from the Klebs-Loeffler bacillus.

Certain French authors, however, had pointed out that, while the phenomena observed in diphtheria were mainly attributable to the poison elaborated by the Klebs-Loeffler bacillus, we should not forget that other morbid agents were also concerned in their production, such as the streptococcus and the staphylococcus, which were often found in internal organs where the former did not exist.

Having related instances to show the extreme contagiousness of diphtheria and the tenacity of its germs, Dr. Smith alluded to the fact that damp, foul places such as sewers either have the power to propagate the Klebs-Loeffler bacillus or by means of the emanations from them to convert the benign bacillus mentioned into the latter. In this way, was no doubt to be explained the constant prevalence of diphtheria in large cities like New York where, notwithstanding all precautions, people were often exposed to the contamination of sewer gas. Another mode of communicating diphtheria was by means of walking cases. The disease was often so mild in character as to escape notice, and thus children in schools, in city conveyances, in churches and in dispensaries were exposed to the contagion. Diphtheria had also been known to be communicated by milk and frequently through the agency of domestic animals, especially the cat.

Although much had been learned concerning the prevention of this disease, it was still the cause of a heavy mortality in all civilized countries. How much could be accomplished by intelligent prophylaxis, however, was shown by the wonderful results obtained by Graucher, who succeeded in preventing a large number of children, who were sent to diphtheria hospital wards under a mistaken diagnosis, from contracting the disease. Out of one hundred and fifty-three such instances not a single case of diphtheria occurred. Graucher's method of preventing the spread of diphtheria included a metallic screen placed about the patient's bed, the wearing of blouses by all nurses and orderlies, the washing of all napkins, spoons, and other articles used by the patients in a solution of one ounce of bicarbonate of sodium to the pint of water, the daily disinfection of the nurses' blouses, and the repeated washing of the nurses' persons in solutions of corrosive sublimate or carbolic acid. The success attending these prophylactic measures justified the belief that it is possible in almost every instance to limit each attack of diphtheria or scarlet fever to one or two cases. Dr. Smith advised that the physician, before entering the sick room, should take off his coat and waistcoat, and put on a blouse or envelope himself in a sheet. Most medical men, he said, in examining the fauces sat in front of the patient, and thus when coughing was excited they were exceedingly likely to receive infectious matter upon their persons. Repeated instances had been reported in which the disease was

conveyed in this way. In order to avoid this, he should sit beside or behind the patient. Another excellent way was to make the examination through a pane of clear glass. Upon leaving the sick room, he should wash his face, head and hands in a solution of corrosive sublimate or other antiseptic. All articles not actually required for the comfort of the patient should be removed from the room as soon as the diagnosis was made.

In regard to other children in the family, Dr. Smith said that he had formerly contented himself with sending them away. But this was not enough. Their entire persons should be bathed in bichloride solution, and a complete change of clothing made. Every three hours for a week their mouths and fauces should be washed with a solution of peroxide of hydrogen. It was also advised that after seeing a case of diphtheria or scarlet fever the physician should not visit another child for at least one or two hours. The Health Board of New York was to be commended for the excellent work it had accomplished in the last five years. Smallpox, which was formerly quite prevalent, had been practically stamped out: and it was no doubt true that the other infectious diseases were much less prevalent than they would be but for the precautions enforced. It was probable, however, that scarlet fever and diphtheria would never be entirely suppressed. The conditions of tenement-house life were such as to constantly perpetuate infection, and notwithstanding all that had been accomplished, it was a common thing for the brothers and sisters of children ill with diphtheria to attend the public schools. At the meeting of the American Pediatric Association, in 1890, Dr. Auguste Caillé had proposed very wisely that each schoolhouse should be provided with a sanitary inspector, one of whose duties it should be to examine daily (without using a tongue-depressor), the throat of every child when it came to school in the morning. In case of any trouble being found the child could be at once sent home, with a note addressed to the parents stating that it was sick, and that the family, or dispensary doctor should be at once communicated with. The late Dr. Wm. Budl, of England, stated in the *British Medical Journal*, in 1869, that he had never known scarlet fever to extend beyond the house where a case occurred. The means he used for preventing the spread of the disease were, (1) separation, and (2) disinfection.

Dr. Smith said it was his practice to have the bedstead, floors, etc., of the sick room washed every day with bichloride solution, and also to use the following disinfectant: one ounce each of oil of eucalyptus and carbolic acid were mixed with eight ounces of turpentine and of this two tablespoonsfuls mixed with a quart of water were allowed to simmer continually near the sick child. The vapor thus produced, while strong and pungent, was not unpleasant, and he believed that it had a decidedly prophylactic effect. Mr. Charles Smith, now of Australia, employed a similar, though rather stronger solution, with which he saturated cloths which were placed on paper on the bed, and he stated that since he had adopted this plan he had never seen paralysis follow a case of diphtheria. This corresponded also with his own experience in cases in which the disinfection mentioned was resorted to. In scurffata, the skin should be anointed every three hours, until desquamation was completed, with a mixture consisting of one drachm each of oil of eucalyptus and carbolic acid dissolved in seven ounces of sweet oil.

As a spray in both scarlet fever and diphtheria peroxide of hydrogen had a decided prophylactic effect. It should be used in the strength of one part to two or three of water for the fauces, and of one part to six for the nostrils. Of course, the most careful disinfection of the bedding and all utensils used was called for.

Dr. Smith did not believe that sulphur fumigations after a case of infectious disease were of much value, though he thought that Dr. Squibb was right in stating that they were rendered much more efficient when moisture was secured by burning the sulphur over water. A more effective plan, in his opinion, was to wash the bedstead and floor with bichloride solution, and to paint or whitewash the floors and ceiling.

DR. C. A. LEALE considered that diphtheria was the most terrible scourge with which the medical profession had to deal, and that its prevention in large cities was attended with the most serious difficulties. The conditions existing in our tenement-houses were such as to render them almost insuperable, and while the Board of Health was doing all that it could in the circumstances, the constantly increasing tide of immigration from Europe continually tended to increase the obstacles to be contended against. With larger appropriations, and entire freedom from political influences, however, he believed that the Board could accomplish much more than it had as yet been able to do. In the early stages of diphtheritic infection he believed that the use of fruit acids, especially lemon juice, and of the mineral acids, are exceedingly useful in preventing serious trouble. He did not agree with Dr. Smith in regard to sulphur fumigations, but believed that sulphurous acid when combined with moisture was a most efficient disinfectant.

DR. HEPLICH advocated the establishments by the Board of Health of hospitals, to which the children of the poor when suffering from diphtheria or scarlet fever should be taken, even against the will of the parents. This seemed to him the only efficient way of controlling these diseases, and he hoped that in time the public would be educated up to this idea.

Recent Literature.

The Principles and Practice of Medicine. Designed for the Use of Practitioners and Students of Medicine. By WILLIAM OSLER, M.D., Professor of Medicine in Johns Hopkins University, etc. New York: D. Appleton & Co. 1892.

This volume exhibits originality at the very beginning, inasmuch as there is no preface. The author does not take us into his confidence as to his motive for adding another book on the "Principles and Practice of Medicine" to those which have preceded his. He does not tell us whether it is because there were too many good ones or too many bad ones; whether the publisher tempted him, or his University demanded it; or whether it was simply that he had noticed that "they all do it." He skips into the public presence without a word, but with a sort of air which suggests: Here I am! Take me, or leave me, but you had better do the former! He had probably heard that good wine needs no bush; and as he has written a good book, with an excellent dedication and some sound

aphorisms from the Greek on the first sheet, it mattered less about his motives. At any rate, after the table of contents and a list of charts and illustrations, we find ourselves plunging immediately into typhoid fever, which heads Section I, (on "Specific Infectious Diseases,") of this royal octavo volume of 1,080 pages. No preliminaries are devoted to such abstract subjects as nosology, symptomatology, etiology, inflammation, fever, etc. In this respect Osler's book resembles Strümpell's.

This first section of specific infectious diseases has thirty sub-headings, and embraces more than a quarter of the book. It is in the title of the section and in dealing with the description of the diseases included under this section that the work of the bacteriologist and the changes of the last ten years become apparent. It is, perhaps, needless to say that in this important department this book exhibits discreet judgment and an acquaintance with the subject well up to date.

The second section is on constitutional diseases; there are twelve sub-headings, the most important of which are rheumatism, gout and diabetes. Then follow the usual sections based upon an anatomical classification—diseases of the digestive, respiratory and circulatory systems; of the blood, of the kidneys, of the muscles. Then comes a polymorphous section devoted to the intoxications, sunstroke and obesity; and lastly a section covering diseases due to animal parasites.

The sections on specific infectious diseases and on diseases of the nervous system are the most considerable of the book, making up together about one-half of its contents, and considering the intrinsic importance of the subjects as well as the advances made in them in recent years, this is as it should be. The comparatively short section on diseases of the blood and ductless glands is concise but thorough, and, though most of the charts inserted through the volume are clear and distinct, the blood charts seem to us particularly pleasing and graphic. In the treatment of essential anæmia the author relies greatly upon rest in bed.

With the limited space and time at our disposal, we cannot undertake to call attention to all that is good or to affirm that there is nothing which might not be better in Dr. Osler's book. His attitude in regard to a few important and debated points may be noted. For the treatment of typhoid fever he is a very temperate advocate of the Brand method for institutions, though personally sympathizing with those who designate it as entirely barbarous. The employment of medicinal antipyretics he abandoned some years ago; the choice for him, if they are used, lies between antifebrin and antipyrine, with a preference for the former; nothing is said of phenacetine, which he apparently regards simply as an analgesic.

The quotation from Hirsch, "Die Geschichte des Typhus ist die des menschlichen Elends," introduced by the author as tersely stating the etiology of typhus fever, should be before the eyes of our immigration commissioners and quarantine and sanitary officials at the present time.

Dr. Osler admits at once the existence and the rarity of pulmonary syphilis. In the treatment of secondary syphilis the use of gray powder with Dover's powder by the mouth, is, we are glad to note, warmly endorsed. In regard to the question of syphilis and marriage, he thinks the family physician should insist upon the necessity of two full years elapsing between the date

of infection and the contracting of marriage, and there should be at least one year of complete immunity from all manifestations of the disease. He is an advocate of licensing, but to the unmarried man he recommends continence in alluring terms.

Dr. Osler's remarks upon the tuberculin treatment are moderate and judicious. He points out that we are at present in the reaction wave, and that it will probably be several years before we can speak with decision upon the true position of this remedy. The importance of bacteriological examinations in suspected tuberculosis and suspected malaria is strongly insisted upon.

Cases of leprosy, our author states, should be isolated, although the risk of catching the disease is "extremely slight." We are glad to notice that credit is given Beavan Rake for studies in this disease carried out at the hospital in Trinidad.

The pages on perityphlitis and appendicitis give the latest conclusions as to the pathology and management of these perplexing cases.

The pages upon malignant endocarditis reflect the author's Gulstonian lecture, and are, of course, excellent.

Our author seems somewhat sceptical, or at least open to further proof, as to the causation of arsenical poisoning by absorption from wall-papers and fabrics.

The style in which Dr. Osler's book is written is clear, concise and at the same time animated. The type is very good. The finish of the paper is excellent, but the texture is not strong, and we doubt whether it stands well the strain of the eager student who will certainly want to use it often and much, or the inadvertence of the busy practitioner who will sometimes consult it hastily. The book has evidently been "trained down" as much as possible to secure handiness without sacrificing even more important essentials.

We should be glad to be able to think and speak as highly of every medical book presented for review, as we can of this. In truth, had our enemy written it, we should be unable to find much consolation in his commitment.

Atlas of Clinical Medicine. By BYROM BRAMWELL, M.D., F.R.C.P., Edin.; F.R.S., Edin. Assistant Physician to the Edinburgh Royal Infirmary, etc., Vol. I, Parts I, II and III. Edinburgh: Printed by T. & A. Constable, at the University Press. 1891.

We justly reproach ourselves with so tardy a notice of this superb Edinburgh publication, though the delay enables us to form our judgment upon more than one fasciculus and to assure ourselves that the promise of the first part has so far been steadily realized.

As the announcement suggests, the work might, perhaps, be better styled "An Illustrated Treatise on Clinical and Systematic Medicine." The letter-press is worthy of the plates, beautiful and accurate as they are, and Dr. Bryton Bramwell's name is a guarantee of accurate, discriminating and intelligent work in the word-description which supplements the illustration of the artist and the photographer.

The plates are for the most part original, and copies of the water-color paintings and photographs in the possession of the author; they are colored, black and white, and photographavre plates, measuring 14½ by 10½ inches. The original paintings have been drawn from life under the supervision of the author.

The first and second fasciculi contain 48, and the third 44 folio pages. Each fasciculus is announced to contain at least 32 folio pages. Each annual volume will contain four fasciculi and about 30 plates. It is expected to complete the work in three annual volumes containing 90 plates. A volume will not be broken, but subscriptions may be made to single volumes. The price of the first volume to original subscribers is £1. 11s. 6d.

The first fasciculus is taken up with myxedema, sporadic cretinism, and Friedreich's ataxia. The first two subjects are especially interesting at the present time in connection with the experiments which are being made with transplantation of the thyroid gland.

Among the illustrations of Friedreich's ataxia we notice a reproduction of the striking case described by the late Dr. Everett Smith in these columns.

A very beautiful plate showing a typical case of lymphadenoma and one of melancholia with fear finish the first fasciculus.

The plates of the second part are on Addison's Disease and Hodgkin's Disease, with supplementary plates of molluscum fibrosum, xeroderma pigmentosum and mania. The plates of the third part exhibit progressive unilateral atrophy of the face, chronic progressive bulbar paralysis, ophthalmoplegia externa, and additional plates on molluscum fibrosum and xeroderma pigmentosum.

We regret to learn that the recent epidemic of influenza selected the author as a victim, and hence a slight but unavoidable delay occurs in the issue of Parts III and IV. We sympathize with such a visitation and must plead the same excuse for our own shortcomings. We must, however, remind the author that he is to blame if we are impatient for more.

The press-work of these pages does credit even to the house of Constable.

Ninth Biennial Report of the State Board of Health of Maryland, for the two years ending, December 31, 1891. Pp. 381. Annapolis, 1892.

This Report of the operations of the State Board of Health of Maryland is conveniently divided into chapters upon the following subjects: (1) Introductory; (2) Review of the Operations of the Board; (3) Quarterly and Special Reports; (4) Correspondence; (5) Life History of the State and Special Diseases; (6) Adulteration of Food; (7) Mortality and Vital Statistics.

During the past two years the Board has accomplished much valuable sanitary work, under the direction of its efficient Secretary, Dr. Chancellor. Several thousand circulars upon sanitary subjects have been distributed. Attention was called to the need of a properly equipped hygienic laboratory. Good work has been done in the line of food inspection. A special report follows upon the pollution of Lake Roland and upon certain sources of water-supply, notably that of Cumberland, where 587 cases of typhoid (or as it is termed in the Report, entero-miasmatic) fever occurred with 52 deaths.

In the chapter upon the Life History of the State, many valuable suggestions are presented as to the management and control of infectious diseases; but the paragraphs upon alcoholism might as well have been omitted, since the oft-quoted and fallacious statistics of the inquiry of the British Medical Association have already been shown to have no bearing whatever

upon the subject. Notwithstanding the fallacy of the statement that "hard drinkers and drunkards have an average life of 52 years and 14 days, and total abstainers 51 years and 80 days," every trade journal devoted to the liquor interest in England and America had appropriated the statement for its own ends. And yet Dr. Owen, the author and compiler of these remarkable statistics, virtually retracted them at the recent Congress of Hygiene at London in these words: "I have been misquoted frequently, and have never arrived at the conclusion, indicated by the figures, that the total abstainer's life was a worse one than the chronic drunkard's."

Insomnia and its Therapeutics. By A. W. MACFARLANE, M.D., F.R.C.P.E., etc. 8vo, pp. v. 298. New York: Wm. Wood & Co. 1891.

The work before us can hardly be called satisfactory. In his effort to be comprehensive the author has included almost every affection in which insomnia may be a symptom, apparently forgetful of the famous advice of the judge to the young lawyer, that this court may be expected to know a little something. Few, even among the laity, need to be reminded that the flea or the mosquito can produce insomnia, nor is insomnia usually the distressing symptom in acute cystitis. The result is that the author has written what is practically a treatise on general medicine, and, although there is a good deal that is suggestive in the work, neither his pathology nor his therapeutics can be considered as up to date. We find frequent mention of cerebral hyperemia and plethora, for example. In his therapeutics the author is an advocate of hypnotics, and in many respects his advice is hardly sound. One half the cases of functional insomnia are due, he believes, to an inherent instability in the cerebral textures, and, in 273 cases, he finds the chief cause to be neurasthenia, worry, gout, overwork, menopause, dyspepsia, alcoholism and senility.

Pulmonary Consumption, a Nervous Disease. By THOMAS J. MAYS, M.D. Detroit: George S. Davis. 1891.

From a consideration of the published cases in which phthisis and vagus disease coexisted, Dr. Mays has arrived at the conclusion that pulmonary consumption is a neurosis in which the vagi are primarily involved. Among other conclusions which he has drawn may be mentioned that "there is no testimony whatever to show that infection occurs through houses or food" and "that diabetes, beri-beri, leprosy and probably lupus and pellagra, are intimately associated with pulmonary consumption, because fundamentally the evidence appears to show that they are nervous diseases." We fear that to the average reader the evidence and reasoning on which these results are based will not seem absolutely satisfying, and doubt will arise if some cases of phthisis do not exist which are due to other than nervous causes. The therapeutics based on such a pathology do not seem to differ greatly from those advocated by eminent men who still fatuously cling to a belief in the bacillary theory.

Nursing in Abdominal Surgery, and Diseases of Women. By ANNA M. FULLERTON, M.D. Philadelphia: P. Blakiston, Son & Co. 1891.

This book contains the lectures delivered to the pupils of the training-school for nurses connected with the Woman's Hospital of Philadelphia. It supplies

not only what is too often looked upon as the only knowledge necessary for a nurse, the actual care of the patient, but also in addition such facts as will enable the nurse to be an intelligent and competent assistant to the surgeon. Some of these are preparation of room, sterilization of instruments, anaesthesia, names and uses of instruments, etc. In fact, many of these directions might be very profitably studied by the average medical student.

The book ought to be a useful one, and seems well adapted for its purpose.

Principles of Surgery. By NICHOLAS SENN, M.D., Ph.D., Professor of the Principles of Surgical Pathology in the Rush Medical College, Chicago, Ill., etc. Philadelphia: F. A. Davis. 1891.

A captions critic might be inclined to question the accuracy of the title of this book, for it deals more with the principles of surgical pathology, as pathology is generally understood. It is a most satisfactory work. Dr. Senn's indefatigable labors in the field of experimental surgery have entitled his work to most careful attention; and this book, treating as it does of the fundamental principles of modern surgery, is of great interest.

Dr. Senn discusses at length the processes of inflammation, of necrosis, of suppuration, septicæmia, pyæmia, erysipelas, tetanus, hydrophobia, surgical tuberculosis of the various organs, actinomycosis hominis, anthrax and glanders. Each is considered in a very complete manner; full attention being paid, not alone to the pathology, but to the etiology, symptoms, diagnosis, prognosis and treatment. His description of tetanus is masterpiece; and while the book will not be attractive to the general practitioner who simply desires therapeutic points, to the thinking surgeon the book is indispensable.

The reader here finds subjects presented in new lights; and occasionally one is inclined to question the truth of the deductions, yet, in this element lies a great value. It is full of thought and experimental research, and is an addition to any library. The print is too small to be read easily, and the binding is defective.

Surgical Diseases of the Ovaries and Fallopian Tubes, including Tubal Pregnancy. By J. BLAND SUTTON, F.R.C.S. With 119 engravings, and five colored plates. Philadelphia: Lea Brothers & Co.

It is a pleasure to review a book of this character; first, because of the great and growing importance of the subject at the present time; and, second, on account of the admirable way in which the subject is treated. There is no book which so clearly presents the pathology of the branch of gynecology, nor any which combines so happily original research, and a just estimate of the work of others.

It is divided into four parts: (1) Diseases of the ovaries; (2) Diseases of the Fallopian tubes; (3) Tubal pregnancy; (4) Methods of performing operations for ovarian and tubal disease.

The greater part of the book is occupied with the pathology of the subject, only the last fifty odd pages being devoted to the methods of operating. This is fortunate, for our knowledge of the methods of origin and growth of ovarian tumors, the changes which occur in the mucous membrane of the Fallopian tube as a result of disease, and the causes of tubal pregnancy

lags far behind our knowledge of how to treat these conditions. This work is therefore a very welcome addition to the literature of this subject.

The illustrations, most of which are original, add much to the elucidation of the text.

A Treatise on Bright's Disease of the Kidneys: Its Pathology, Diagnosis and Treatment; with Chapters on the Anatomy of the Kidney, Albuminuria and the Urinary Secretion. By HENRY B. MILLARD, M.A., M.D., etc. With numerous original illustrations. Third edition, revised and enlarged. New York: William Wood & Co. 1892.

There are a number of important changes in this new edition of Dr. Millard's well-known book. The author has re-written the chapter on Tests for Albumen in the Urine. He still considers his own test, that with phenic-acetic acid and potash, the most delicate, certain and practical, especially for albumina minima. The other re-agents considered by him, are: nitric acid, heat, the nitric-magnesian test (Roberts), and Tauret's with the double iodide of mercury and potash.

New matter has been added upon the albuminuria of pregnancy, the ocular lesions and mental disturbances attendant upon Bright's disease, the use of anesthetics in nephritis, curability, the dietary, the use of mineral waters, and the treatment.

The author has renounced his former opinions and conclusions recognizing the existence of "physiological" or "normal" albuminuria. A revision of the material upon which his previous position was based, in addition to the consideration of extremely careful and accurate experiments made by Lecorché and Talaman, has led him to the present conclusion that albumen, when secreted by the kidneys, can never be surely predicted to exist in health; that it is never physiological but always pathological and dependent upon histological changes in the kidneys.

The Mediterranean Shores of America—Southern California: Its Climatic, Physical, and Meteorological Conditions. By P. C. REMONDINO, M.D., etc. Fully illustrated. Philadelphia and London: The F. A. Davis Co. 1892.

The author writes from San Diego, but seems to write impartially of the whole of Southern California, without any attempt to promote any particular locality. He considers the nice adjustment between temperature and relative humidity — the humidity diminishing as the temperature increases and *vise versa* — to be, at once, the distinguishing peculiarity of the region of which he writes, and the key to its beneficial effects. There is, we believe, much truth in this statement.

The author divides the climates of Southern California into six distinct classes, all having a therapeutic value and application, as follows: (1) A purely insular climate; (2) a peninsular climate; (3) a coast climate; (4) a foot-hill and valley climate, 200 to 2,500 feet elevation; (5) a mountain climate, 2,500 to 9,000 feet elevation; (6) a desert climate, from 360 feet below sea-level to 2,500 feet elevation.

This book will be found of interest and of service to those who advise others about climates, or to those thinking of going themselves to Southern California.

The Mayor of Barfleur (France) has forbidden the wearing of low-neck dresses by the women of the commune, as being prejudicial to peace and social morality.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, APRIL 14, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 28 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

RECENT RESEARCHES ON BILIARY INFECTIONS.

THE bacteriology of biliary infections has been but recently studied.

Netter¹ claims priority in investigations of this kind, he found various benign and pathological microbes in morbid states of the bile and bile-passages. Naunyn and Duclaux, Vignal, Gilbert and especially Ernest Dupré have still more recently done good work in this department of experimental inquiry.

Normally, like pancreatic juice and freshly voided urine, the bile is aseptic. Though the common bile-duct opens into a cavity which is itself markedly septic (the duodenum), the bile-ducts, like the bile, are normally free from microbes. Only the entrance of the excretory canal is infected; the mucus and epithelium lining the ducts do not constitute a good culture field for germs, and bile is itself toxic to microbes.

In certain diseased conditions, the opposing barrier is broken, and microbes of various kinds, the staphylococci, the streptococcus pyogenes, the bacterium coli, the typhoid bacillus, or the bacillus tuberculosus may penetrate the biliary passages and the hepatic parenchyma from the duodenum, and produce an infectious icterus of mild or grave nature, according to the kind of resistance offered by the organism and the quality of the infectious agent.

The liver may become infected in four different ways: (1) through the peripheral lymphatics (but this is a rare event); (2) through branches of the vena portae which may bring pathogenic germs from the intestine as occurs in the abscesses of dysentery; (3) by the hepatic artery, as when, in the course of general septicæmia, the microbes of suppuration are conveyed in the arterial blood to the parenchyma of the liver, constituting the miliary abscesses and metastatic purulent collections of pyæmia; lastly, by the bile-

ducts, and this infection may come about by two orders of lesions, mechanical and septic.

Nowhere have we found so complete and so clear an account of these infections as in the lately published treatise of Ernest Dupré.²

The mechanical lesions of obstruction causing infection are foreign bodies, calculi, compression of the bile-ducts by tumors, extrinsic or intrinsic, etc. The septic lesions are inflammatory, catarrhal, or suppurative, and constitute the angiocholites.

In infectious secondary to mechanical lesions, the obstruction produces stagnation, then alteration of the bile, which becomes thick (like mud), and mal-nutrition and degeneration of the protective epithelium of the ducts; the medium is favorable for microbes if they can only obtain access thereto. When the obstruction is extrinsic, the compressing agent, which may be a tumor or a hydatid cyst, while opposing an obstacle to the outflow of bile, also presents a barrier to the passage of infecting germs upwards. It is quite possible, as Dupré has proved by numerous experiments on animals (tying the choledochus under rigidly aseptic conditions), to have a completely aseptic obstruction of the bile-duct. The symptoms will be icterus by retention, augmentation of volume, then shrinkage of the liver and gall-bladder, without fever or signs of local inflammation. Anatomically, there will be mechanical dilatation of the bile-ducts, vascular engorgement, then cloudy tumefaction or stenosis of the hepatic cells; these cell-degenerations being probably dependent on the irritation exercised on the cells by the resorbed bile. It is probable that in nature the conditions are seldom favorable for a continuance of asepsis; sooner or later the appearance of fever of a remittent or intermittent character and the signs of local inflammation give evidence that microbes have penetrated either the bile-ducts or the gland tissue proper.

The foreign bodies which may by their presence in the bile-duct cause obstruction and favor infection are generally of intestinal origin; worms (ascarides distomata), cherry-stones, various seeds, etc. Frerichs, in 1877, reckoned thirty-seven cases of biliary helminthiasis. If such bacteriferous causes of infection are rare, this is not the case with calculi, which when lodging in some part of the duct, cause biliary stasis by retention, dilatation of the ducts, ulcerative folliculitis of the mucosa and diffuse peri-lobular sclerosis. The more cachectic the patient from any cause (alcoholism, malaria, tuberculosis, senescence), the less feeble the resistance, and the more speedy and thorough the infection. The form of the calculus has its rôle in the biliary infection: thus sharp points and edges wound the epithelium of the ducts and favor the invasion of bacteria. Numerous small calculi in the choledochus or cystic duct are much more likely than a large solitary calculus to multiply points of contact with the mucosa and occasions of traumatism.

(To be continued.)

¹ Progrès Méd., 1886; Archiv. de Phys., 1886.

THE VITAL STATISTICS OF MASSACHUSETTS
FOR THE YEAR 1890.¹

WITH a census population of 2,238,943 in Massachusetts, of whom 51.42% were females, there were 57,777 births, 20,838 marriages, 654 divorces, and 53,528 deaths in 1890, showing a birth-rate of 25.81, a marriage-rate of 9.31, a death-rate of 19.44, the averages for five years (1886-90) being 25.8; 9.3; 19.4.

The excess of births over deaths in the five years ending in 1890 was 68,298, or 205,409 less than the increase in population in the same time, showing the effect of immigration.

The average rate of increase of the population (excess of birth-rate over death-rate) is about half that of Germany, England and Scotland, somewhat more than that of Ireland and more than double that of France. The proportion of children born of native parents has decreased from 41.62% in 1881, still further to 34.82% in 1890. The illegitimate births were 2.03% of all births.

The average age at marriage was, of men, 28.8 years; of women 25.5. Marriages of native-born were 46.11% of the total; of foreign-born 31.50; of one native and one foreign-born 22.32, the latter showing a steady increase.

From birth to five years of age, the deaths per 1,000 living were between 60 and 70; from ten to fifteen 3.7; and again from seventy to eighty over 70. The death-rate of males like the birth-rate somewhat exceeds that of females.

The registration of deaths shows only 1.19% where the causes of death were not returned; and 519 deaths were reported as from unknown or ill-defined causes, not including 175 deaths from dropsy, 12 from ascites, 161 from infantile, 700 premature and 1,235 from paralysis.

The mortality from the infection-diseases, 3.61 per 1,000 of population, was considerably less than for either of the previous three years 4.09, 4.14, 4.14, in spite of the excessive number of deaths from influenza, which caused 411 deaths, as compared with 27 in 1889 and 11 in 1888. There was only one death from small-pox. For 1890 and the previous four years in order the rates were, per 1,000, measles .050, .088, .112, .234, .067; scarlet fever .087, .095, .259, .305, .170; diphtheria and croup .726, .140, .942, .848, .802; cerebro-spinal meningitis .070, .077, .088, .066, .053; whooping-cough .162, .159, .126, .119, .139; typhoid fever .373, .459, .485, .475, .412; erysipelas .078, .091, .109, .095, .090; influenza .184, .014, .006, .009, .007; diarrhoeal diseases 1.52, 1.61, 1.60, 1.56, 1.42; ague and remittent fever .027, .039, .033, .024, .014; pneumonia 1.80, 1.77, 1.91, 1.72, 1.46; hydrocephalus caused 16 deaths as compared with

14 in 1889, 2 in 1888, and none in the previous two years.

The decrease in reported mortality from pulmonary consumption continues, 5,791 deaths were returned or a rate of 2.59 as compared with 3.39 in 1871, or 13.3% of all deaths, which is the least ever recorded in our State.

The death-rates from brain diseases (apoplexy, softening of the brain, paralysis, insanity, cephalitis and brain disorders) have increased, as given by census years, from 1.21 in 1860; 1.43 in 1865; 1.43 in 1870; 1.64 in 1875; 1.70 in 1880; 2.00 in 1885 to an estimated rate of 2.2 in 1888 and 1.96 in the census year 1890.

The reported death-rate from cancer has steadily increased from .33 per 1,000 living in 1871 to .62 in 1890, partly a result, probably, of better diagnosis. In a similar way part, at least, of the great increase in kidney diseases (27 deaths in 1851 to 1,273 in 1890) and all the decrease from dropsy (390 to 175) may be accounted for.

The number of deaths reported from heart disease increased from 352 in 1850 to 3,417 in 1890, while the ratio to the living population increased from .354 per 1,000 to 1.58.

Since the beginning of our registration the increase of the urban population has been steady and rapid. In 1842, the population of towns having more than 10,000 inhabitants (of which there were only six) was 24% of the total population, while in 1890 the population of the twenty-eight cities was 61.3% of the total population. The facts bearing upon the distribution of the people in the State and vital statistics of the cities and rural population are most interestingly brought out in tables 130 and 131. The average death-rate for the twenty-eight cities, for the last five census years, is 21.4, as compared with 17.5 in the rest of the State, but the birth-rates are respectively 28.4 and 22.0.

An increase of deaths from illuminating-gas poisoning has very quickly followed the introduction of water-gas. The number of these deaths, 11 in 1890, was greater than the whole number from that cause in Massachusetts, for the entire period of nearly fifty years previous to the introduction of that dangerous agent.

THE TREATMENT OF TYPHOID FEVER.

As long as typhoid fever is as widespread and as frequent a disease as it is now, and has been in the past, attacking every year in all parts of the world a considerable percentage of the vigorous and active element of urban and rural populations, causing a mortality of from seven to fourteen per cent. of those attacked, and, even under the best of results where life itself is spared, incapacitating its victims for participation in the world's work for a period measured by weeks or months — so long its treatment will be a subject of great professional interest. And, notwithstanding a more intelligent prophylaxis, greater atten-

¹ Forty-ninth Report to the Legislature of Massachusetts, relating to the Registry and Returns of Births, Marriages, and Deaths in the Commonwealth for the year ending December 31, 1890, together with the Reports relating to the Returns of Licenses for Divorce and to the Returns of Deaths investigated by the Medical Examiners for the year 1890. Prepared by the Secretary of the Commonwealth, with editorial remarks by Samuel W. Abbott, M.D. Boston: Wright & Potter Printing Co., State Printers, 19 Post-Office Square, 1891.

tion to ventilation, and improved water-supplies and drainage, until all men become prudent and wise, typhoid fever, like the poor and like syphilis, is likely to be about us to offer this source of professional interest.

This winter is no exception to others in bringing its quota of papers, of books, and of discussions upon this important subject. In fact, it may be said that such contributions have been rather more numerous than usual. The cold-water treatment by Brand's and other methods is receiving more consideration in our cities, and is being tested in some of the large hospitals. We shall await the results, after a sufficient trial has been made with such material as presents itself at our hospitals and under the conditions which prevail there, with some curiosity. The aim, of course, should be to get the actual results of a given method, not to prove a given method to be either a good or a bad one. Typhoid fever in our hospitals is a different thing from so-called typhoid fever in a German army corps under the charge of a disciple of Brand, and the facilities for service differ. We do not know positively how far such an army corps is more prone to have typhoid as well as more prone to recover from it, than another corps similarly situated and of the same number of men under different medical management.

Some of the Philadelphia daily papers were much occupied last autumn by the use of Brand's method in the German Hospital there; we have published in our last issue and in this, a paper by Dr. A. L. Mason (which was read at one of our societies) on typhoid at the Boston City Hospital; the New York *Record* publishes in its last issue an abstract of a discussion of the treatment of typhoid fever, held at the Practitioners' Society of that city; and we have before us an octavo volume of two hundred pages, by Dr. James Barr, of Liverpool, upon treatment by continuous immersion for a week or ten days at a time, in a tank of water at a temperature of from 90° F. to 98° F., according as the body temperature of the patient is above 100° F., or approaches normal. Dr. Anderson, of Edinburgh, is very successful with a little perchloride of iron, administered every hour, day and night, and another practitioner has admirable results from a table-spoonful of a one per cent. solution of chloroform hourly, day and night.¹

The general sentiment at the Practitioners' Society seemed to be in favor of the use of the tub, and represented a moderate amount of experience at St. Luke's, the New York, Bellevue, and the Presbyterian Hospitals; though all the speakers were not equally impressed with its merits. The President, Dr. G. L. Peabody, thought the only drawback to the Brand method, as a method, was its expense. It required an abundance of fresh water, sometimes ice, and at least four able-bodied men to apply it—two for day service and two for night service. An interne at the New York Hospital had devised a so-called bed-bath, a rubber sheet was put under the patient, and the depression was filled with water which was kept cold

with ice. This was superior, he thought, to cold sponging. The cold coil was serviceable, but not equal to the tub.

It is to be hoped that in the investigation of the merits of the Brand method by our American physicians, the patient as an individual entity will not be forgotten. And it is also reasonable to hope that, if cold and humid cold is positively shown to be the most desirable agent at command to diminish the trying symptoms and the mortality of typhoid fever, American ingenuity may devise some less disturbing, cumbersome and barbarous mode of application than frequent "tubbing."

MEDICAL NOTES.

SURGEON-GENERAL OF THE NAVY.—The President has appointed John Mills Browne, to be Surgeon-General and Chief of the Bureau of Medicine and Surgery in the navy, with the rank of commodore.

THE POPULATION OF NEW YORK STATE.—According to the recent State census, the population of New York State is 6,479,730. The Federal census of 1890 gave the population at 5,997,853. This increase comes principally from the cities.

NEW CHAIRS AND PROFESSORS AT THE JEFFERSON MEDICAL COLLEGE.—The Board of Trustees of the Jefferson Medical College, at their meeting, April 7, 1892, instituted a Chair of Clinical Gynecology, with a seat in the Faculty, and elected to the new Chair Dr. E. E. Montgomery, who has been for a number of years Professor of Gynecology in the Medico-Chirurgical College. They also established the following Clinical Professorships, electing Dr. F. X. Dercum, Professor of Nervous Diseases; Dr. E. E. Graham, Professor of Children's Diseases; Dr. H. Augustus Wilson, Professor of Orthopedic Surgery; Dr. H. W. Stelwagon, Professor of Dermatology, and Dr. W. M. L. Coplin, Adjunct Professor of Hygiene.

VICTOR HORSELY ON EPILEPTIC DISTURBANCE.—Victor Horsley reaches the following conclusions in summing up a recent address on the origin and seat of epileptic disturbance: "Whatever be the point which the epileptogenous agency first attacks, we must conclude that the principal seat of the disturbance of a general or idiopathic fit must be the cerebral hemispheres, and especially their cortical mantle. Further, that the condition of the cortex during the attack is one of congestion, and not anæmia; and finally that in all probability this portion of the encephalon is actually the place of origin of the disturbance."

CAUTION IN DISPENSING POISONS.—The value to a druggist of extreme care in dispensing poisonous substances was forcibly brought out in the recent Harris trial in New York. The apothecary was able to show that the assistant who prepared the medicine took from the closet morphine contained in a black bottle, labelled poison; that he weighed out the directed

¹ See Therapeutic Notes, p. 378.

quantity of the drug, and that this operation was witnessed by another assistant. The second assistant testified that he had seen the proper weight in one pan of the scale and just enough morphine in the other to balance it, and that he then noted his observation in a book kept for the purpose.

VIRGINIA MEDICAL LAW.—The Supreme Court of Virginia has decided that the medical law of the State is unconstitutional. The case before them at which this decision was given was that of a largely advertised doctor from Boston against whom complaint had been brought by the State Medical Board, alleging that he had no right to practice under the laws of the State.

THE TEETH OF SCHOOL-CHILDREN.—Last year the British Dental Association undertook the examination of a large number of school-children to determine the condition of their teeth. As a result a record was obtained of about twenty thousand teeth. They found in this number that about eighteen hundred temporary teeth required attention, while of the total number of children examined, there were only fifteen per cent. whose teeth were sound and called for no interference on the part of a dentist. A very large number of permanent teeth required filling. The authors of the report draw attention to the fact that by neglect of the teeth at the age at which children attend school, a large amount of unnecessary trouble and suffering arises in later years. A large amount of good would be done if the teeth of school-children could be systematically cared for by competent dentists.

CHANGES IN THE REGULATIONS OF THE ARMY MEDICAL CORPS.—By a recent law no medical officer in the army can be promoted to the rank of captain until he has passed an examination for promotion. Heretofore the medical officers of the army have been promoted to the rank referred to at the end of five years' service without an examination, while their less favored brethren of the navy and of the marine-hospital service have had to prepare at the end of three and four years' service, respectively, for an examination preliminary to promotion that was quite as rigorous as that given for admission into the corps. The Senate has recently passed a bill giving to officers of the medical corps holding the rank of colonel the grade of assistant surgeon-generals, and to those holding the rank of lieutenant-colonel the grade of deputy surgeon-generals. These are new titles in our army and are similar to those of the British army medical corps.

PHARMACOPEIAS.—At the recent meeting of the Naturforscher Society, Dr. Thoms mentioned some of the results of a comparison of the various pharmacopeias, made by Dr. B. Hirsch and himself, with a view to drawing up propositions for securing uniformity of composition and characters in medicinal preparations in general use. The number of names of drugs, chemicals and galenical preparations contained in all the pharmacopeias at present legally authorized was stated to be 3,762. Of these, 2,069 occur in only one

pharmacopeia, and 618 in two, whilst no more than 154, or about four per cent., are included in all. But if the calculation be limited to the six pharmacopeias issued recently, those for Austria, Germany, Hungary, Japan, Netherlands and Russia, the approximation to uniformity appears to be greater, for out of the 1,162 articles made official in these works, 224, or 19.28 per cent., are included in all of them.

NEW ENGLAND.

MORTALITY IN BOSTON.—The number of deaths reported last week was 231, a death-rate of 26.1. The deaths from consumption were 34, pneumonia 34, persons over sixty years of age 42.

A BICHLORIDE-OF-GOLD HOSPITAL.—The Massachusetts House at Lexington has been leased, and is to be used as an establishment for the "Keeley Cure for Drunkenness." This house was the one erected in Philadelphia by the State of Massachusetts at the time of the Centennial Exhibition, and in 1878 was purchased and removed to Lexington, Mass., where for some years it was used as a hotel.

BOSTON CITY HOSPITAL.—Rough drafts are being made by the city architect for enlargements of the City Hospital. The additions contemplate an entirely new group of buildings, some of one story and none over two stories in height. These buildings are to include an autopsy house, boiler house, a new morgue, and a new ward for contagious diseases—scarlet fever and diphtheria. The plans are still incomplete, subject to more or less essential modification. The new buildings will occupy the lot recently added by the closing of a portion of Springfield Street, throwing it into the hospital site, and the land on the opposite side of Springfield Street. The wards will be directly in the rear of the Nurses' Hall.

THE BABY-FARM BILL.—The bill recently reported to the Massachusetts Legislature to regulate baby-farming is recommended by many charitable societies. The bill changes the licensing power from local Boards of Health to the State Board of Lunacy and Charity, and is not opposed by the local boards. The State Board is now charged with investigating parentage of foundlings and deserted infants, and many of these children come from baby-farms. Recent developments prove the necessity of inspecting places where illegitimate infants are boarded. The bill is also designed to prevent the buying and selling of infants, and the irresponsible and reckless handling of them from one person to another for mere money gain or reward. It is not intended that any responsible person cannot help another to the adoption of an infant. The bill also permits public authorities and incorporated charitable institutions to assist in procuring adoption for such compensation toward the support of an infant as the parent may be able to pay. One important section is that proving the identity of an infant and establishing his legal rights under law; another section protects and gives temporary aid to persons in distress and unable to provide for themselves.

NEW YORK.

THE ORTHOPEDIC HOSPITAL.—At a recent mid-lent fête, lasting two days, which was given at Sherry's for the benefit of the New York Orthopedic Hospital and Dispensary, the handsome sum of \$3,200 was realized.

CRIMINAL CHARITY.—What may well be called a case of criminal charity is reported from Hackettstown, N. J. Five children in a single poor family were taken with malignant scarlet fever; of whom three died, and the other two are hardly expected to recover. In investigating the cause of the disease it was found that the family had been presented with a bundle of clothing that had belonged to a child who had died of scarlatina.

DEATHS FOR THE WEEK.—The number of deaths reported during the week ending April 2d was 874, which, while two in excess of the mortality of the preceding, was fifty-five below the average of the corresponding week in the past five years. There were no deaths from either small-pox or typhus fever; but since then one of the female nurses employed at the hospital on North Brother Island, died of the latter disease.

TYPHUS FEVER.—The three new cases of typhus fever mentioned in the JOURNAL of April 7th, were all discovered on April 4th. One was a female patient at Mount Sinai Hospital, and the other two were male inmates of institutions on Blackwells Island, one of the workhouse, and the other of the almshouse. The Mount Sinai Hospital patient, who had come from a down-town tenement house on the east side of the city, had evidently contracted the disease from some of the Russian immigrants. One of the Blackwells Island cases was traced to Bellevue Hospital, where the man had come in contact with typhus patients; but in the other one it is not known in what manner the infection was caught. In the institutions on the island the most vigorous measures were at once taken to prevent a spread of the disease, including the detention beyond their terms of sentence of a number of prisoners at the workhouse. On April 6th, a fourth case of typhus was discovered, the patient in this instance being an immigrant who had been in the country four months, but who is known to have been in communication with the infected Russians; and on the following day a fifth case was reported from Bellevue Hospital. This patient is a woman thirty years of age, and it is not known in what way she contracted the disease. According to the last reports from North Brother Island, the number of typhus patients under treatment, including these five new cases, was twenty-three.

SMALL-POX.—A number of cases of small-pox have been discovered during the past ten days. Four of these were reported on April 5th, and no less than eight on April 7th, in different parts of the city. It was ascertained that two of the patients removed to North Brother Island on April 5th, both young

women, had been visitors at a certain low resort on Bleeker Street, and an investigation of the place, which is almost within a stone's throw of the Health Department buildings, revealed the unpleasant fact that the mistress of the house, a woman sixty-six years of age, had been ill with small-pox for nearly three weeks. During all this time the house was kept open, and men and women came and went at all hours of the day and night. The woman, who was then convalescent, professed to be ignorant of the name of the physician who had attended her and whose criminal neglect to report the case had imperiled so many lives.

Miscellany.

PUBLIC INCUBATORS.

A NUMBER of the towns in France have been studying measures to prevent the steady decrease in population in the country, and have adopted one notion that may have its application, if extended to other places.¹ It is to prevent the death of the children born before term, by establishing artificial maternities, where the use of the hatching-machine, or "couveuse," could be given to the public at a small rate or for nothing, depending on the case. Some of the cities, like Marseilles, have had a meeting of the city councils, and have passed laws regulating such establishments, and have voted certain sums towards their maintenance, and charitable persons have been asked to contribute towards them, not only as a charity, but also as a patriotic saving of soldiers to the country. An automatic *couveuse* is used, based on Dr. Auvard's model, which has been improved. Each room of the place used may contain a dozen of the hatching-machines, and one or two attendants can attend to the children placed in them. It is hoped in this way to save many infants born before term, belonging to poor people who either could not, or would not, provide such treatment. It is also thought that, raised in this way, away from the hospitals, such children will have a better chance than when put into such apparatus in the obstetric wards of the hospitals, as at present.

ASPIRATION, FROM THE PATIENT'S STAND-POINT.

DR. WALTER BENSEL describes, in the *New York Medical Journal*, his own sensations as follows: "Shortly after the blizzard of a few years ago I contracted a pleurisy with effusion, from exposure during the storm. The effusion became so large and caused such considerable dyspnoe, dysphagia, and displacement of the heart that it was deemed advisable to aspirate and withdraw some of the fluid. The first needle that was introduced was a small hypodermic-syringe needle, simply for diagnostic purposes. The only thing that I observed at this time was that the pain was much more considerable than I had supposed it would be. Soon afterward another larger-sized needle was introduced to remove the fluid, and then I noticed that there were two distinct sensations of pain, equal in

¹ Archives of Pediatrics, March.

intensity, but different in character, one as the point of the needle passed through the skin, and the other just before the fluid was reached. The second was precisely the same as the "stitch in the side" felt with a dry pleurisy. A re-accumulation of serum occurring in a few days, a needle was again introduced. Only a small amount of fluid was removed before the lumen became obstructed in some way and the needle was withdrawn and re-introduced in another situation. A few minutes before each of these two aspirations, a four per cent. solution of cocaine was injected hypodermically, so that no pain was felt as the needle passed through the skin. The same degree of pain occurred as before, however, when the needle passed through the pleura. These facts would seem to indicate that the pleura possesses nearly, if not quite, as great sensibility as the skin itself.¹²

LISTER ON ANTISEPSIS.

In his contribution to the *Virchow Festschrift* Lister reviews the history of antiseptic surgery, and gives his opinions of antisepsis as now practised, from which the following is abstracted:

The attempt to exclude microbes entirely from wounds was followed by results which more than fulfilled the highest hopes entertained of it. Yet the advance of knowledge has shown that to carry out such an idea in its entirety is on the one hand impossible, and on the other hand unnecessary. It has been ascertained that many common bacteric forms produce spores which resist for a long time the germicidal action of all known agents which could be used in operations. Hence to exclude living microbes entirely from wounds is an impossibility.

It is, on the other hand, happily unnecessary. In the first place, it appears that none of the bacteria which can cause mischief in wounds are of the spore-bearing kinds (exceptional occurrence of anthrax from infected catgut noted), while the sporeless bacteria have been shown by the most careful recent investigations to be deprived of life within a minute by a 1 to 20 solution of carbolic acid, the agent which we have always trusted for the purification of sponges and instruments, the hands of the operator, and the integument of the patient at the seat of operation.

These are the points of greatest importance to attend to during the performance of an operation, the once dreaded atmospheric dust being, as it would seem, a matter that may be disregarded. . . . The effects of micro-organisms upon the living body are greatly influenced by the dose — that is to say, by the numbers in which they are present at the seat of introduction. This seems to provide a clue to understanding how bacteria, in the attenuated and subdivided form in which they are present in the atmosphere, may be effectually disposed of by the natural antiseptic action of the blood and tissues.

The glowing accounts published by Koch two years ago of the antiseptic properties of corrosive sublimate led us to adopt solutions of that substance in place of the 1 to 40 carbolic lotion for washing and irrigating our wounds. But it turns out that the effects of the bichloride, supposed to be due to germicidal action, were in reality caused by the inhibitory power which that agent possesses even when present in extremely minute proportions. We cannot suppose that corro-

sive sublimate can have acted with germicidal effect upon the *staphylococcus pyogenes aureus*. My practice has been to abstain from irrigation during the operation, and at its conclusion to wash the wound with 1 to 500 solution, and irrigate during the application of the sutures with a 1 to 4,000 lotion.

It would be a mistake to suppose that no good can ever be done by corrosive sublimate used in the manner which I have described. Resisting as the *staphylococci* have shown themselves to that agent, there are other microbes very mischievous to wounds — such as the *streptococcus pyogenes*, the *streptococcus of erysipelas*, and the sporeless bacillus *pyocyanus*, which are destroyed by very much weaker solutions.

If we think it prudent to wash our wounds before stitching them, it will be wise for us, in the present state of our knowledge, to revert to the 1 to 40 solution of carbolic acid. This agent has been shown to be far more uniform in its action upon micrococci than corrosive sublimate.

When first I witnessed the entire cessation of suppuration as a result of relieving abscesses of their contents, and at the same time preventing the access of organisms from without, I inferred that microbes could have nothing to do with the production of the pus. This was disproved with regard to acute abscesses by Ogston, and with regard to chronic ones by Koch's discovery of the tubercle bacillus. I conceive that the acrid products of putrefaction act injuriously upon the pyogenic membrane, and prevent destruction of the micrococci by the natural antisepsis which is always disposed to operate, but, so long as the abscess is unopened, is hindered by the disturbing influence of tension caused by the rapidly accumulating pus.

THERAPEUTIC NOTES.

EXODYNE AND QUICKINE. — According to the *Pharmaceutische Zeitung*,¹ *Exodyne*, an American antipyretic, an analysis of which was made by Dr. F. Goldmann, contains approximately ninety per cent. acetanilide, five per cent. sodium salicylate and five per cent. sodium bicarbonate; alkaloids could not be detected in this mixture. *Quickine*, an American antiseptic is said to contain one part carbolic acid and 0.02 parts mercuric chloride in 1,000 parts of a mixture of alcohol and water.

TIFFOID FEVER. — Among the many methods of treating this disease, recently recommended, is that by Dr. Anderson, of Edinburgh, which consists in administering five drops of the solution of the perchloride of iron in a little water with glycerine or syrup and a few drops of the tincture of ginger, every hour, day and night.² If the patient has nausea this is relieved by four-grain doses of subnitrate of bismuth, given before each dose of the perchloride of iron.

Dr. Werner has published a *résumé* of 130 cases of typhoid fever treated by a one per cent. solution of chloroform with the greatest success.³ The patients take a tablespoonful of the solution every hour, night and day, during the acute period of the malady. When the symptoms abate the dose is diminished, but the treatment is not abandoned for several days after the complete cessation of the fever.

³ Medical Press.

CRYSTALLIZED ARTIFICIAL CARLSBAD SALT.—According to the German Unofficial Formulary,¹ this may be made as follows:

R. Sodium sulphate (cryst.)	5 parts.
Sodium carbonate (cryst.)	2 parts.
Sodium chloride	1 part.
Hot water	12 parts. M.

Dissolve the salts in the hot water, filter the solution, and evaporate it until a film begins to form on the surface, then set it aside to crystallize. Separate the crystals from the mother liquid and transfer them (without washing them with water) to bottles. The mother liquid is to be rejected.

The resulting crystals are colorless, with a tendency to effloresce, and are soluble in 2.5 parts of water.

FAT SOAP, OR MOLLIN.²

B. Solution of potassa (18.75 per cent.)	40 parts.
Lard	40 parts.
Alcohol	4 parts.
Glycerin	15 parts. M.

Heat the solution of potassa, add the lard, and stir well during half an hour; then add the alcohol, maintaining the temperature, during twelve hours, at 50° to 60° C., and lastly add the glycerine.

DIURETIN IN CHILDREN.³—According to Demme this drug can be given to children between two and five years of age in doses of 0.50 grammie daily, and in doses of 1.50 grammes to those between six and ten. In infants under one year it is liable to cause gastrointestinal irritation. It has proved of service in the dropsy of scarlatinal nephritis as well as in that due to micturial disease, after digitalis had proved ineffectual. Its action is not cumulative, but in one case of amyloid degeneration of the liver, kidneys, and spleen its use caused an erythematous rash, accompanied with profuse diarrhoea.

Correspondence.

A NEW USE FOR AN OLD REMEDY.

CAMBRIDGE, April 7, 1892.

MR. EDITOR:—After reading an article in the *Lancet* upon a new method of intestinal anastomosis, in which Woeder's solution—compound tincture of benzoin, containing a small quantity of iodoform, was employed for sealing the line of incision, it occurred to me that this would be an excellent substance for protecting the wound in perineal operations. The success of this operation, especially when buried animal sutures have been employed, depends not only upon the aseptic precautions during the operation, but also upon the maintenance of the aseptic condition of the wound after the operation. The latter is the more difficult part of the procedure, since the urine is liable to get into the wound and do harm, and the wound may also be contaminated by discharges from the rectum. To protect it from this danger, a seal of absorbent cotton and colodion has been employed, but this will not adhere to a mucous surface and therefore is imperfect.

The compound tincture of benzoin answers this function very well. In recent work on the perineum, I have applied three coats at the time of operating, and an additional coat every time I wished to draw the urine. I have not tested it as yet in primary restoration of these parts, but think it may be useful. Applied in this manner, it protects very satisfactorily the scratch-like remains of the wound that is left after its closure with buried sutures.

Yours truly, ALBERT H. TUTTLE, M.D.

Deaths reported 3,026: under five years of age 1,080; principal infectious diseases small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers 388, acute lung diseases 357, consumption 380, diphtheria and croup 164, scarlet fever 81, diarrhoeal diseases 46, typhoid fever 28, measles 18, erysipelas 15, whooping-cough 14, cerebro-spinal meningitis 11, diphtheria 10, small-pox 2, cerebral fever 2. Principal typhoid fever New York 7, Philadelphia 6, Brooklyn and Cleveland 3 each, St. Louis, Boston, Cincinnati and Washington 2 each, Pittsburgh and Cambridge 1 each. From measles New York 12, Cleveland 3, Brooklyn 2, Philadelphia 1. From erysipelas New York 5, Brooklyn 4, St. Louis, Milwaukee and Washington 1 each. From whooping-cough Philadelphia 3, New York, Cincinnati and Pittsburgh 2 each, Brooklyn, Boston and Washington 1 each. From cerebro-spinal meningitis New

York 6, Washington 2, Philadelphia, Boston and Quincy 1 each. From malarial fever New York 5, Brooklyn 3, Pittsburgh 2.

In the thirty-three greater towns of England and Wales with an estimated population of 10,185,736, for the week ending March 19th, the death-rate was 24.8. Deaths reported 4,818: acute diseases of the respiratory organs 1,010; whooping-cough 109; diphtheria 14; diphtheria and croup 51; diarrhoeal diseases 36; fever 24; scarlet fever 22; small-pox (London) 2.

The death-rates ranged from 13.8 in Croydon to 33.4 in Oldham; Birmingham 23.4, Bradford 24.7, Gateshead 21.8, Hull 21.1, Leicester 21.8, Liverpool 33.1, London 24.3, Manchester 29.4, Newcastle-on-Tyne 17.4, Nottingham 20.8, Portsmouth 21.3, Sheffield 24.8, Sunderland 25.9, Swansea 2.1.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 2, 1892, TO APRIL 9, 1892.

MAJOR ALBERT HARTUFF, surgeon, U. S. A., granted leave of absence for six months, to take effect on or about July 10, 1892, with permission to go beyond the sea, and to apply for an extension of two months.

FIRST-LIEUT. ALFRED E. BRADLEY, assistant surgeon, U. S. A., ordered to Columbus Barracks, Ohio, for temporary duty at that station, during the illness of CAPTAIN AUGUSTUS A. DE SOFFRE, assistant surgeon, U. S. A.

FIRST-LIEUT. WILLIAM E. PURVANCE, assistant surgeon, U. S. A. (recently appointed) will proceed from Rossville, Illinois, to Fort Riley, Kansas, and report for duty at that station.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 9, 1892.

J. MILLS, BROWNE, re-appointed Chief of Bureau and surgeon-general, U. S. N.

J. C. BOYD, detailed as assistant to the Bureau of Medicine and Surgery.

M. W. BARNUM, assistant surgeon, ordered to the Naval Hospital, Washington, D. C.

HOWARD SMITH, surgeon, granted leave of absence for six months with permission to leave the United States.

CHAMP CARTER McCULLOUGH, commissioned an assistant surgeon in the navy.

SOCIETY NOTICES.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday, April 20th, at 7.45 o'clock.

Drs. Lena V. Ingraham and Grace Walcott, "Ulcerative Endocarditis with Death of Valve." Autopsy and specimen.

Dr. George B. Shattuck, "Malignant Endocarditis following Typhoid Fever." Autopsy.

Dr. F. C. Shattuck will open the discussion.

Dr. Myles Standish, "Ocular Headaches."

ALBERT N. BLODGETT, M.D., Sec'y, 390 Boylston St.

E. G. CUTLER, M.D., Chairman.

IOWA STATE MEDICAL SOCIETY. — The forty-first annual session of the Iowa State Medical Society will be held at Des Moines, Ia., Wednesday, Thursday and Friday, May 18, 19 and 20, 1892.

MEDICAL ASSOCIATION OF GEORGIA. — The forty-third annual session of the Medical Association of Georgia, will be held in Columbus, Ga., April 20, 21 and 22, 1892. Members of the medical profession are cordially invited to attend.

DAN H. HOWELL, M.D., Secretary, Atlanta, Ga.

RECENT DEATHS.

EDGAR PARKER, M.D., M.M.S.S., died in Bridgewater, April 9th, aged fifty-nine years. He served in the war as assistant surgeon of the Thirteenth Massachusetts regiment and was severely wounded at Gettysburg. He received the degree of M.D. from Harvard in 1861. He practised medicine in Boston until 1867, when he went to sea as surgeon of the steamship Ontario. He subsequently devoted himself to portrait painting and was an active member of the Papyrus and Boston Art Clubs.

Original Articles.

ON THE VALUE OF ELECTRICITY IN MINOR GYNECOLOGY.¹

BY EDWARD REYNOLDS, M.D., BOSTON.

THE current literature of the day is constantly occupied with statements and counter-statements of the value and the worthlessness of electro-therapeutics in gynecology; but, in looking over the statements which are made upon one side and the other, I think it will be found that there is a marked difference between its advocates and opponents, in that all the former speak of its use in definite terms by differing methods of application, and with the use of different currents; while the majority of the latter condemn the use of electricity undefined, usually speaking of it as dangerous and painful. I cannot but believe that this difference of method indicates the reason for the difference of opinion; that is, that those whose experience has been unfavorable are, for the most part, men who have attempted the use of an agent as powerful for good and evil as perhaps any other in general use in medicine, without a sufficient preliminary study of the natural laws which govern its production, and of the natural history of the effects of the different currents upon the human tissues.

Since the different varieties of the electric current produce almost exactly opposite effects upon the tissues, one current stimulating, another soothing, a third encouraging, and yet another controlling hemorrhage, it is almost self-evident that their indiscriminate use must sooner or later be attended by considerable danger and severe pain.

Personally, I do not rank myself among the most enthusiastic advocates of the use of the current for each and every gynecological trouble, but I certainly wish to be regarded as one of those who believe it to be a most valuable agent in a large proportion of cases, holding it as I do to be, upon the whole, more frequently valuable than any one of our other conservative agents. I should feel that if I were obliged to give up some one of the methods which I habitually pursue in office practice, I should more readily abandon the use of the glycerine tampon, tincture of iodine, tamponade of the vagina, or massage of the uterus and its adnexa, than to lay aside my battery.

In this paper, it is my object to describe a simple armamentarium, with which it seems to me that most cases can be treated, in the absence of more elaborate preparations for the use of the current; to state briefly the amount and kind of electrical knowledge which I think essential to success in gynecological therapeutics, together with the technique of the applications; and, finally, to speak briefly of a few of the pathological conditions which are most uniformly benefited in this way, noticing in passing the indications and contraindications for the current in each case, and occasionally giving a brief outline of a specimen case.

The greater the knowledge of electrical physics which the physician possesses, the more sure is he to apply it to the needs of his patients with intelligence and skill, and to contribute to the progress of medical science; but for practical purposes comparatively little will suffice. He who thoroughly understands and can apply Ohm's law, that, the electro-motive force is equal to

the potential divided by the resistance, together with its numerous corollaries, knows all that is absolutely necessary for the comprehension of electro-therapeutics: but in making such a statement, I wish to emphasize the fact that he must possess this law and its corollaries with the utmost thoroughness, with the most complete understanding, and not by a mere mechanical effort of the memory. Such a knowledge can be acquired by any educated man with but a comparatively few hours' study of any of the more ordinary electrical text-books.

When once equipped with this knowledge, the physician must further acquire a clear understanding of the effects of the galvanic and faradic currents upon the human tissues, and must learn the modifications of their action which are produced by the use of one or the other pole as the active electrode, by the form of electrode employed, and by the degree of tension, or potential, of the current.

The situation and character of the organs with which we, as gynecologists, deal, enables us to use much more powerful galvanic currents than are within the reach of other electro-therapeutists. The insensitive condition of the mucous membranes, their separation from the skin of the abdominal wall by but a few inches of tissue, and the large expanse of surface which is there offered for the application of the dispersing electrode, are advantages enjoyed by no other body of specialists.

ARMAMENTARIUM.

If we except the use of electricity for the destruction of fibroid tumors and other new growths, we, however, seldom need to employ a galvanic current of more than from 80 to 120 milliamperes; and for ordinary office use, a battery with a maximum potential of 40 volts is usually sufficient. Any battery which is convenient, and furnishes a tolerably stable current, may be used for the purpose; but it may be remarked that the latter requisite implies necessarily the use of fairly large cells, since the resistances in gynecological work are so low that the portable chloride of silver and other small cells are exhausted with extreme rapidity. I have, myself, used for some years with satisfaction, a twenty-cell bichromate of potash battery, for the generation of the galvanic current.

In order to obtain the full benefit which it is possible to derive from the faradic current, it is necessary to possess a battery which is furnished with two induction coils, one composed of coarse, and the other of fine wire, and which is also possessed of several interruptors of varying rapidity, such as that devised by Dr. Engelmann, of St. Louis. Then, in addition to the batteries, it is necessary that the physician should supply himself with a reliable milliamperé-meter; it is highly desirable that he should possess a rheostat, or current controller; and finally, his outfit should include a set of flexible abdominal electrodes of various sizes, and a number of others for vaginal and intravaginal use.

For the negative, or dispersing pole, upon the abdominal wall, the wire gauze instruments now commonly sold have seemed to me as valuable as any, and more convenient than most. I have them covered upon one side with a thick layer of absorbent cotton and a single thickness of cotton cloth, upon the other with oiled silk. For the active pole, a vaginal electrode of a size which permits the metallic surface to be

¹ Read before the Fall River Medical Society.

thickly covered with clay or absorbent cotton, a set of olive-tipped intra-uterine bougies with insulated stems, an intra-uterine electrode insulated to within two inches of its tip, and shaped like the common applicator, to be wrapped with cotton, and one whose last two inches are of the shape and proportion of the ordinary uterine sound, are all that are strictly necessary; though the possession of a large metallic vaginal electrode, and one for bi-polar intra-uterine use, is occasionally an advantage. The entire outfit may probably be purchased for about one hundred dollars.

The technique of the application is simple. The patient should be placed in the ordinary dorsal position. It is unnecessary to remove or even loosen any of her clothing, unless an unusually powerful current is to be employed, since the smaller sizes of abdominal electrodes which are used with mild and medium currents can easily be slipped under the clothing from between the thighs.

The abdominal electrode, if not already prepared, should be covered with a clean piece of absorbent cotton of from one quarter to half an inch in thickness, when wet. This should be dipped in very hot water, and the superfluous fluid expressed until its moisture is just such that the water will not drip from it and wet the patient's clothing. It should be carefully arranged upon the electrode in such a way that the edges and angles are fully protected, placed upon the abdomen while still warm, and allowed to remain there during the few minutes that will be occupied by preparing and testing the battery; the object of this preliminary placing of the abdominal electrode being to permit the dried epidermis to become thoroughly moistened, thus greatly lessening its resistance. The battery and milliamperemeter should then be connected, and the connections tested by passing a weak current through the resistance of the rheostat, in order to see that everything is in working order. The vagina should be exposed by a speculum, and disinfected with the utmost care. If an intra-uterine electrode is to be used, it should be introduced with the utmost gentleness, any abrasion of the mucous membrane being certain to be followed by local cauterization; and should be allowed to remain in position, unconnected with the battery, until the sensations due to its passage have been forgotten.

The connection with the electrode should then be made while the battery is shut off from the circuit. The current should be turned on so gradually that the patient receives no shock, that being a phenomenon which is only experienced from an abrupt change in the electro-motive force. When the patient first begins to complain of uncomfortable sensations, the current should be checked, maintained at that height for from two to five minutes, and as gradually decreased; great care being taken that the connections are not broken until the battery has been wholly shut off from the circuit.

In administering the galvanic current, its strength may be increased by either one of two methods; the choice depending upon the variety of current which is desired. When the current of low tension is used, its increase is secured by the gradual addition of new cells to the circuit, by means of the cell collector. When the case requires a current of high tension, the whole resistance of the rheostat is at first included in the circuit. The force of the battery is then gradually turned on by the cell collector, until the desired effect

has been secured; or until its whole electro-motive force is in use. In the latter case, the current is again decreased by gradual diminution of the resistance of the rheostat.

ACTION OF THE DIFFERENT CURRENTS.

Before proceeding to the discussion of the various conditions in which electricity is of use in gynaecology, it is necessary to define briefly the effect of the different currents, and to speak of the contra-indications to their use.

The Galvanic Current.—The galvanic current of high tension is that which is produced by a large number of cells and then reduced to the amount desired by the interposition of a high resistance. The galvanic current of low tension, or of quantity, is that produced by a small number of cells acting through a low resistance. The first excels in power of cauterization, the second in electrolytic action. Cauterization is most marked when a metallic electrode is used, electrolysis when it is moist and non-metallic.

When the negative current of low tension is used with a non-metallic electrode, its action is almost wholly limited to intra-polar electrolysis; that is, the stimulation of retrograde metamorphosis and the partial reduction of the interposing tissues into the ordinary products of such metamorphosis. The lowly organized tissues, such as the pelvic exudates, are much more actively affected by this process than the more highly developed, normal tissues. The effect upon the mucous membrane which is in contact with the electrode, is in this application reduced to its minimum.

When the negative current of high tension is used with a metallic electrode, much less electrolysis of the intra-polar tissues is to be expected; but the tissues in contact with the electrode are likely to be somewhat extensively cauterized. The use of the negative pole as the active pole, in general, tends to the increase of hemorrhage, and is perhaps more likely to increase than decrease pelvic pain, at least for the few days which immediately succeed its use. It may often be advantageously combined with the sedative action of the faradic current of high tension.

The positive current of low tension with the non-metallic electrode is somewhat sedative in its effect and may be used for electrolysis; but it is mainly useful for the decrease of any haemorrhagic tendency, since it has no other advantage over the corresponding negative current and its use necessitates the application of the more painful negative pole to the sensitive abdominal wall.

The positive current of high tension with a metallic electrode is a highly effective chemical cauter which is attended by but little pain, and tends to decrease hemorrhage. Its advantages over other forms of cauterization are due to the fact that while when properly used its effect is limited to the mucous membrane, it tends from simple laws of electrical conduction to extend itself to the whole of the mucous surface, even including the recesses of the crypts, an advantage which can be claimed for no other caustic.

The positive current as a whole tends to decrease hemorrhage and relieve pain.

The Faradic Current.—The faradic current of high tension is that produced by an induction coil made up of many turns of fine wire, while the faradic current of low tension is produced by a coil which

contains but a few turns of coarse wire. The effects of both varieties of current are much modified by the number of interruptions per minute which is employed.

The faradic current of high tension with many interruptions to the minute, is perhaps more potent in alleviating pelvic pain than any other therapeutic agent which we possess. It has but little other effect. The faradic current of tension with few interruptions produces less marked relief of pain. It has a decided tendency to render the tissues anæmic, and is therefore often of value.

The faradic current of quantity, or low tension, is a sharp stimulant, and promotes contraction of both striped and unstriped muscular fibres, and thus relieves congestion and engorgement by hastening the current in the veins and lymphatics of the tissues through which it passes. Its effect is intensified by any reduction of the number of interruptions to the minute.

CONTRA-INDICATIONS TO ELECTRICITY.

Any acute inflammatory condition in the pelvis contra-indicates the use of electricity and must be most carefully excluded before the current is applied. The faradic current of tension has been recommended for use in acute pelvic inflammations. I have not myself as yet had sufficient courage to undertake its application, but have preferred to trust to slower, and, it seems to me, less dangerous methods; and indeed, am even accustomed to restrict myself to the less active of subacute cases.

The presence of pus in the pelvis, and of tubes whose uterine ends are occluded, is a contra-indication for any use of electricity, except electro-puncture, which I have never attempted and can say nothing about; believing as I do that where drainage is necessary, the use of the knife is the preferable procedure.

When much tenderness is present, the early applications should be restricted to the faradic current of tension. As this grows less, gentle galvanic currents may be resorted to, preferably in combination with it. The faradic current of low tension should never be used in the presence of inflamed tissues.

INDICATIONS.

It can be readily seen that the use of so many and such different agents as the various electric currents, either alone or in combination, opens up a field of such complexity that its complete discussion might well occupy a volume; and it seems to me that the only method by which discussion can be profitably elicited by a single brief paper, is the description of the methods employed in a few given affections, and a brief report of typical cases.

CONGESTION OF THE PELVIC ORGANS AND STENOSIS OF THE INTERNAL OS.

CASE I. Mrs. X., thirty years old, came to my office with the following history:

Her menstruation had always been irregular. She had been married six years, and had never been pregnant. Had always been liable to dysmenorrhœa, which had, however, increased greatly since marriage, and of late was becoming rapidly worse. Connection was frequent, but not improperly so. Physical examination demonstrated the presence of moderately well-marked anteflexion of the cervix, and intense congestion of all the pelvic organs. She had not seen her catamenia for nearly three months, and was complaining, as was usual at such times, of heat, discomfort,

and bearing-down sensations, referred to the pelvis. There was no pelvic tenderness. She was given the negative galvanic current of low tension, with a non-metallic intra-uterine electrode, for ten minutes, and was directed to use four quarts of the hottest water bearable, under a hydrostatic force of three feet, twice daily.

At the end of two weeks, she returned, and reported that within three days she had menstruated more freely than for some years, and with but little pain. The same application was made and she was directed to continue the use of hot water; to insert a glycerine tampon after each injection, and return before the next catamenial period. The congestion of the vagina and cervix was greatly decreased. Feeling much better, she neglected to report until after the next period; but as this was less free and much more painful, in spite of the persistent use of hot water and glycerine, she returned for another application of the current. Her next period was preceded by a fourth application of the same character, and was free and painless. She then left town for the summer. On her return in the autumn, she reported that she had continued well, and had now no complaint to make, except of her sterility, which appeared to me to be due to a stenosis of the internal os, caused by the sharp bend in the canal. The posterior cul-de-sac was deep, the external os was not directed forward to any unusual degree, and I believed that if the canal were freely patent, conception would follow, and the permanency of the cure would be assured.

In this belief, I applied the negative galvanic current of 20 to 25 millampères through an intra-uterine sound electrode (metallic) for five minutes; and this application was repeated four times; the first three at intervals of from five to seven days; the last after an interval of three weeks, due to her failure to report sooner.

This application was made October 31, 1891. She has not menstruated since, and from repeated vaginal examinations I have now every reason to believe that she is about three months' pregnant.

This case illustrates both the action of the faradic current of low tension in stimulating the functions of the uterus and the activity of the pelvic circulation, and also the electrolytic action of the negative galvanic current; it being plainly evident that each succeeding passage of the sound through the internal os was easier and less painful than that which had preceded it. The metallic electrode was used in accordance with my belief that the stenosis was partly due to a congestion and hypertrophy of the mucous membrane which would be best relieved by cauterization.

CHRONIC SUB-INVERSION OF THE UTERUS AND ITS LIGAMENTS.

CASE II. Mrs. B., thirty-seven years old, married sixteen years, the mother of six children, complains of a dragging sensation, great nervousness, unexplained crying spells, inability to leave the house alone. Physical examination resulted as follows: Moderate laceration of the pelvic floor, deep bi-lateral laceration of the cervix, its lips enlarged and everted; uterus large, soft, and low in the pelvis, freely movable; both ovaries large, heavy, and somewhat low; tubes normal. No pelvic tenderness. The faradic current of low tension was applied, at first through a vaginal, later through an intra-uterine non-metallic electrode, in sit-

tings of six to ten minutes, repeated every week. The uterus was supported by a suitable pessary. The patient was recommended an operation for the repair of the cervix and perineum, but told that better results would follow if she submitted to some weeks or months of preparatory treatment by electricity.

At the end of four months, the uterine body was of normal size, the cervix much smaller and less everted; the ovaries were as a rule in normal position, though subject to prolapse when the patient was fatigued; the vagina had decreased in size so greatly that the pessary which she then wore was of about two-thirds the width of that which was at first employed. She was able to go to New York with her husband, and spend the day in shopping, alone, without discomfort, an event of which she spoke to me as, "Something which I never expected to do again." During the summer months which succeeded, she came to town each month for the adjustment of the pessary; but owing to the fatigues of the journey, was not subjected to any electrical treatment. In the autumn, she considered herself well, and when told that nothing but the most constant care could insure her remaining in that condition, so long as the lacerations were not repaired, she decided that in view of her improved condition, she would prefer to remain under observation and defer the operation.

She has remained in good health for more than a year, and no longer requires a pessary, but is again considering the question of operation, which is now advised chiefly on account of the liability of a relapse from want of support.

This case is an illustration of what I consider one of the chief advantages of the faradic current; that of promoting the return of relaxed sub-involved organs to their normal size. It is of great value as a preparation for an operation, whenever the condition is due to a lack of support; and in assisting in enabling the patient to dispense with the pessary in cases of retroversion from laxity of the ligaments, where the supports are unimpaired.

PELVIC EFFUSIONS AND DISPLACEMENTS DUE TO CONTRACTED LIGAMENTS.

CASE III. Miss S., single, twenty-six, tailoress, complains of backache and pain in the right groin, running down into the thigh, of about two years' duration. Physical examination shows the uterus to be retroverted and adherent; the right broad ligament shortened, much thickened and very sensitive, especially on motion of the cervix toward the left side. Directed to use glycerine tampons.

At the end of three weeks, the pelvic tenderness was decidedly less; the uterus somewhat more movable. The negative galvanic current was applied, for five minutes, at each visit, through a non-metallic vaginal electrode, with a strength of 20 to 25 millampères, increased after a few sittings to between 40 and 45, and was followed at each visit by systematic tamponades of the vagina through a Sim's speculum. At the end of eight weeks the mobility of the uterus had greatly increased; it was in nearly normal position, and the patient was able to tolerate a retroversion pessary, which, with occasional intermissions on account of exacerbations of pelvic tenderness, she has now worn for two years.

This case is a type of those of its class which I have subjected to electrical treatment. If I am unable to

report the brilliant successes in the rapid dispersion of large pelvic exudates which some other observers have seen, it is because I have hesitated to apply the current to acute affections, in the belief that success could be as surely and more safely, although certainly more slowly, effected by other means; and also because in more chronic cases I have never as yet trusted to the current alone, but have thought it best to supplement its effects by the other and more familiar methods which are at our disposal.

CHRONIC PELVIC PERITONITIS, PARA- AND PERIMETRITIS, SALPINGITIS AND OVARIITIS.

CASE IV. Mrs. M., thirty-eight, mother of five children, two years ago complained of slight pain in the right side soon after the birth of the last child. Was recommended by her physician, without vaginal examination, to apply hot vaginal douches. She used one, and was attacked by severe burning pain in the right groin, for which morphia was administered for several days, and which in less severe form has never left her since. On examination, universal pelvic tenderness, most marked on right side and over uterine body. Faradic current of high tension, with moist vaginal electrode, about 1,500 interruptions to the minute for five minutes; used glycerine tampons. One week later, stated that though she still felt some pain, it had been distinctly less from the time of the electrical application. The same current was re-applied; patient not seen since; is reported to have continued well.

This case is an extreme example of the favorable effects of the faradic current of high tension in chronic pelvic tenderness, due to a slight inflammation of one or more of the pelvic organs. In my experience, its influence is usually favorable, but as marked an effect as this cannot always be expected.

ENDOMETRITIS.

CASE V. Mrs. F., forty-five, slight backache, especially when tired, moderate but increasing dysmenorrhea since one year after birth of last child; when during an unusually painful catamenial period, she passed a small oblong body, which, on rough inspection appeared to be an ovum of from a week to ten days' advance in gestation. On microscopical examination by an embryologist, it was declared to be a cast of the uterus from a case of pseudo-membranous dysmenorrhea. Application of the positive galvanic current, 65 millampères strength, from the metallic intra-uterine electrode, for about fifteen minutes; use of hot-water douches recommended; patient not seen again for six months, when she stated that since the application of the electricity, menstruation had been but slightly painful, though it was somewhat more scanty than before, and she had considered herself well. Had used the hot water faithfully during all that time, and was recommended to discontinue it. A large amount of froth had oozed from the external os at the time of the application, and it was felt that a thorough cauterization of the uterine cavity had been made. The patient's menstruation was always somewhat scanty, and it was probably an error of judgment to have used the positive, in place of the negative, current. She did not return for treatment until nearly a year later. At that time she considered herself well, but thought that her dysmenorrhea was somewhat worse. After six applications of the negative galvanic current, 50 to 60 millampères of five minutes each,

she menstruated much more freely and with less pain than usual, and said that she felt much more cheerful and in better condition than for some years. A metallic intra-uterine electrode was used, in the belief that the dysmenorrhœa was dependent on the existence of endometritis.

CONSTIPATION.

CASE VI. Mrs. F., sixty-three, pelvic organs senile, complains of pain in back. This was thought to be due to shortened sacro-uterine ligaments and constipation. Vagina packed, and given elixir rhamnus Purshiana Co., N. F., teaspoonful t. i. d. In the course of six weeks, some relief from pain. Packing somewhat inefficient from laxity of the vaginal outlet. Cathartic increased to two teaspoonfuls t. i. d., without satisfactory effect. Given faradic current of low tension, with small sacral and abdominal electrodes, twice weekly. After five applications, was able to obtain a daily motion with one teaspoonful of the cathartic three times daily. Bowels have since continued in fair condition under the continued use of the same prescription.

If it be urged, in discussion of these cases, that they have been selected as favorable instances of the value of the current, I must at once plead guilty to the indictment. All cases do not make as favorable a showing as this. These were successful cases, and selected as an argument in support of the use of electricity, and of the view which I myself personally support warmly, that in properly selected cases it is a therapeutic agent of great efficiency. If in cases which are less fit for its employment it acts less well, and in improper cases does harm, that is no more than must be admitted for every potent therapeutic agent. The use of electricity is an art which must be carefully studied, which requires in its application much care and judgment, and, above all things, an accurate diagnosis of the presence or absence of its contra-indications. I must freely confess that when I first began to use the current, in many of my cases the result was not satisfactory, and I was obliged to discontinue electricity and resort to other means. In one of my early cases, positive harm resulted from an injudicious application of the faradic current of low tension, in the presence of a subacute inflammation; but with increasing experience, the proportion of marked successes has become considerable; the proportion of cases in which I have secured the alleviation of symptoms has become large, while the percentage of unbefited cases steadily decreases: and I find that as time goes on the proportion of cases in which I use it is steadily though slowly increasing. I cannot help believing that in the hands of well-trained practitioners of intelligence, it is likely to be more and more highly rated year by year.

ETHER DRINKING.—Russia has become infected with the vice of ether drinking, and the pernicious habit has spread so rapidly that the Government has judged it necessary to prohibit the free sale of ether and of certain of its compounds, and to schedule it among the poisons the sale of which, even by pharmaceutical chemists, is surrounded with severe restrictions, as was lately done in Ireland at the suggestion of Mr. Ernest Hart. The measure has been very effectual in Ireland, and we hope it may be so in Russia.

CASES OF DYSPEPSIA WITH TREATMENT BASED UPON AN EXAMINATION OF THE GASTRIC JUICE.¹

BY GERTRUDE W. VAN PELT, M.D., BOSTON.

THE hope of a scientific basis for treatment in gastric disorders, and the fascinating possibilities suggested by the chemical analysis of the juices, aroused in the early days of this study, a natural enthusiasm; but, as the looked-for results often failed to follow the administration of the chemicals so clearly indicated, there has perhaps been a decrease in the general interest. Possibly too much was expected of it, for the truth of the text-books' teachings — that the stomach is outside the body — must not be forgotten. In treating it we are but at the threshold of the domain which is to be put in order, and the folly of considering any one symptom here, rather than in its relation to other symptoms and to their underlying causes, is true of dyspepsia, as of any disease. Still, a knowledge of the condition of the stomach is a certainty amid uncertainties. Even though that condition be dependent upon distant or obscure causes, such knowledge affords an aid too valuable to be discarded, and often plays an important rôle in helping to solve the varied and intricate problems which each separate case presents. In support of this belief I would like to present to you the histories of a few cases.

Before passing on to them, however, I will take occasion to show an arrangement for extracting the gastric juice, which I have found to facilitate very much the operation. To the tubes inserted in this glass can be attached by rubber tubings, the stomach-tube and an aspirator, and the glass can be held in place and concealed from the patient by placing it in a partly closed table drawer. Then after the introduction of the tube, if its eye happens to be in the liquid, and the air in the glass has previously been rarefied; the moment the stopcock is turned, a little liquid is forced into the glass. If the liquid does not run, it is due either to the stomach's being empty; to the eye of the tube being occluded, or what is more common, to the tube being pushed in too far or not far enough, so that the eye does not dip in the liquid. Always, before readjusting the tube, or withdrawing it, the air must, of course, be allowed to re-enter, so as to avoid any possible irritation from suction on the mucous membrane.

CASE I. Patient had been nervously tired for four or five years and at times had suffered from dyspepsia. For four months before treatment she had suffered constantly from it. Her symptoms were, heaviness in the epigastrium, occasional acidity and burning, failure of appetite, constipation, much loss of strength, nervous depression, sleeplessness and sudden attacks of dizziness, coincident with a distress in the region of the heart. During these four months, there were a few days when the symptoms were much aggravated, as she could take only milk gruels in small quantities,

¹ Read before the Section for Clinical Medicine, Pathology and Hygiene of the Suffolk District Medical Society, February 17, 1892.

and was unable to leave her bed. The first examination of the gastric contents was made five hours after a test-meal of soup, roast beef, potatoes and bread. The juice contained .17% of lactic acid. HCl was absent. There was much mucus, and much of the meat was undigested. Forty drops of a four per cent. solution of HCl were prescribed, to be taken in a glass of water during the first hour after meals, and the stomach was washed daily. This treatment was continued for three weeks, without any marked change in the symptoms, except that the patient was relieved for a while after each washing, and passed better nights. About this time she complained of a burning sensation, which was relieved by the washing, and which was, she thought, like the burning she had often felt before. Another specimen was taken, and what was surprising, it bore all the characteristics of a specimen taken from a patient suffering from hyperacidity; that is to say, there was an abundance of clear liquid, and a sediment of farinaceous food, which fell at once to the bottom. On examination there was found .45% of HCl, no organic acids, no mucus. The burning sensation before washing was, of course, due to the excess of HCl, as it had previously, no doubt, been due to the presence of organic acids. From symptoms alone, it would have been difficult, if not impossible to have recognized the change. The administration of HCl was stopped, and there was considerable difficulty in quieting the irritation of the gastric glands. The daily washing was continued and alkalized given, but the condition did not improve decidedly until coffee was given up, and only the blandest food eaten. Since this experience, I have begun treatment, in most cases, with smaller doses of HCl, and watched its effect more carefully.

At the end of six weeks, or nine weeks from beginning treatment, the secretion was normal; the appetite was much improved; the patient slept better; the sudden attacks of dizziness had entirely disappeared, and there was no distress in the stomach. The constipation was a more obstinate symptom, and did not disappear until several months later, after there was a gain in general strength. As soon as possible after the digestion became normal, the amount of nourishment was increased gradually, as the patient could bear it. During the year following, she gained fifteen pounds in weight, and very much in general strength. At times, after some unusual exertion, she suffered from dyspepsia, but rest, and a few washings always restored her.

CASE II. Miss K., thirty-one years of age. Had dyspepsia of ten years' standing, for which she had at various times been treated. She was subject to attacks of vomiting, so that, at times, for days together she could retain but little food. After an attack of pneumonia two years previous, her health was worse, and later the dyspepsia grew more serious, as she was often kept awake by it the greater part of the night. She suffered at time of beginning treatment from occasional vomiting of froth, with or without food, but the most distressing symptom was a constant sensation of gas rolling about in the stomach, which sometimes caused palpitation with a feeling of great weakness. There were attacks of gastric pain, which were relieved by mustard plasters; acid eructations; constipation and anorexia. She did not notice that certain kinds of food disagreed. Tongue was flabby and pale, and she was very anaemic.

Physical examination. Stomach extended on left

side to a point half way between umbilicus and pubes, and was not found at all to right of umbilicus; tenderness on pressure over this region; heart sounds normal; apex beat on a line with nipple; pulse 90, and irregular, full and compressible. Urinalysis, normal. Analysis of the gastric juice three hours after a test-meal; total acidity .37%; HCl absent.

As the patient dreaded having her stomach washed, the following treatment was ordered: eight drops of the fluid extract of *Pinus Canadensis*, in a glass of hot water, to be taken half an hour before meals; three drops of the dilute HCl in half a pint of water, to be taken during the first hour after meals. Her bowels were regulated; and she was treated with the constant current, 30 milliamperes, twice a week, one electrode being over the stomach, the other opposite it on the back. At the end of two weeks she was feeling somewhat better, and a second analysis of the gastric juice was made, medicine having been omitted for that day. It was as follows: total acidity .4%, HCl .02%. Artificial digestion complete in 3 hrs. 39 m. With HCl added to the juice to make it .2%, it was complete in 2 hrs. 27 m., and with HCl to .2% and pepsin added, complete in 3 hrs. As the progress did not seem to be sufficiently rapid, the patient was persuaded to have her stomach washed daily; and the HCl, and galvanic current were continued also; in two weeks iron was added to the treatment.

The symptoms of dyspepsia rapidly disappeared, and four weeks later she said her stomach had not felt so well for years. Examination of the juice at that time showed the following condition: Total acidity .3%, all of which was due to HCl; artificial digestion complete in 1½ hrs. The constant current and HCl were stopped; and an analysis three weeks later showed the total acidity to be .1%; all of it due to HCl. She had at this time no symptoms of dyspepsia, if she confined herself to a simple diet, and her appetite was good. She remained free of dyspepsia for four months, until she caught a heavy cold. She is of a delicate constitution, has a marked strumous diathesis, and is subject to severe colds. These always reproduce the same gastric condition, which is, however, relieved by the same measures.

I will say, in regard to the galvanic current, that my employment of it was based upon some experiments made in Germany, which showed that it had the power to increase the secretion of gastric juice. I have since applied it for the same indication, directly to the walls of the stomach, by means of a deglutible electrode, devised by Dr. Max Einhorn, and described in the *Medical Record* of May 9, 1891. I used, on grounds purely theoretical at that time, the positive pole. Later I had this electrode, which I will pass around, made for me by Codman & Shurtleff. It is patterned after Dr. Einhorn's, but differs in being much smaller, in having a stronger and stiffer wire, so that the electrode can be pushed down, which makes it easier of introduction and less disagreeable to the patient; and in being much more securely fastened, so that there is no danger of leaving the electrode within the stomach. The copper-tip unscrews, so that if the wire should show signs of weakening at any point, it can easily be replaced by a new one.

To test the immediate effect of electricity upon the secretions, I have begun a few experiments, which were conducted as follows: The stomach was thoroughly washed, and the water, when clean, analyzed

for HCl. If none was present, 200 cm. of tepid water was given, and allowed to remain in the stomach ten minutes, then withdrawn and analyzed quantitatively. The same procedure, with the deglutible electrode in the stomach ten minutes, using the positive pole and a current of 25 ma. The same was repeated at another time, applying a current of 25 ma. externally. These experiments were so few that I will not report them in detail, but mention simply that the positive pole increased the secretion of HCl, as did also, to a less extent, the external application. In the case which I will report next, however, there was no secretion of HCl after the use of the current, but as she greatly improved under these applications, I inferred that they in some way improved the nervous tone of the stomach, and this is, I am inclined to think, the most important result of this therapeutic measure. Dr. Einhorn has published a most interesting article on this subject in the *Medical Record* of January 30, 1892.

CASE III. March, 1891. Mrs. T., fifty-nine years of age. Had never been very strong, but did not consider herself an invalid until about two years previous. During that time she had been a great sufferer, and had been confined to bed about half the time, with much pain and loss of strength. When she presented herself for treatment, she had almost abandoned hope of relief, and said she found life unendurable. Her chief symptoms were pain, loss of strength and attacks of vomiting. For months she had not been free from a burning pain in the middle of the back, which rendered her very nervous and prevented sleep. She had acid and gaseous eructations, no nausea as a rule, and rarely headache, but great loss of strength and enormous development of adipose tissue. Appetite was good, but as all food caused distress, she ate but little. Constipation and hemorrhoids. Examination showed no enlargement of the liver, but bowels and stomach much distended with gas. Heart sounds normal. Analysis of gastric juice four hours after a test-meal: Total acidity .27%; HCl absent. Liquid abundant and greenish. Gmelin's bile test, negative. Residue contained an enormous quantity of mucus, some starchy food and large particles of meat. Stomach was washed thoroughly after removing the specimen, and for the remainder of that day and the night following, there was great relief from the pain in the back, so that she slept six hours, a thing she had not done for a long time. As indicated by the analysis, HCl was prescribed. In two days her symptoms were aggravated and other specimen was taken. A quart of liquid was easily removed, bearing all the appearance of hypersecretion of HCl. Analysis showed it to contain .25% of acid, all of which was HCl. After this, a daily lavage of the stomach with a weak solution of *Pinus Canadensis* (which she soon learned to do herself) and the faradic current twice a week, constituted the treatment.

Frequent analyses of the gastric contents were made, with no uniformity in the results. The secretion of HCl was once as high as .3%, and often was completely lacking. Artificial digestion was attempted once when .25% of free HCl was present, but it was incomplete in eight and one-half hours, both with and without the addition of pepsin. The only constant condition seemed to be that there was always very much in the stomach, and food was often removed which had been eaten twenty-four hours or more before. The stomach was clearly dilated, though on account of the quantity of fat in the abdominal walls,

physical examination was difficult. After six weeks' time the patient was much improved. She slept well and was relieved entirely of the pain in her back soon after beginning lavage of the stomach. But she was still weak, and seemed as incapable as ever of digesting more than a small amount of the food she ate. It seemed doubtful whether she would ever be materially better, and she was told that relief from pain was all she must expect, and that possibly she might always need to wash her stomach. She possessed great courage and perseverance and said that seemed to her as nothing in consideration of the relief which it afforded.

The apparent irregularity in the secretions, suggested some nervous disturbance, and in the hope of influencing that, she was treated twice a week for two weeks with the constant current (10 ms.) over the pneumogastric nerve. A specimen removed after this contained what had been found once previously, a normal amount of free HCl, and no organic acids, but there was no added improvement after this treatment. The application of the galvanic current directly to the mucous membrane of the stomach was then tried by means of the deglutible electrode. The negative electrode four by six inches in size was applied over the liver or stomach anteriorly. This seemed to act very beneficially. She digested better; was able to eat more; and said she never felt the burning in the stomach, which had been so frequent up to that time. These applications were made twice a week, for six weeks, with a medium strength of 20 ma. During this whole time and four months after, the secretion of HCl was normal, varying from .15% to .2%, and no organic acids were present three hours after eating. On seeing her again two months later, it was found that, although the other conditions continued improved, mucus was still present in quantities, and the muscular tone of the stomach remained defective. For these conditions the stomach was washed three times a week with a solution of silver nitrate, twelve grains to a pint of water; which was immediately preceded and followed by a washing with clear water; and twice a week the faradic current (with the coarse wire of Gaiffe's battery) was used within the stomach. In four weeks' time there was no perceptible mucus and but little food at the washings. Her general health at this time was wonderfully improved. She was obliged to attend closely to hygiene, but was free from pain, could do her own light housework, and was able to walk four miles at times without fatigue.

A satisfactory explanation of this case has not suggested itself to me, and I hope that some one here may be able to throw more light on it than I can. I do not understand why there should have been in the beginning such a difference in the secretions from day to day. The secretion of mucus was unusual in amount, out of proportion to the other symptoms in a case of gastric catarrh, and I have thought that, possibly, owing to this, the muscular atony and consequent dilatation, the food swallowed did not practically come in contact with the walls of the stomach, and that therefore the gastric glands were not stimulated to secretion; while at other times, owing perhaps to a difference in the character of the food, or to some different mechanical condition, the gastric glands were stimulated.

CASE IV. Miss E., aged eighteen years, was a delicate girl, of scrofulous history and somewhat anemic. She complained of distress after eating, which was not great but constant, and her stomach felt raw after

taking a cold. Appetite was poor, bowels regular. As I disliked to propose stomach washing in this case, and as the symptoms seemed to indicate a slight gastric catarrh, HCl was given from time to time during a period of three months. But as there was no constant or decided improvement, a specimen of gastric juice was removed five hours after a test-meal. The total acidity was .33%, free HCl .16%. The solid residue which was small, contained considerable mucus and amyaceous material. Albumen digested in one and one-half hours in the oven.

Owing to a bad cough, which interfered with the use of the stomach-tube, she was ordered to drink half a pint of a weak solution of *Pinus Canadensis*, as hot as possible, one-half an hour before each meal; but four weeks later, there being little improvement, the stomach was washed daily with a weak solution of *Pinus Canadensis*, for six weeks, when she left the city. At first there was much food in the stomach at the washings, but this gradually decreased, so that towards the end, the stomach was generally empty. A specimen taken shortly before her departure contained .18% of HCl, and no organic acids nor mucus. She had distress in the stomach occasionally, but it was much decreased. Six months later she wrote that her stomach was not troubling her.

CASE V is a case of Dr. Morton's, for whom I made one analysis, and who has kindly permitted me to repeat it.

Mrs. R., sixty-eight years of age, was strong when young, but for fifteen or twenty years had suffered from dyspepsia. It began by distress after eating and a weak feeling in the stomach. At one time she had had catarrh of the bowels badly, which had disappeared. She used also to have pyrosis. At time of beginning treatment, suffered only from loss of appetite and weakness. Bowels, though regular, were sometimes much distended with gas. Never pain, but there was often a full feeling after eating a small amount. Weight 98 pounds, once weighed 130 pounds. Pulse 92. Stomach, somewhat dilated. Gastric juice three hours after a test-meal contained .29% of free HCl, and no organic acids. Peptones abundant. Artificial digestion complete in fifty-five minutes. Solid residue contained mucus and bloody mucus. This seems to me to be an instructive case, and illustrates well the difficulty of making a diagnosis from symptoms alone. A treatment by HCl would have been suggested in this case, almost, if not quite as much as in the last one, and yet there was a hypersecretion, whereas in the other, there was a normal amount only after several weeks' use of the drug. Had treatment been instituted to increase this secretion, it is quite possible that gastric ulcer might have resulted. For although the etiology of gastric ulcer is not yet determined, recent study has shown that in the majority of cases, this condition of hypersecretion and irritability exists. As the patient lived at a distance, and only came to the city once for a few days, she could not be closely watched, but under a general treatment tending to quiet the irritation and improve the nutrition. Dr. Morton tells me she has improved.

CASE VI. Mrs. T., forty-eight years of age. She had had for three weeks a constant burning pain in the stomach. Was nervous and frightened about herself. For some time she had had a domestic trouble, which had been a source of great anxiety. Stomach not dilated. Specimen of gastric juice three and one-half

hours after a test-meal: Total acid .1%, all of which was lactic acid. HCl was given and the stomach washed almost every day. After each washing she was relieved from the burning pain for the rest of that day, but the result was not permanent, and the treatment was not persisted in. Later, after a removal of the cause of mental anxiety, the dyspepsia disappeared.

CASE VII. Miss S., aged thirty, was extremely anxious, apprehensive and nervously depressed. She had suffered much from dyspepsia for over two years, and had been steadily growing weaker. Appetite poor. Troubled much with eructations and rolling of gas in the stomach, but suffered no pain, except much headache. She slept poorly, was very thin, having lost a great deal of flesh. She unfortunately was obliged to work hard, and was never free from worry. She had been treated in various ways for a long time without any great improvement. Heart sounds normal. Stomach extended three fingers below umbilicus and was entirely on the left side. Specimen of gastric juice four and one-half hours after a test-meal: Quantity of fluid very abundant, total acidity .46%, HCl absent, peptones present, mucus abundant. The diet was first carefully regulated, HCl was ordered, and the stomach washed daily with a solution of *Pinus Canadensis*. In two weeks there was a normal secretion of HCl and .25% of organic acids. Once a week the stomach was washed with nitrate of silver (gr. xv to a pint of water). In four weeks there was no mucus observed, and these washings were discontinued. The secretion of HCl failed once again and the drug was renewed; also the positive pole of the galvanic current, with a strength of 25 ma. was applied directly to the stomach. After four treatments extending over four weeks, the secretion was normal, and she was feeling better. But as digestion was still very slow, faradism was used four times within the stomach, with the coarse wire of Gaiffe's battery. At the same time, washings with salicylate of soda, and salol internally, were used successively to control the abnormal fermentation.

She has had twelve treatments in all, which have been very irregular, owing to her living at a distance, and she is still under treatment. The secretion of HCl has been normal for a long time, but fermentation from organic acids has not been controlled. The lower border of the stomach is at the umbilicus, and there is so little food at the washings, that it is only washed occasionally. Her appetite is excellent, and she sleeps well. She has no headaches, but is troubled with rolling of gas more or less. Her strength has greatly increased. She is cheerful and able to do much work without fatigue.

The next case is especially interesting to me because I questioned at first whether I had not a disturbance of purely nervous origin to deal with, which could not be cured by treatment directed alone to the stomach. Results, however, seemed to indicate that it was a case in which removal of a peripheral irritation was able to avert a threatened nervous disturbance in a person who had such tendencies.

CASE VIII. Miss P., forty-eight years of age. Father died of apoplexy, and one sister has for years suffered from a severe form of migraine. Patient herself has never been very strong, though generally well and is able to work at the millinery business regularly. She comes for treatment on account of severe attacks

of pain in the stomach, which occur every five to seven days usually, but are occasionally delayed as long as two weeks, never longer. They are preceded by a nervous, restless and apprehensive feeling, which lasts from several hours to a day. She has occasionally, pain in the back of the head, and along the left side, in the arm and leg, and she thinks she is more apt to have that at the time of a gastric attack. In the intervals of these pains in the stomach, she is troubled very much with a distress which is relieved by eructations of gas. She has had this trouble for about ten years, but lately it is worse. She is well nourished, weight, 190 pounds. Bowels regular, but movements never well formed. Sleeps well, except just before one of her attacks. Urine, normal. The stomach tube was passed twice after a test-meal, but the aperture became clogged with large pieces of meat, and the operation was not persisted in. A drop of the juice which remained at the bottom of the tube, did not affect Congo paper, showing that HCl was probably absent and certainly insufficient. She was ordered to take five drops of dilute HCl in a glass of water during the first hour after meals; eight drops of the fluid extract of *Pinus Canadensis* in a glass of hot water one-half hour before meals, and she was recommended to chew her food carefully.

Two weeks later she said her stomach felt stronger. She had had no attacks of pain and had less gas. Analysis of gastric juice: Total acidity .2%, HCl .07%. A very small amount of liquid came through the tube, probably on account of the abundant quantity of mucus. One week later was feeling well; had had no attacks of pain. Total acidity of gastric juice .2%, all of which was free HCl. The stomach was washed with water after the specimen was taken. A week later the patient came for the fourth time, having been under treatment five weeks. She had been overworking a few days and had been very tired. She was annoyed somewhat by gas in the stomach, but otherwise had no trouble. The stomach was washed with nitrate of silver (gr. xv to the pint), preceded and followed by a washing with clear water. She was ordered to continue taking three drops of dilute HCl after meals and drinking hot water before, for two weeks and to see me if she had any further trouble. Four months have passed, and I have not yet seen her.

In three cases, which I will not report in detail, this method of examination has been most useful in excluding a gastric disease, when the symptoms seemed to point to it. One of these cases had been twice in a hospital to be treated for gastritis. All the discomfort and distress was felt in the stomach, but the main trouble was in the liver and to treatment directed to that organ she responded at once. I have treated a few other cases in this way, but as they were somewhat similar to the preceding, I will not take your time to report them.

School Trustee. — "Your class in physiology does not appear to be up to the standard, Miss Birch."

Teacher. — "I've done the best I could with the chart that I found here, Mr. Small."

School Trustee. — "Um—er—what did the charts consist of?"

Teacher. — "Six views of a whiskey stomach."

PROVISION FOR PATIENTS WITH CHRONIC DISEASES IN THE CITY OF BOSTON.¹

BY PHILIP COOMBS KNAPP, A.M., M.D.,

Physician for Diseases of the Nervous System to Out-Patients, Boston City Hospital.

The object of this paper is not to present anything materially new; it is merely to call attention to a long-recognized defect in our institutions for the care of the sick, and to elicit discussion.

Although the provision for the treatment of contagious diseases and disorders that come under the care of the specialist is not all that can be desired, yet it is a fact that our present hospitals can provide reasonable accommodations for patients with acute diseases. Now, if it be incumbent upon us to provide for the proper treatment of such cases, why is it not equally incumbent to provide for patients with chronic disease? It is point of fact the provision is most inadequate. The Massachusetts General and the City Hospitals are crowded with patients with acute diseases; the latter institution refuses incurable cases, and questions closely the reasons for a stay in the hospital beyond two months, although it gives temporary relief and shelter to many chronic cases. The Carney Hospital receives a few such cases; the Home for Incurables has sixty beds, and other smaller homes and institutions provide for perhaps as many more.

There is a large class of patients, of whom we see many in out-patient clinics and free dispensaries, who are victims of chronic incurable disease, phthisis, cancer, Bright's disease, paralysis, chronic surgical disorders, etc. How many such cases there are it is not easy to say, but that there are many requiring hospital care is a fact familiar to all of us and we can seldom find a permanent shelter for them. Of course, many patients with chronic diseases prefer to remain at home with their families and friends, free from the routine of an institution; but many others have no homes or need hospital treatment.

In one class of chronic diseases—those of the mind—the hospital treatment becomes imperative; but the provision which the city makes for its insane is not adequate; out of 1,118 insane belonging in Boston who were in public institutions on January 1, 1891, only 399 were in the city asylums. The rest were boarded at the city's expense at the State asylums. In consequence of the repeated urgings of Dr. Fisher, however, further provision is now making for the city's insane within the city limits.

Setting aside the limited provision which can be made for patients with chronic diseases at the Carney Hospital and small private charitable institutions, the only places to which patients with chronic diseases can be sent is to the city almshouses at Long and Rainsford Islands. At Rainsford Island is the institution for female paupers, with 300 or more inmates.² Here there is a very old hospital with 50 beds, to accommodate acute cases among the inmates, and all the maternity cases. On Long Island is the institution for male paupers with about 300 inmates.³ The sick are cared for in the dormitories, and among them are 75 women, chronic cases, who have never been removed to Rainsford Island for lack of accommodation. January 1, 1891, there were 227 patients re-

¹ Read before the Section for Clinical Medicine, Pathology and Hygiene, of the Suffolk District Medical Society, February 17, 1892.

² Maximum number of females in 1880, 463. Average number of females at both islands, 457.

³ Maximum number of males in 1880, 436. Average number of males at both islands, 308.

maining in the hospital; 763 had been admitted during the year, 135 had died, 5,732 had been treated at sick call.⁴ A new hospital is now building to accommodate 100 patients; the present accommodations are confessedly inadequate and over-crowded.

During the summer these institutions have been made the subject of considerable adverse criticism in the public press. Whether this criticism were just or not, I am unable to say. The results obtained there seem to be admirable, despite the disadvantages under which the physicians work. There are reasons, apart from any question of good or bad administration, which render it undesirable to send patients with chronic disease to them.

The first of these objections is sentimental, and therefore of much greater importance. An industrious man or woman, who becomes incapable of further self-support by reason of disease, can, without loss of self-respect, go to a lunatic hospital or to a city hospital for free treatment, but such a person will go to the almshouse only as a last resort, and the act of going to such an institution is the last drop in the cup of their degradation. The good old Yankee prejudice against the poorhouse still holds, and when it is crushed, you have crushed not only the self-respect of the patient but that of the family; and from that to absolute pauperism is but a short step. Anything that tends to pauperize a family must be deprecated, and, although theoretically the difference between a hospital and the hospital ward of a poorhouse may be only that "twixt tweedledum and tweedledee," nevertheless it is just such trifling differences which make the great distinctions of life.

The second objection is the remoteness. It takes from half to three-quarters of an hour from the wharf to reach the islands, and the boat makes but two trips a day. The public institutions of New York are also on islands, but they can be reached in a few minutes from the wharf, and a tug makes frequent trips. This remoteness and inaccessibility render the visits of friends infrequent and difficult; in cases of sudden changes in the patient's condition it becomes impossible for the family to be summoned promptly, and the seclusion taken from the publicity which is desirable as a guard against abuses. Furthermore, since it is difficult to keep up the personal associations which make for the patient's mental hygiene, this inaccessibility renders it impossible to employ in such a hospital a visiting-staff as in the other hospitals. That an efficient visiting-staff and training-school would be an improvement on the present state of things is self-evident, and such a statement casts no reflection upon the present management.

In spite of the boards of the overseers of the poor in the different towns, it has been clearly shown that the condition of the insane in our town almshouses varies from tolerable to intolerable. Nowhere can it compare to the condition of the insane in the asylums, and in most places it is a disgrace. The condition of patients with other diseases in our almshouses is doubtless better, because the general practitioner, or the town physician, can deal better with such cases than he can with insanity, but I doubt if even in these cases, the treatment, as a rule, can be favorably compared with that of a large hospital. Of course in such a statement I mean to except the conditions of patients in a large chronic hospital like Tewksbury.

⁴ Report of the Commissioners of Public Institutions. 1890.

What should be done? A hospital should be established within the city limits, near the line of some railway or horse-car route, so as to be at all times accessible. It, of course, need not be as central as the hospitals which have to treat acute diseases and accident cases. It should be a hospital — not a poorhouse — with a sufficient visiting-staff, and with wards or beds for special diseases, under the care of specialists — syphilis, paralysis, cancer, tuberculosis, epilepsy, all should be provided for. Such a hospital may consist of various moderate-sized pavilions, and room should be provided for growth, for eventually it would have to provide for 500 or 1,000 patients. Such a hospital might be in the same grounds and under the same general supervision as a hospital for the chronic insane, which would reduce some of the expense. This union of the two hospitals is seen at Blockley in Philadelphia, and at the Charité in Berlin.

The objection, of course, is the cost. The original building cost would be about \$300 a patient, as in the new building at Austin Farm. The cost of maintenance would also be much higher than at the poorhouse, perhaps higher than at the Lunatic Asylum, but lower than at the City Hospital. It is therefore more probable that a people's forum or a free university or some other demagogical scheme will get an appropriation first.

THE CAUSE OF SEA-SICKNESS.¹

BY CHARLES NORTON BARNEY.

PLUTARCH, who thought that sea-sickness was caused by the smell of the salt water, was probably the first theorist on the subject, and since his day there have been advanced numerous theories not very much more satisfactory than his in their practical results.

But before showing what theories are most generally accepted, I wish to make a distinction between genuine sea-sickness — that which is mechanically induced — and the subjective form which is purely emotional cause. There are some sensitive women who are nauseated at the first tremor of the boat; some even at the thoughts called up by the sight of the ship; and others who get sick on packing in preparation for the voyage. All these are representatives of the second form, and in such persons there is a predisposition to sea-sickness which shows itself on land as well as on the water in a condition of general sensitiveness or neurasthenia.

Some have said that all sea-sickness is of this subjective form. But one may wake from a sound sleep in the very worst paroxysms. Then again, if a dog be deprived of consciousness, and tied to a platform which is made to go through the movements of ship in rough weather, all the symptoms of sea-sickness occur, and in such a case emotional causes, such as fear, owing to the conditions of the experiment can have no part in the etiology.

Perhaps the most plausible theory to explain how motion *per se* can cause sea-sickness, is the one which places the origin of the trouble in the inner ear. Among the chief physiological facts established during the past forty years is the knowledge that our bodies are endowed with a special sense whose function is "to

¹ Read at one of the Physiological Conferences of the Harvard Medical School.

determine the position of the head in space," and to regulate the mechanism by which equilibrium is maintained. The principal seat of this faculty is in the semicircular canals of the inner ear. It had been long doubted whether these had any connection with the sense of hearing, until some time ago Ferrier and others noticed that injuries to the canals did not impair hearing, but caused interesting effects in the loss of equilibrium. For instance, in pigeons, when the vertical canal was cut, the bird turned a series of back somersaults in a most extraordinary manner; and when the horizontal canal was cut, the pigeon whirled around in a horizontal plane. Much doubt has been thrown on the results of these experiments as to the direction of the motion, but the chief fact remains that injury or irritation to the canals produces loss of equilibrium, and, what is especially interesting, such irritation is nearly always followed by vomiting.

Sea-sickness seems to be essentially a disturbance of this faculty of equilibrium. It seems that to be most favorable to the coming on of the disturbance the motion should be either backward, downward, or oscillating, and we shall see why this is so a little later when we notice that the ampulla are all at the upper front parts of the canals. A combination of these conditions is the most effective, especially if the motion is at the same time irregular. Hence many persons who feel no discomfort from the regular swing of a yacht, become sick in a row-boat or a steamer.

But we are anticipating; we have not yet seen how motion can cause irritation of the semicircular canals. The endolymph follows the motion of the head in those canals whose plane corresponds most nearly to the direction of that motion, and when the motion is suddenly reversed by the oscillation of the ship, or changed in direction by a new wave striking her on another point, the endolymph continues in its original direction until stopped by friction. This causes undue pressure in one or more of the ampulla, by which wrong impressions are conveyed to the sensorium, and incoordination, giddiness, etc., result. The otoliths in the endolymph are washed up against the nerve filaments at the front of the canals and produce an excessive irritation, which is expressed in vertigo and vomiting.

But the semicircular canals alone, even in sea-sickness from motion are not always the only cause of the trouble. There is another class of cases to which Dr. Irwin applies the term, "Labyrintho-musculo-visceral vomiting"; by which he means "vomiting due to mechanical disturbance of the viscera, permitted by incoordinate muscular action, the result of faulty labyrinthine impressions. The violent and complicated movements of a ship in a heavy sea have a tendency to displace the abdominal viscera. In one accustomed to the life, involuntary muscular action protects the organs from contusion." In others, the course of events is as follows: The endolymph, as already stated, follows the motion of the head, and, after that motion has stopped, continues for a second or so to move on in the original direction. During this second, "erroneous impressions are conveyed to the sensorium, which in turn sends a mistaken message to the abdominal muscles, a wrong set are brought into action," and complete abdominal chaos is the result. The intestines bulge forward at the end of each descent of the ship, so stretching and irritating their attachment that the abdominal vessels are gorged with blood and vom-

iting sets in. This class of vomiting is very violent. It is relieved in the same way as the other class (that is, by remedies directly affecting the nervous system, as anodynes and sedatives), but with the addition of a tight bandage round the abdomen.

There is probably a minor kind of sea-sickness caused by the mere churning about of the food in the stomach, irritating the nerves there as they would be irritated by an emetic. This is often the sort experienced in small boats, and is at once relieved by vomiting.

That sea-sickness can exist independent of visual impressions is shown by the fact that one may be attacked while sleeping, and, besides, it is well known that the blind are not exempt. There can be no doubt, however, that stimulation of the sense of sight has an important influence in some cases, as has also stimulation of the other senses. Bad tastes and odors will often cause symptoms like those of sea-sickness, and I know of a nervous woman in whom these symptoms were always brought about whenever she heard a regular succession of noises; for instance, when some carpenters happened to be working on a house near by.

The power of the imagination as one of the causes of sea-sickness — that is, the subjective form — must not be overlooked. Whether it is more powerful here than in other diseases it would be hard to say, but the mental effort is so prominent that Mr. Bache, some years ago, wrote a very interesting article on the subject, in which he maintained that sea-sickness was wholly of mental origin. Wollaston started the theory that the blood rose and fell like the mercury of a ship's barometer during a storm, and that resulting mechanical congestion of the brain was the cause of sea-sickness. Stocker thought it largely due to a partial vacuum in the lungs, and Naylor suggested spasms of the capillaries.

The reason why one does not get sick riding horseback is explained by those who hold the semicircular canal theory to be that the motions here are not violent, and also that the rider can adapt his position to them as is not the case with the complex movements of a ship. Dr. Rosenbach, the German, who has lately written a very elaborate pamphlet on the subject, opposes this theory, saying that the motions of a ship are not, after all, greater than those of the rocking-chair, but he leaves out of count the movements up and down of the ship as a whole.

The explanation of the fact that lying down with the head low and the feet toward the stern affords relief is simply anatomical. "The ampulla of all the semicircular canals are on their anterior extremities, and in consequence, when the body is recumbent and the head low the endolymph and otoliths rest at the back of the canals — on the parts which are least sensitive." Riding backwards is distressing to some persons for the same reason, as here, of course, the otoliths drag forward and irritate the anterior and most sensitive parts of the canals.

Menière's disease confirms this theory. Here we have the reverse of sea-sickness, the irritation of the canals causing the unusual movements, while in sea-sickness, the movements of the body which result from the pitching of the ship, cause the irritation of the canals; and both are accompanied by vomiting. Then again, Professor James found another strong confirmation in noticing that all deaf mutes who were insusceptible to dizziness, on account of the impairment of their semicircular canals by disease, were also free

from sea-sickness. He also thought he had prevented an attack in himself while crossing the English Channel by setting up a counter-irritation in the canals.

The objection is always offered to every theory which attempts to explain the cause of sea-sickness, that these theories do not account for the fact that some persons are never sick on the water. This can not be considered a valid objection for so many things must be taken into account—the constitution of the individual, etc. But for my part, I have never known an instance where a person of average sensibility going to sea for the first time has not felt, at least, a little disturbed until he has learned to let his abdominal muscles take care of themselves without the intervention of his will.

The question arises how all the phenomena of seasickness have a tendency to pass away. They pass away for this reason: We learn to walk on shipboard without getting sick just as a rope-walker learns to walk on a high rope without getting dizzy. Through habit we learn to disregard those mistaken impressions which the semicircular canals send in—to be in a condition of "absent-mindedness" toward them. A sailor is in this condition so habitually that on returning to land after a long voyage he staggers for hours, even if he is not drunk.

Clinical Department.

A CASE OF GLYCOSURIA CAUSED BY A LESION PROBABLY SITUATED NEAR THE FOURTH VENTRICLE.¹

BY A. K. STONE, M.D.

A GIRL, thirteen years old, of good family and personal history, had an alveolar abscess and later an otitis media. This was followed by attacks of headache mostly located upon the left side. There was increase in thirst and in the amount of urine passed. During the headaches there was diplopia. When first seen she had lost about seventeen pounds of flesh, was weak, with persistent headache over the left eye, bowels constipated, skin harsh and dry. Paresis of the sixth nerve on the left side. Absence of all tendon reflexes. Urine: five pints, pale, and specific gravity 1,050; no albumen; sugar, nine per cent. by the polariscope. On limited diet she improved for a time, then the headaches became more severe and a general neuritis appeared. The muscles of the neck were tense. There was a return and exaggeration of all the reflexes and ankle clonus was present. During the starvation diet of the semi-conscious period, the sugar in the urine gradually fell until just before her death the analysis showed specific gravity 1,030; albumen a trace; sugar absent. Two days before death there was paralysis of the right side, with marked signs of irritation on the left side, followed the next day with paralysis of the left side.

As there was no autopsy the case was simply interesting from its probabilities. The persistent headache, the diplopia and hemiplegia followed by paraplegia, would point to the head as the seat of the trouble, while the glycosuria, the left diplopia and crossed right paralysis would point to the vicinity of

the pons, and the unexplained purulent otitis media would suggest that the lesion was tuberculous in origin.

Diabetes in children I found was confined to reports of one hundred and seventeen cases, while there are only eleven cases where glycosuria was proved by the autopsy to have been caused by tumor near the fourth ventricle.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY. SUFFOLK DISTRICT. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

ALBERT N. BLODGETT, M.D., SECRETARY.

REGULAR meeting, Wednesday, February 17, 1892, Dr. E. G. CUTLER in the chair.

DR. GERTRUDE W. VAN PELT read a paper on CASES OF DYSPESIA, WITH TREATMENT BASED UPON AN EXAMINATION OF THE GASTRIC JUICE.¹

DR. A. L. MASON: I have been much interested in these cases. I notice she mentions that one patient did not get better until coffee had been abstained from. Is it usually found especially objectionable?

DR. VAN PELT: I think that usually increases the secretion of hydrochloric acid.

DR. MASON: Is it found necessary to give up coffee altogether in these cases?

DR. VAN PELT: In that one, where there was hypersecretion, it was given up for a short time only.

DR. MASON: I have supposed coffee was troublesome for dyspeptic patients very often, but it seems harder to make them give it up than almost any other article they use. They miss, I suppose, its stimulating effect.

DR. J. J. PUTNAM: I was quite interested in some of the cases which would ordinarily have been diagnosed as nervous dyspepsia. It seems undoubtedly true that in many of these cases, although there is no distinct evidence of catarrhal disease without such examinations as these, nevertheless there is sometimes relief from the use of the stomach-tube. I have recently had one such case where the relief has been very marked indeed. I should like to ask whether there is any real reason to think the small doses of hydrochloric acid actually, by their acting as an acid on the food, help in the digestion, or whether they simply act by stimulating the stomach.

DR. VAN PELT: I think in both ways, but chiefly by stimulating the stomach to secrete.

DR. PUTNAM: The quantity is so small it does not seem as if it could be of much use. I should like to ask whether the experiments that have been made in regard to the use of electricity in dyspepsia have shown anything more than a temporary increase of the secretion of gastric juice.

DR. VAN PELT: I think the impression is that the nervous tone of the stomach is improved, though I suppose there have not been sufficient experiments to show exactly what it can do.

DR. PUTNAM: I should like to ask whether electricity used in that way is distinctly more effectual than electricity used in other ways as a general tonic.

¹ Synopsis of a paper read before the Section for Clinical Medicine, Pathology and Hygiene of the Suffolk District Medical Society, February 17, 1892.

¹ See page 382 of the Journal.

DR. VAN PELT: Dr. Einhorn has published a number of cases and followed them up by that treatment alone, in which they seem to be distinctly improved. I did not mention that in some of my cases I used also central galvanization; and I did not notice the effect on the stomach from that treatment so much as I did from treatment applied directly to the stomach. The general tone of the system was improved, but the stomach was not so much improved by central galvanization as by electricity applied to the stomach.

Dr. Van Pelt stated, in answer to a question, that in the few experiments she had made, the direct effect was much greater with the electrode in the stomach than with electricity applied externally.

DR. LEIRMANN: Is the electrode applied directly to the wall of the stomach, or is water first introduced?

DR. VAN PELT: Water is first introduced. There would be no current unless it is dipped in water, on account of the hard rubber on the outside.

DR. KNAPP: I would like to ask if in any of the cases of galvanization or faradization of the stomach there were unpleasant symptoms. Some years ago I experimented on such cases; and I think at that time, galvanizing the stomach through the abdominal wall and faradizing, I occasionally got rather unpleasant symptoms. The patients complained of a good deal of pain in the stomach and nausea following the application of electricity. I never tried the intragastric application of electricity, but the external application with one electrode on the back and one over the stomach.

DR. VAN PELT: I have not noticed that.

DR. KNAPP: Did the patients bear comfortably a current of thirty milliamperes?

DR. VAN PELT: They scarcely felt it in the stomach at all.

DR. KNAPP: What size of electrode was used on the outside?

DR. VAN PELT: Four by six inches.

DR. KNAPP: What galvanometer?

DR. VAN PELT: Gaiffe's.

DR. KNAPP: I found it very difficult to get beyond ten milliamperes without getting burning of the skin. Some years ago Ewald advised the giving of hydrochloric acid, with the idea, in cases where it was diminished or absent, of getting into the system about as much hydrochloric acid as would be required in the ordinary process of digestion. He gave forty-five minims of the dilute acid in divided doses about an hour after eating. I should like to ask if this is given up.

DR. VAN PELT: So far as I know it is. It was not used in Paris or in Germany when I studied this subject. It was used in a good deal smaller doses.

DR. MINOT: I would like to ask Dr. Van Pelt if she has ever employed dilute phosphoric acid in the treatment of these cases, or had an opportunity to compare it with the hydrochloric acid.

DR. VAN PELT: I have not.

DR. MINOT: I suppose we all have used hydrochloric acid in patients labelled dyspeptic with more or less benefit, and also the phosphoric acid. I have used phosphoric acid in cases of difficult digestion. I can't say whether they were dyspeptics from too much or too little acid in the stomach, but in my experience it is really a very useful remedy indeed. I have seen some cases remarkably benefited by it where they have complained of pain, sense of weight or load in the epigastrium, and sometimes nausea. It is very diffi-

cult to mark out a line of cases that would be benefited by phosphoric acid or any other, but certainly a great many cases with those symptoms have, in my experience, done remarkably well.

DR. CUTLER: I wish to congratulate Dr. Van Pelt on the success of her treatment. I have had a certain amount of experience in this line, and I know how difficult it is to make a patient come and do what one likes. I think the cases reported have been extremely interesting.

DR. A. K. STONE read a paper on

GLYCOSURIA CAUSED BY PROBABLE TUMOR IN THE FOURTH VENTRICLE.²

DR. MASON: I had supposed that diabetes in young subjects is rapidly fatal. I think it is stated by Prout that out of six hundred cases but three were living at the end of ten years.

DR. MINOT: We see, however, a great many persons who live many years with the disease and suffer little inconvenience. I have a patient sixty-five years of age, under my care, who is in very good health, and he has been under observation several years.

DR. KNAPP read a paper on

THE PROVISION FOR PATIENTS WITH CHRONIC DISEASES IN THE CITY OF BOSTON.³

DR. ROWE: I think Dr. Knapp under-estimates the large amount of good work that is done by the public and private charities of Boston in the care and treatment of chronic cases. If the total number of beds used by chronic cases in the large hospitals were summed up, together with the beds devoted to similar cases in such institutions as the Channing Home, Adams Nervine Asylum, and others, they would make a very good showing for the work done in the city.

The ideal hospital for chronic diseases does not, as far as I know, exist in this country. I mean a hospital built on modern lines of hospital construction, where patients have the benefit of first-class specialists, a trained corps of nurses, and where the treatment is carried out in the same general method adopted in large general hospitals. Philadelphia, through its municipal hospital, which is practically an almshouse hospital, and the special wards at the University of Pennsylvania, does a larger amount of professional work than most other cities.

Dr. Knapp's objections to treating the chronic sick in connection with almshouses are perfectly good, and it is not right that we should rid ourselves of this sentiment. It would undoubtedly be a charitable and generous action, should the municipality of Boston establish a hospital of five hundred beds, where patients having chronic diseases could be intelligently and scientifically treated. Such cases would not respond to the ordinary medical treatment, but would come largely under the care of specialists. It is a fact, however, that it is not easy to get sufficient means to keep up with the demands upon the city in supplying beds and accommodations for those suffering from acute illnesses and injuries; and if we are unable to obtain funds for the treatment of acute cases, we can hardly expect the city to furnish means, at the present time, for those suffering with chronic diseases, other than that which is now given at the almshouses on the islands.

² See page 392 of the Journal.

³ See page 390 of the Journal.

In recently looking over the statistics of London hospitals, I find that outside of the Parish Poorhouse Infirmary, there are not, in all London, over three hundred beds intentionally devoted to the treatment of chronic diseases. At the Boston City Hospital there are always chronic cases which we are obliged to receive. We keep them until their immediate symptoms are relieved, and then transfer them to some other hospital or institution.

It follows, of course, that if the municipality of Boston should build a hospital for chronic cases, it would be only for those who have a legal claim upon the city, which means that a man must have lived in Boston five consecutive years and paid three poll taxes. A very large proportion of those who appeal for public relief on account of chronic sickness are those who have not this legal settlement. There is a large class of people, composed of old servants, artisans and laborers, such as Dr. Knapp mentions, who undoubtedly have a legal settlement, but the larger proportion of those who seek treatment for chronic diseases have not this legal settlement; and in case the city of Boston should establish a hospital for this purpose, such cases would not be refused.

There are two ways out of this difficulty; first, the creation of public sentiment, by repeated agitation of the question in various ways. Much can be accomplished by constant reminders of the wants of those who are powerless to help themselves. A good instance of this is the fact that it is only during the last two years that any decided action was taken in regard to establishing a hospital for epileptics, and yet by constant agitation, appointment of committees, and special work in aid of that cause, the Governor of the Commonwealth in his last inaugural recommends that provision be made for such purpose. It seems to me that the same policy should be pursued in regard to furthering the cause of the chronic sick. The second method would be to enlist the sympathies of some philanthropic person of means, who should endow a hospital, or a ward or wards in connection with a general hospital. This has been done in Philadelphia, in a building consisting of three wards devoted entirely to the treatment of chronic and incurable cases. This building was the gift of a philanthropic citizen, who specified that the wards should be used for this particular class of cases.

I think that a word of commendation is due to the management of the institution at Tewksbury, for the great improvement in recent years, not only in wards constructed on modern lines, but also in better medical care and improved nursing system now existing at the Tewksbury State Hospital.

DR. MASON: It has seemed to me for many years that there was no better field open to the rich philanthropist, in which to perpetuate his name, than to endow a hospital for the incurables in Boston. Almost every week a case comes up that does not want to go to the poorhouse, and should not go there; and it is extremely difficult to find a place for them, especially the males. The small hopes spoken of take but a small proportion of the deserving cases. Last year, I wanted to get boy with cardiac disease, who was totally unable to take care of himself, into some place where he could die in comparative comfort, and it took four or five months, I think. During that time, fortunately, the authorities at the City Hospital were able to allow him to remain. I have no doubt that many

such cases are turning up in Boston every week, and it is greatly to be hoped that some endowed institution will before long be instituted.

DR. PUTNAM: I think what the other gentlemen have said in favor of continued agitation is proper, and I wish we could put ourselves on record every year as making an appeal to the wealthy people to do what they can toward the establishment of hospitals of this sort.

There are one or two things to be said in regard to the present state of affairs. In the first place, I think we do not want to remove the pressure on the people to make provision for themselves as far as they can. Many people are only too willing to throw themselves on any one who is willing to take care of them.

As regards the matter of the city and the poorhouses, it should be said that another way is opening for the city to do a good thing in the line of hospitals, and that is in placing them within reach, and establishing a good staff of visiting physicians. It is true that patients in hospitals soon learn whether they are receiving first-rate medical attention, and also that, when they have come to believe they are getting first-class treatment, they no longer look upon the hospital as an institution for paupers, but rather as a place where people go to receive the best care during their illness; and when they have once come to regard it in this light they care very little if it be in any way connected with the poorhouse.

DR. JEFFRIES: I think it is extremely desirable that we should have something of the kind. In my own dispensary practice I am constantly meeting a large number of males who are crippled, more or less utterly helpless, for whom I cannot find any provision. It has always seemed to me that quite a number die from starvation.

DR. CUTLER: In the Old Men's Home and Old Women's Home, with both of which institutions I had something to do, it was not the custom to take in patients who were sick. The person must have a certain amount of health to be admitted. There was an age limit and a health limit.

DR. KNAPP: I did not mean to overlook the provision the City Hospital makes for chronic cases, but that is necessarily limited, and, furthermore, I know there are many cases which have no settlement.

THE NEW YORK ACADEMY OF MEDICINE. SECTION ON PEDIATRICS.

STATED Meeting, March 10, 1892, W. P. NORTHUP, M.D., Chairman.

EMBOLISMAL APOPEXY IN A BOY OF TWELVE YEARS.

The case was reported by DR. LEWIS SMITH. The boy had had rheumatism, but there was no cardiac murmur. The disease is rare at this age.

EMPYEMA IN CHILDHOOD: IS IT EVER PRIMARY? ITS RELATIONS TO PNEUMONIA AND TO PLEURITIS WITH SEROUS EFFUSION.

DR. HENRY KOPLIK read a paper on this subject. The etiology of pleurisies, both serous and sero-purulent, has been cleared up in many respects during the last decade, chiefly through bacterioscopic science. We know that children may develop an effusion in the

chest not as the result of constitutional causes alone, but of causes to which we also trace the development of pneumonia.

An estimate of an effusion as serous or purulent from simple inspection of the fluid without the microscope is highly unsatisfactory, and may lead to grave error in diagnosis and treatment. Children are prone to develop sudden effusions in the pleural cavity, and we are struck with the overwhelming frequency with which such effusion is purulent. It often happens that a clear, serous-looking effusion changes to a purulent one. This, however, is apparent rather than real. This we now know to be erroneous. All exudations apparently serous at first which subsequently become purulent do so from causes independent of external interference but inherent in themselves. Such a serous exudation, if examined microscopically, will be found to contain not only leucocytes and blood-cells but pus-producing micro-organisms. In children, acute exudations without micro-organisms are the exception. Such fluid is but one step removed from actual pus. The custom of refraining from informing ourselves as to the character of fluid in the chest by puncture for fear of contaminating that fluid is untenable.

Another point of importance is the question as to whether in children empyema may be primary; that is, whether it may occur without any connection with external infection or processes in the lung. While cases have been reported in which no other diseased condition was detected upon autopsy, they are extreme rarities, so much so that the writer in a large experience has never seen one.

Can the effusion be purulent from the outset? Undoubtedly it may be and frequently is so. The connection between pleurisy and disease of the lung is thus seen to be very close. It often happens that the illness begins with high temperature and all the symptoms of pneumonia, but after a few days the condition changes, fluid is detected in the pleura, giving the impression that an error in diagnosis has been made. In such cases, microscopical examination shows the same germ in the pus from the pleural cavity as is found in the lung, — the pneumococcus of Fränkel. The tendency of this germ to cause suppuration is well known, and it is found in other complications of pneumonia marked by pus, as meningitis. Its presence in empyema renders the close relationship of that disease to pneumonia very certain. They probably invade the pleura through the sub-pleural lymph spaces.

There are other exudations which still cause discussion, in which we do not find the pneumococcus but other germs of less marked selective tendencies, as the streptococcus and staphylococcus. There is reason to believe that these are also metapneumonic though the specific germ does not appear.

There are other cases complicating the secondary pneumonia and occurring without pneumonia in the infectious diseases. These effusions usually show the presence of the streptococcus.

THE DIAGNOSIS OF EMPYEMA,

was the subject of a paper by DR. S. W. BRANNAN.

As symptoms are obscure the diagnosis must rest chiefly on physical signs. It is easy when the classical signs are present — immobility of the affected side, loss of vocal fremitus, flatness on percussion, and diminished respiratory sounds. In young children, however, these signs are rarely distinct. There may be

no distention of the side whatever, and vocal fremitus, even if it can be obtained, is of no significance. Signs obtained by auscultation are often difficult to interpret. The normal respiratory sounds are so loud and the pleural cavity so small, that a considerable collection of fluid may cause but little change. Displacement of the apex beat is a sign of the greatest value. It is caused by no other condition. The two most constant signs are percussion, dulness and displaced apex beat. Exploratory puncture affords the most positive and in many cases, the only certain evidence of fluid. As to the character of the fluid, symptoms and signs are very uncertain guides. The needle is the only sure test. Pleurisy following pneumonia or complicating the infectious diseases and traumatic pleurisy is apt to be purulent. Though the needle often fails to obtain fluid when present, its use when the fluid does not quickly disappear, should never be omitted.

It has been alleged by Bacchelli that whispered voice is always present when the effusion is purely serous, but absent when sero-purulent or purulent. This is explained on the ground that sound is more readily transmitted by a homogeneous medium like serum. The certainty of this sign is quite doubtful.

OPERATION FOR EMPYEMA,

was considered by DR. J. H. RIPLEY, in a brief paper.

Operation should be performed as soon as a diagnosis has been made. Unless the amount of fluid is very great or the symptoms are urgent, a delay of a few days will do no harm. The location of an incision must depend largely upon the focal conditions. It may usually be made in the seventh intercostal space below the angle of the scapula. An incision an inch or more in length should be made down to the costal pleura, through which a small opening should be made.

Through this a director should be passed and the incision enlarged with a blunt-pointed bistoury. A drainage-tube of large size should then be passed several inches into the cavity, with a safety-pin attached to the outer end to prevent its slipping out of sight. If there is not sufficient space for the tube between the ribs, a portion should be removed subperiosteally. The wound should be dressed with oakum, which should be changed every day.

EXPANSION OF THE LUNGS IN CASES TREATED BY INCISIONAL DRAINAGE,

was discussed by DR. J. WEST ROOSEVELT.

The idea that fluid in the chest causes compression of the lung has been completely disproved. The lung tends to retract from the chest wall whenever fluid or air is present in the pleural cavity. It becomes retracted and condensed, but is compressed only when the amount of fluid is very large. Compression can only occur when the elastic recoil of the lung has been destroyed. Expansion of the lung to fill its normal position almost invariably follows early operation performed at the lowest part of the cavity where drainage can be free. The earlier the operation when pus is known to be present the better. The prognosis is far better with the chest full of air than with the chest full of pus.

Expansion is aided by the action of the other lung, especially when the glottis is closed as in coughing. The air is forced by the sound lung into the contracted lung during expiration, and expansion will be seen at that time rather than during inspiration. Granulation

tissue, by contracting, also aids in drawing the lung out to the chest wall.

Removal of sufficient rib to permit drainage is perfectly proper. Removal of rib for the purpose of causing contraction of the chest wall is almost criminal. It should not contract, and can only do so by interfering with the lung and obliterating space that the lung requires, and if properly managed, would undoubtedly occupy.

DR. KOPLIK said that while primary empyema was a possibility, it was very rare.

DR. RIPLEY said that in a child dulness was not always present, and but little fluid was required to produce bronchial breathing. Displacement of the apex was a valuable sign, but it was very difficult in some cases to detect the apex beat.

DR. ANDREW H. SMITH had often found a line of egophony just above the fluid, and regarded it as a valuable sign. He said that the lung in the empyema was contracted not compressed.

DR. HOLT referred to the absence of râles and friction sounds, where they had previously been heard, as a very valuable sign of fluid.

DR. EWART also referred to silence, where there had before been crepitations, as an important sign. He did not believe that Baccelli's sign was to be relied upon. A high or oscillating temperature, associated with a persistent dry cough for a long time, was a suspicious symptom.

DR. ROOSEVELT said that aspiration with the idea of expanding the lung by the suction was foolish. At the best, it is a waste of time.

DR. CAILLÉ objected to irrigation on the ground that it breaks up the adhesions.

DR. BERG advocated extenction of a rib to aid drainage.

DR. WINTERS believed that most undiagnosed cases died from exhaustion or tuberculosis, but encysted cases often recovered. He had never seen a case of pure serum changed to pus. Serous effusions were not uncommon in connection with the infectious diseases. He had frequently seen cases of empyema in which a diagnosis of pneumonia had been made at the outset. He had formerly thought that an error in diagnosis had been made, but now believes that that was the usual way in which empyema developed.

Recent Literature.

The Treatment of Typhoid Fever, and Reports of Fifty-five Consecutive Cases with only One Death. By JAMES BARR, M.D., Physician to the Northern Hospital, Liverpool, etc. Introduction by W. T. GAIRDNER, M.D., LL.D., etc. London: H. K. Lewis. 1892.

The author dedicates this book, which follows a paper published a year or more ago in one of the London medical weeklies, to his former teacher, Professor W. T. Gairdner of Glasgow. Professor Gairdner contributes an introduction, in which he says: "If heat-abstraction is an object of so great importance, why not do it continuously, but in such a way as shall cause no distress at the time, shall avoid violent transpositions, and allow of natural rest, and, as far as possible, a normal periodicity of all the functions, undisturbed

by the perpetual interference at all hours of the day and night, which characterized the earlier antipyretic methods?"

To this the disciples of Brand would probably reply: But, it is not the abstraction of heat we are now after, it is the action on the nervous centres; and to secure this, things must be made lively for the patient, cold-tubbing must be kept up briskly as often as the temperature rises above a certain point, whether by day or night.

Whatever the cause, whether accident or the therapeutic effect of his use of continuous immersion of severe cases in water, Dr. Barr has had excellent results in a series of seventy-one successive cases, there having been only two deaths. Of course, the number is too small for positive conclusions. There are two things, however, which deserve notice, the continuous bath was only used in severe cases, and the patients, apparently, were not thus treated for typhoid fever and pronounced cured, before the diagnosis could be fairly established.

His rule is as follows: As long as the temperature in the patient's mouth is over 100° F. the temperature of the tank need not rise above 90° to 93° F., but as the body temperature approaches the normal so should the tank temperature. One patient was immersed thirty-one days. Some of the cases which recovered were very serious cases.

The book is an octavo of about 200 pages. Those interested in the treatment of typhoid fever (and what practitioner is not!) should read it, and so should the admirers of Brand's method.

Principles of Bacteriology: A Practical Manual for Students and Physicians. By A. C. ABBOTT, M.D., First Assistant, Laboratory of Hygiene, University of Pennsylvania, Philadelphia. Octavo, pp. i-viii, 13-263. With illustrations. Philadelphia: Lea Brothers Co. 1892.

The demand for a book that would give a summary of the best of the methods of bacteriological research has been increasing for some years, and it has been partially supplied by various manuals published during the last year. None of these have seemed to be just what was needed for laboratory teaching or a guide for the single worker, until the publication of Dr. Abbott's work. This seems to furnish very nearly what is required for those to whom the German textbooks are not accessible, and for laboratory use with personal instruction added will be exceedingly useful. That some such summary of methods is needed is shown by the increase of attention devoted to the subject of which it treats, which is obtaining a foothold in the required courses of the best medical schools.

The feature of suggesting work to be carried out by the beginner, adds to the value of the book for instruction.

H. C. E.

Physical Diagnosis and Practical Urinalysis. By JOHN E. CLARK, M.D. Detroit: The Illustrated Medical Journal Company. 1890.

This little book suffers, as all such books must, from the author's desire to condense his material into too small a space. It is too much to expect that the symptoms of any important disease can be adequately described in a dozen lines. Criticism should be directed rather to the plan of the book than to the way in which the author has carried this out.

RECENT RESEARCHES ON BILIARY INFECTIONS.¹

THE primary acute biliary infections are divided into such as are spontaneous and protopathic (supervening without previous mechanical lesion), and the deuteropathic, which are constituted by biliary infections accompanying (as a part of) and complicating general infections. The bond which unites them all is the etiological bond of infection.

Primary acute biliary infection is mild, moderate or grave :

(1) The mild form is the catarrhal icterus, with which nearly every one is familiar from his own experience.

(2) The second form of medium intensity is characterized by more violent symptoms, by the relapsing type of the fever, by the albuminuria, the haemorrhages and the augmentation of the volume of the liver and spleen. It is, in fact, the febrile icteroid affection so well described by Weil, in 1886, though previously known to Mathieu and Lancereaux, and made the subject of a monograph by the latter in the *Revue de Médecine*, 1882. Since the publication of Weil, much attention has been called to this form of icterus by the papers of Goldschmidt, Hueber, Fiedler, Kirchner, and other German observers. Mathieu, who also claims priority over Weil in the discovery and description of this disease, which seems to have been improperly named after the German pathologist, thus comments on the pathogenicity of this affection (the remark equally applies to other biliary infections): "We must admit the possibility of the ascension of pathogenic agents from the intestine into the bile-passages, and their subsequent penetration into the blood, just as the bacteria of suppuration may ascend the ureters from the bladder and invade the renal pelvis, the calices and the uriniferous tubules."

¹ Concluded from No. 15, page 273.

(3) Lastly, we have the grave form of acute biliary infection, which is characterized by the intensity of the nervous symptoms, by the haemorrhages, the intense prostration, and the profundity and extent of the hepatic lesions, which led Rokitansky, in 1843, to designate it as *acute yellow atrophy of the liver*. This is the grave essential icterus of Ozanam, the typhoid icterus of Lebert, the pernicious icterus of Wunderlich, the essential haemorrhagic icterus of Monneret, etc. Frerichs, in his "Clinical Treatise" (1858), gives a good description of this disease; but Budd, thirteen years before (1845), in his then classical work, described it nearly as well under the title, "Fatal Jaundice."

This grave infection, according to Dupré, may appear as an isolated affection, independent of any anterior lesion of the liver, or it may terminate a previous hepatic affection (cirrhosis, lithiasis, cancer); and it is possible for the milder forms of jaundice to pass, by an insensible transition, into this grave and fatal form.

We have not space in this review for a consideration of the deuteropathic forms of biliary infections, or even of the chronic forms. The pathogenic agents of the biliary infections are multiple; in fact, there is not one infectious germ but may find in the biliary passages or gland-substance favorable conditions for its depredations. Perhaps more frequently the staphylococci and the streptococci of abscesses and of suppuration — the septicæmic cocci — are concerned in the infection.

We do not yet know precisely what conditions annihilate the natural resistance of the bile and the gall-ducks to septic agents, so that even simple catarrhal states of the duodenum, with their entire bacterial outfit, may be propagated upward into the liver. The comparison with the urinary bladder holds good: in healthy states, infection by a foul catheter is not easily conveyed, while in morbid states (stricture, hypertrophied prostate) a microbe invasion is almost certain to follow the introduction of a dirty catheter.

It is less difficult to understand the infection of the liver by specific bacteria during the prevalence of exhaustive diseases. In numerous instances on record, where in the course of typhoid fever the liver has become secondarily infected by migration of the Klebs-Eberth bacillus from the duodenum, the bile and portions of the hepatic parenchyma have been examined after death, for microbes, the typhoid bacillus has been identified by its form and its reactions to staining-fluids, has been cultivated, and inoculated in animals with results sufficiently confirmatory of the previous identification.

Chronic biliary infections lead to hypertrophic cirrhosis. Into this subject we have not now time to enter. There is a common form whose onset is spontaneous, and whose direct causation is little understood; and a secondary hypertrophic cirrhosis following biliary obstructions, in which the infectious element plays a certain part. After a variable time, the irritative

process, whose seat is the biliary network, engenders angiocholitis and peri-angiocholitis with an enormous connective-tissue growth, whose final result is an atrophy of the glandular substance as complete as that which attends ordinary cirrhosis.

CAUSES OF DEATH IN ITALY FOR THE YEARS 1889 AND 1890.¹

This very complete summary published by the Italian Minister of Agriculture, Industry and Commerce, contains the vital statistics of the Kingdom of Italy, so far as relates to the causes of death, in full for the year 1889, with a summary for the year 1890.

The estimated population for 1889 upon which all the ratio of mortality are based for that year, was 29,969,654.

The death-rate per 1,000 for 1889 was 25.63. From certain specified diseases the mortality was as follows, per 10,000 of the population :²

	1889.	1890.
From small-pox	4.5	2.4
" measles	4.6	4.8
" scarlet fever	2.2	2.5
" diphtheria	6.1	4.1
" whooping-cough	4.1	4.3
" typhoid fever	7.6	6.8
" malarial fevers	5.4	5.2

The deaths from hydrocephalus were 103 in 1887, 106 in 1888, 118 in 1889, and 75 in 1890.

	1889.
Dysentery	1.9 per 1,000
Typhus fever	0.15 "
Puerperal fever and other maladies of parturition	2.04 "
General tuberculosis and phthisis pulmonalis	14.3 "

There were 3,113 deaths from pellagra.

The deaths from violence are very thoroughly classified, and amounted to 13,199 or 4.4 per 10,000 of the population, of which 3.4 were by accident, 0.49 by suicide, and 0.49 by homicide.

By occupations, the guardians of public funds, and soldiers, furnished the highest ratio of suicides, and farmers and weavers the least.

Statistics of duels are subject to careful record. Of these, there were 2,759 in the ten years ending with 1889, and 177 in 1890. Out of this whole number only 52 were attended with fatal results, or 1.7 per cent. The greatest number of duels were fought in the three summer months, and the least in November and December. The causes of duels were quarrels, insults, newspaper criticism (these furnish the greatest number), politics, intimidation, assaults and jokes. Military men, journalists, lawyers and students furnished the greatest number of duelists, and there were but very few physicians among the number.

Statistics of 1,089 hospitals are also presented, in which 339,873 patients were treated in 1887, and of

932 hospitals and 311,575 patients in 1888. The deaths in these hospitals were 40,683 in 1887 and 38,481 in 1888, of which number 365 in 1887 and 489 in 1888 were nearly dead at the time of their admission. The most important causes of admission were as follows in the order of their greatest number: Malaria fevers, diseases of the trachea, larynx and bronchi, contusions and wounds, diarrhoeal diseases, tubercular diseases, gastritis, abscess and skin diseases, pneumonia, pellagra, typhoid fever and fracture.

Some tables are also presented giving the ratio of mortality from different infectious diseases in other European countries.

THE REGULATION OF MEDICAL EXPERT TESTIMONY.

At a meeting of the New York Society of Medical Jurisprudence and State Medicine, held April 14th, Dr. Benjamin Sachs read a paper on the subject "What the Law can do to mitigate the Evils of Medical Expert Testimony." As a consequence of experts being called in each case by interested parties, he said, the facts bearing on the case were never fully and impartially stated to the man who was expected to give a decisive opinion; and this was unjust both to the physician and to the law. As a remedy, he suggested that a standing commission of physicians and surgeons, selected from every department of profession, and, of course, including analytical chemists, should be appointed by the courts to serve on all cases, to which they could only be summoned by an order of court. To this board should be submitted all the testimony on which they were to give an opinion. At present, he went on to say, all expert testimony is verbal, and this was necessarily an evil, since a clever physician fully competent to answer the questions fairly and plainly stated, if unused to law courts and the prevailing system of cross-examination, might become so confused as to either contradict himself flatly or appear uncertain on the most vital points. The remedy for this was to compel all expert testimony to be submitted to the court and to the jury in writing.

Another evil mentioned, and one which it was suggested had been emphasized in recent trials, was that cross-examination of experts is largely made up of personal abuse, ridicule and purposely misleading questions and statements. The personality of the witness should have nothing to do with the case. The remedy suggested for verbal testimony would cover this. In conclusion, Dr. Sachs recommended that a committee from the Society, to consist equally of representatives from the several professions represented in it, should be appointed to confer as to the most feasible way of arranging for the establishment of such a board as he had mentioned.

Similar propositions have already fallen several times in this State and elsewhere upon the unpropitious ears of legislative committees. They will have very unusual good fortune if they get beyond a committee-room.

¹ *Statistiche delle Cause di Morte in tutti i Comuni del Regno. Confronti con alcuni stati esteri. Anni 1889 e 1890.* pp. xvi, 182. Roma, 1-91.

² The general death-rate is usually reckoned as a ratio per 1,000 and not from each disease per 10,000 of the living population.

³ The highest ratio in 1889 from malarial fevers was, in Sardinia, 29.1, while it was of rare occurrence in the northern provinces of the kingdom.

MEDICAL NOTES.

UNITED STATES CONSULS ON THE LOOKOUT FOR TYPHUS. — The Acting Secretary of the State has, by request of the Treasury Department, given instructions to United States consular officers in Russia to forward immediately special reports concerning the existence in their districts of typhus fever, using the cable when necessary.

CHOLERA IN ASIA MINOR. — Under date of February 19th, the United States Commissioner writes that the epidemic of cholera has entirely disappeared from Turkey in Asia. He adds that the disease has not ceased by sanitary steps taken by the authorities, but on the contrary, has disappeared of itself.

EPIDEMIC DYSENTERY OF JAPAN. — Ogata has studied the epidemic dysentery which every year appears in Southern Japan, and has succeeded in separating and cultivating a short, small bacillus, which is probably the specific organism of the disease.

THE MEASLES BACILLUS. — It is reported by cable that Dr. Canon of the Moabit Hospital in Berlin, has demonstrated a specific bacillus of measles.

THE PURIFICATION OF AIR. — Sir Douglas Galton states that the only way in which, so far as he has found, the removal of dirt and fog from a large volume of air required for ventilation has yet been practically effected, is by means of a wet screen, as used at the Western Infirmary, Glasgow. The air is here renewed six times in an hour, and is first filtered and washed by being passed through a screen of cords formed of horse-hair and hemp, which is kept continually wet, and which effectually removes all dust and soot from the air. An automatic flushing tank discharges twenty gallons of water over the screen every hour, and thus washes away any substances which have adhered to the screen. The action of such a screen, it is said, removes every vestige of fog, renders the air beautifully clear and bright, and might be easily applied to private houses.

DENHOLM v. TAIT. — This libel action against Mr. Lawson Tait, which has recently come before an English court, has created much comment among medical men in England. The particulars are briefly as follows: Dr. Denholm had attended a patient for several years for fibroid tumor. The Apostoli treatment by electrolysis had been tried and on one occasion an accident occurred with the electrodes which resulted in a vesico-vaginal fistula. Finally, Mr. Tait was consulted, who removed a tumor by abdominal section which weighed twelve pounds. The patient died within forty-eight hours. Mr. Tait wrote a letter expressing the opinion that death was attributable to hemorrhage due to sloughing, as a result of the electrical treatment. Dr. Denholm, hearing of the existence of this letter, obtained a post-mortem, the results of which seem to be more or less doubtful, but were stated to show that death was caused by peritonitis. A suit for libel was begun, and argued before a

jury, but before it was finished the case was settled out of court and withdrawn.

BOSTON AND NEW ENGLAND.

DEATH-RATE IN BOSTON FOR MARCH. — There were 995 deaths in the city during the month of March as against 813 for the corresponding month last year, making the death-rate 26. The deaths due to diphtheria were 35, scarlet fever 28, consumption 114, bronchitis 55, pneumonia 119.

THE CARNEY HOSPITAL APPROPRIATION. — It appears to have aroused much excitement at the State House. In spite of the failure of the Committee on Public Charitable Institutions to report the bill, the house took it up and passed an appropriation of \$10,000. It now waits the action of the senate. This amount has been given in the two preceding years.

THE BOSTON PUBLIC INSTITUTIONS FOR THE INSANE. — The committee appointed by the Mayor to investigate certain of the public institutions for the city, have recently submitted their report. The committee consists of Frank Morison, Thomas F. Ring, Annette P. Rogers, Chas. P. Putnam, Elizabeth M. McCarthy, Elizabeth G. Evans and Morton Prince. With regard to the condition of the quarters provided for the insane at South Boston and Austin Farm, the commission says that both are overcrowded, while the condition of things in South Boston is very bad. The recommendations are, that the chronic insane be located upon Austin Farm, additional buildings being erected and additional land acquired. The Insane Hospital at South Boston is an old building, not fit for its present use, and it is inexpedient to attempt to re-construct it, but it would seem best to continue to use it until the city is ready to build a hospital on a piece of ground quite separate from Austin Farm, and suitable for the class of patients for which it is intended. The commission is inclined to believe that for the present a hospital for 150 beds, including a building for fifty excited patients, would answer all immediate demands. More land for the erection of this hospital should be purchased. For this purpose appropriations aggregating \$273,000 are recommended. A further recommendation is made of an additional dormitory at Austin Farm. The committee are in favor of a plan to use the Austin Farm for acute cases, altering the present buildings and adding others for the purpose of establishing a true hospital, and purchasing a large tract of land, two hundred acres or more, in a rural district, on which to build the asylum for chronic insane. The cost of such a place would be \$307,000. This allows for fifty-eight more patients than the first plan. Either of these plans vacates the South Boston Lunatic Asylum, which is much needed for the additional cells to the house of correction. In conclusion the commission comments severely on the manner in which the city of Boston has of late years provided for its insane. Other recommendations in the report are a separate parental school, as requested by the school committee, and an appropriation of \$90,000 for six hundred new

cells at the House of Industry at Deer Island. The Mayor, in transmitting the report to the Aldermen, says, "As to the choice between the alternative plans for improved accommodations for the insane suggested by the committee, my personal preference would be for that plan which contemplates buying a large area of land on the outskirts of the city, or without its limits, rather than to get a smaller area in the immediate vicinity of Austin Farm. I would suggest that I be authorized to advertise for land, situated within fifteen miles of the City Hall, and convenient of access from the steam railroads. If in this way an area of two hundred acres of land could be obtained at a reasonable price, we should be, for the first time in our municipal history, in a condition to supply the wants of the present and the probable needs of the future, in respect to the proper care and treatment of the insane."

THE MASSACHUSETTS COLLEGE OF PHARMACY.—R. W. Greenleaf, M.D., has been appointed Professor of *Materia Medica* and Botany, in place of Dr. C. P. Pengra, deceased. G. F. H. Markoe, Ph.C., has been appointed Professor of Theory and Practice of Pharmacy, *vice* E. L. Patch, Ph.C., resigned.

SEA-SHORE HOME FOR INFANTS.—The inhabitants of our suburban towns seem to be most energetically opposed to having this institution as a neighbor. Two years ago it was voted out of Winthrop. Recently, all arrangements were made to transfer it to Quincy this spring, but now the citizens of Quincy have declined to receive it. The only place in which it is not likely to arouse opposition appears to be on one of the islands in the harbor.

PHYSIOLOGY IN THE PUBLIC SCHOOLS.—In the report of the Massachusetts State Board of Education recently issued, Mr. G. H. Martin comments upon the teaching of physiology and hygiene under the law of 1885. This law had special reference to the effects of stimulants and narcotics upon the human system, and the instruction was expected by some of the promoters of the law to inculcate in the youthful mind an abhorrence of intoxicating liquors. Mr. Martin arrives among others, at the following conclusions: The outcome in accurate knowledge resulting from much of the work done is meagre and out of proportion to the time spent upon it. Many false impressions are left in the minds of the students, physiological details are not suited to young children. However defective the instruction may be, the sentiment of the schools is sound—the conviction that alcohol and tobacco are bad things to use seems universal, where exaggerated notions of the effects of stimulants have been acquired, there is danger of a reaction of sentiment in the light of after-knowledge. Among the suggestions which he makes are, that teachers prepare this subject with more care and see that their statements are true, and by frequent tests ascertain that their teaching is properly comprehended, and that the use of text-books should be limited to the older pupils; the moral and

social effects of the abuse of intoxicants should be made more prominent, and abstinence be advised for other reasons than such as concern only the body.

NEW YORK.

DEATHS FOR THE WEEK.—During the week ending April 9th there were 983 deaths reported in the city, an increase of 109 over the previous week. No deaths were caused by small-pox, but this disease, through a failure to report the cases, either from negligence or through inability to diagnose the disease by the medical attendants, or from other causes, increased to some extent. On April 11th it was stated that since January 1st, 77 cases of small-pox with 10 deaths had been reported. Since then, a few other cases have been reported. During the past week three or four new cases of typhus fever have been reported, the most of them among patients who applied for admission to the city hospitals.

MANAGEMENT OF HOSPITALS AT NORTH BROTHER ISLAND.—At a meeting of the Board of Health held April 12th, the following resolution was adopted: "*Resolved*, That upon due consideration of the testimony taken at an investigation in respect to the management of Dr. F. R. Percival, of the Riverside Hospital, at North Brother Island, in connection with typhus fever cases, this Board concludes that the persons sick with typhus fever have been properly treated and cared for, and that no further action is necessary in the premises at present." Soon after the investigation referred to was commenced, Dr. Percival was removed from the charge of the typhus fever cases and transferred to the charge of patients ill with other contagious diseases at North Brother Island, and he is still on duty in the latter position.

A CASE OF SMALL-POX IN A GENERAL HOSPITAL.—Through the failure of an ambulance surgeon of the Seney Hospital to recognize the true nature of the case, a patient suffering from small-pox was on the night of April 13th placed in a ward of the hospital which contained fifty or sixty other patients; and the fact of his having small-pox was not discovered until the following day, when there naturally resulted a considerable panic in the ward.

SUICIDE UNDER Puerperal Mania.—A young married lady, who was sent to New York from Charleston, S. C., to be confined, on account of special difficulties in her case, recently threw herself from a window on the third floor of a private hospital while suffering from puerperal mania, and was instantly killed by fracturing her skull.

THE WEST INDIES AT THE PAN-AMERICAN CONGRESS.—Dr. Wm. F. Hutchinson has arrived from the West Indies, where for the past two months he has been exciting interest among medical men in the Pan-American Congress, to be held in Washington in September next. He visited St. Thomas, Santa Cruz, St. Martins, St. Kitts, Antigua, Trinidad and Jamaica, and in every place he was assured that the West Indies could be well represented at the gathering.

29istellamp.**THE VENICE CONFERENCE.**

THERE has recently been in session in Venice, a congress composed of delegates from fourteen European powers, with the object of establishing international sanitary control of the Suez Canal, in order to prevent, as far as possible, the importation of cholera into Europe. Although the official report has not yet been published, it is understood that all ships coming through the Canal will be classified in three categories.¹ In the first are ships which have no shadow of suspicion; these will pass through the canal without hindrance. The second category will consist of ships that have sailed from a port where cholera prevails, even though there may not be any case of cholera for several days previous to the departure of the ship. These suspected vessels will simply be disinfected. Very powerful and large disinfecting stations are to be established, and bedding and clothes will be purified by superheated steam under pressure. The third category consists of ships in which cases of cholera have occurred during the voyage. These ships will be more thoroughly disinfected and a delay not to exceed five days may be demanded. It is proposed to establish a sanitary department at Suez and to modify the sanitary council of Alexandria. Four medical men will be permanently on duty at Suez. Expenses are to be paid by a tax of twenty cents on each passenger. The English proposition that contaminated vessels should be allowed to pass through the canal on condition that they had no communication with the shore and that they were bound to an English port, was rejected. Ten nationalities have signed the agreement, delegates of the other four having referred the matter to their respective governments.

A MONUMENT TO THE LATE SAMUEL DAVID GROSS.

The friends and admirers of Dr. Gross have desired to erect to his memory such a monument as will commemorate his life and character.

To further this most praiseworthy object, the American Surgical Association, at its last session, adopted the following resolution:

Resolved: That the President be empowered to appoint a committee with authority to confer with the friends and admirers of the late PROF. SAMUEL D. GROSS, and with the *profession at large*, for the initiation of a movement on the part of the Association, having for its object the erection of a monument to DR. GROSS in the City of Washington, D. C."

The subjoined committee from the Association has been appointed, with authority to confer with the *profession at large*, and solicit subscriptions.

It is not the purpose of the American Surgical Association to claim the honor of erecting this monument to the memory of one of its most distinguished Fellows; but rather is it its intention to initiate a movement in which the entire American profession should feel an equal interest: because Dr. Gross was of no exclusive faction, but a leading member of the whole profession.

Hence it is, that each member of the committee is instructed to appoint sub-committees in his own State,

¹ Lancet, April 24.

irrespective of fellowship in this, or any other Association, which sub-committees will aid him in the collection of contributions to the general fund. Any contributions may be sent to DR. JNO. B. ROBERTS, 1627 Walnut Street, Philadelphia. He is the Treasurer of the Association, and will receipt for the same, and from time to time acknowledge subscriptions through the columns of the *Journal of the American Medical Association*. In the event of a failure to collect a sum sufficient to complete the monument, the contributions will all be returned to the subscribers.

J. R. WEIST, M.D., *Chairman.*

C. H. MARTIN, M.D., *Secretary.*

Committee.—DRS. WM. T. BRIGGS, TENNESSEE; LEVI C. LANE, CALIFORNIA; SOLON MARKS, WISCONSIN; L. S. PILCHER AND A. VANDERVEER, NEW YORK; JAMES McCANN, D. HAYES AGNEW AND J. EWING MEARS, PENNSYLVANIA; S. H. WEEKS, MAINE; HUNTER McGUIRE, VIRGINIA; L. McLANE TIFFANY, MARYLAND; N. P. DAUDRIDGE, OHIO; H. H. MUDD, MISSOURI; J. COLLINS WARREN, MASSACHUSETTS; B. A. WATSON, NEW JERSEY; D. W. YANDELL, KENTUCKY; N. SENN, ILLINOIS; CHAS. B. NANCREDE, MICHIGAN; W. H. CARMALT, CONNECTICUT.

APPENDICITIS.

DR. CHARLES McBURNEY lately discussed six cases of appendicitis before the New York Academy of Medicine,¹ and reached the following conclusions:

"The feebleness of old age, unusual obesity, complicating diseases, and unmanageable over-distension, may justify the surgeon in refusing to offer with the aid of the knife the relief perhaps most urgently called for. Probably the most conservative practitioner, knowing the lesion which existed in R. W.'s case would not advise, under similar circumstances, the trusting of his patient's life to any medical measure known to science. The extraordinarily great variety in the signs and lesions of the disease under discussion will probably prevent us from ever formulating a set of rules such as some writers delight in referring to as routine practice. It will, however, always be good routine practice to study critically every individual case of a disease which belongs to a class that often enough destroys life, and to be willing to carefully weigh the value of experience even if contributed by those who observe from a different standpoint.

"Let us remember that it is not so very long ago, quite within the clear recollection of many of us, that we were taught that idiopathic peritonitis was a common enough disease, and that peritonitis in general was to be treated by medical measures only. Since then we have added to our store of knowledge, first by one observer and then by another, much valuable information in regard to the causes of peritonitis, and the possibility of attacking these successfully. The surgeons, and chiefly those of America, deserve the credit of having added most largely to our knowledge of appendicitis, the most frequent of all causes of peritonitis in the male. To them chiefly belongs the credit of having demonstrated the practicability and safety of treating this disease by the incomparable method of removing its cause. If we would accomplish the most by our discussions on this topic, then physicians and surgeons must join hands, the physicians accepting the fact that the surgeon does not always wish to operate, and the surgeon gladly stepping aside when he sees

¹ Medical Record, April 16, 1892, p. 421.

that success can be attained by his colleague's gentler methods.

"Five years ago we stood a little timidly on the edge of the new country, determined to go on; but dreading the discovery of hidden dangers, perhaps of insuperable difficulties. To-day I do not hesitate to say that never in the history of surgery has a major operation so soon established itself in so strong a position, so well supported by sound knowledge and unimpeachable facts as the timely operation for appendicitis."

Dr. McBurney seems scarcely conscious that the impulse to explore this new country, upon the edge of which he and others stood timidly five years ago, came from a physician!

DR. HENRY INGERSOLL BOWDITCH.

THE following abstracts are from an obituary of Dr. H. I. Bowditch by Dr. W. T. Gairdner, of Glasgow, which appeared in the *Edinburgh Medical Journal* of April :

Although the number of those who made the acquaintance of this distinguished physician on his visit to this country in 1861 must now be sadly diminished, it may be permitted to us in this journal to offer a brief tribute to his memory, from one who is perhaps the only hospital physician now in a position to do so among those who gave a hearty greeting to Dr. Bowditch in the Edinburgh Royal Infirmary more than thirty years ago. The writer was thoroughly attracted at that time, not only by what appeared to him an eminently noble personality, but also by the narrative of successful results in the treatment of pleuritic effusions by the method of what was then called *Suction*, although under the more pretentious name of *Aspiration* it came, many years later, to be made a *boom* in Paris without the slightest reference to the first employment of the method in America. Dr. Bowditch always attributed the invention of this method and the appropriate instrument to Dr. Morrill Wyman of Cambridge, Mass., who performed his first thoracentesis by suction in 1850. But neither Dr. Wyman nor Dr. Bowditch seem have cared to put in a claim of priority, although, at the date of a most interesting and lucid letter to the author of this notice, bearing date May 22, 1862, no fewer than 160 operations had been performed upon 85 persons, and with remarkably favorable results. Dr. Bowditch was even then, although in the prime of life and vigor, by no means a young man, and the steady, persistent, and indeed brilliant work he had done connection with this subject deserved a better fate than to be lost sight of amid the struggles for *éclat* of a young French hospital physician not at all careful as what had been done before him. Dr. Bowditch made converts in Edinburgh in those days, and at least two of the hospital staff began to use thoracentesis by suction from that time onwards. One of the two is the writer of these lines, and Dr. Bowditch has been known to say that Dr. Budd of King's College, London, and the present writer were the first in this country to adopt the improved procedure. But Dr. Bowditch, though a most eminent thoracentesist, was far more than this. He was a most admirable and cultured physician in all respects, and not only showed in diagnosis and in treatment a wide and well-ordered knowledge and a cultivated judgment, but he appreciated also as comparatively few then did, the importance of the preventive service of humanity in its relations to the curative. The researches which he first brought before the public in 1862 into the connection of moisture in subsoils, and the effect of drainage, or the want of it, on the local distribution of phthisis in Massachusetts, became stimulus to further fruitful researches, which in England were undertaken at the instance of the medical officer of the Privy Council, by Dr. George Buchanan of London, now the chief of the medical service under the Local Government Board. Had Dr.

Bowditch done nothing else but these two things, his merit would still have been great; but in fact his was a most busy and valuable life, from many different points of view.

THERAPEUTIC NOTES.

A DELICATE TEST FOR ALBUMIN IN THE URINE.—Spiegler¹ suggests the following formula for the discovery of albumin in the urine as being the most delicate test we possess:

B	Hydrog. chlor. corrosiv.	8 parts.
	Acid. tartar.	4 parts.
Aq. dest.		200 parts.
Seach. alb.		20 parts. M.

The test-tube is filled one-third with the reagent. The urine is filtered and made strongly acid with acetic acid. It is then allowed to flow down the side of the tube, drop by drop, until it lies in a layer over the reagent. If albumin is present, a sharp white ring is seen lying between the two layers of fluid. If it is necessary to test heavy diabetic urine, more sugar may be added to the reagent, in order to raise its specific gravity. It is necessary to decompose any carbonate that may be present, in order that it may not form a precipitate with the sublimate. But the precipitate may be recognized by the fact that when shaking the liquid the apparently caseous precipitate will disappear and the fluid become clear.

CAMPHORATED OIL.—Taussia² states that he had used camphorated oil with good results in many cases of influenza in which collapse from cardiac paralysis appeared to be imminent, and in pneumonia, typhoid, etc. He gave the drug dissolved in oil of sweet almonds in the strength of one to two, and sometimes four to five per cent. Essence of peppermint was useful in disguising the taste. Liberal doses (two to four grammes *per diem*) were always given; the remedy was always well borne, and no disagreeable effects were observed. The remedy should be given before the patient is in *extremis*, when an active stimulant and expectorant is required, and when it is not contraindicated by the existence of great cerebral excitement. In cases of pneumonia, broncho-pneumonia, and typhoid fever, the drug produced increase of arterial pressure, freer expectoration, and a feeling of physical well-being which lasted a considerable time. Taussia insists that only the best Japanese camphor should be used, the artificial preparation having, according to him, no therapeutic value.

Correspondence.

BOARDING OUT THE INSANE.

PHILADELPHIA, April 14, 1892.

MR. EDITOR:—In your review, April 7th, of the Thirteenth Annual Report of the Massachusetts State Board of Lunacy and Charity, you are good enough to refer with favor to my paper upon "Lunacy Administration in Scotland"; but you remark, that, although I "touch upon the improved care received in the homes of such patients in this country" [the boarded-out insane], you "miss the warm advocacy of the measure and of its development in this country which my former reports and other contributions would lead you to expect."

¹ Wiener klinische Wochenschrift, January 14, 1892.

² British Medical Journal.

As many of my friends have made similar observations, I deem it proper to say that the State Board omitted to publish nearly all that part of my paper which spoke of the further application of the Scotch system in Massachusetts.

I have not changed my views regarding the care of the insane in private families.

It has never been my belief that the boarding-out system would relieve the lunatic hospitals and asylums to anything like the extent which some, unacquainted with the practical care of the insane, supposed possible; and it is my opinion that unless there is a change in the lunacy laws of Massachusetts, patients cannot be boarded out from the hospitals in greater numbers than the Board of Lunacy and Charity is now doing.

Although I am not now a resident of your State, I trust I may be permitted to say a few words upon this matter, for my former connection with the charities of the Commonwealth has acquainted me with their administration; besides other communities are interested in the family care of the insane.

The chief obstacle in the way of the boarding-out system in Massachusetts is, to my mind, the practice by overseers of the poor, of confining the insane in almshouses, more than 800 being so placed; and your characterization of that part of the Board's report dealing with poorhouses, as "the usual depressing chapter," is a truthful reflection.

There are, as I have stated elsewhere, only sixteen almshouses with lunatic wards, in Scotland, which can, by any possibility, be compared with Massachusetts almshouses; and in that country license is not granted for the care of less than sixteen lunatics in one almshouse, all of which establishments are subject to rigid rules made by the General Board of Lunacy, which has supervision over them. No patients suitable for family care are allowed to remain in Scotch poorhouses.

Were the same rules and restrictions to be applied in Massachusetts that are in operation in Scotland, there would be many to add to the boarding-out list. The 450 patients who are now in almshouses having less than sixteen insane inmates could nearly all be provided for in this manner, as could two-thirds (and probably more) of those resident in almshouses of greater capacity, making, with those now boarded in various places by overseers of the poor, a total of nearly 675, which, if added to those in private families under the care of the Board of Lunacy and Charity, would swell the list to nearly or quite 850, a showing which by no means suffers when all the conditions are kept in mind. Were the feeble-minded included, as they are in Scotland, the aggregate would be considerably larger.

As the system of treating lunatics in Scotland has certain prominent features considered of great value, I believe so far as circumstances will permit, advancement in this country should be along the lines found advantageous there. No lunatic should be kept in a local almshouse who can be provided for in a private family, and the indigent insane should be wards of the State, supported at the expense of the Commonwealth. With such arrangements the boarding-out system could be very much extended, and the lot of the pauper insane greatly improved. Family care of the insane has a fixed place in Scotland; and it should be made a positive factor in the lunacy administration of every State having, like Massachusetts, a rural population capable of furnishing a sufficient number of suitable guardians.

In any event, the administration of the system should be in the hands of a staff of experienced physicians, who, under the supervision of the Central Board, should devote their whole time to the work.

Very respectfully,

A. R. MOULTON, M.D.

The British Medical Journal expresses discontent with the assurances that the practice of spraying arsenic on American fruit-trees to kill insect life is harmless to the fruit, and demands a further official inquiry on the subject.

METEOROLOGICAL RECORD.

For the week ending April 9, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 2,646; under five years of age 1,000; principal infectious diseases (small-pox, measles, diphtheria and erysipelas, diphtheritis, whooping-cough, erysipelas and fevers) 338; diphtheria and croup 121; scarlet fever 62; diarrhoeal diseases 45; measles 35; typhoid fever 20; cerebro-spinal meningitis 15; whooping-cough 15; erysipelas 10; typhus fever 2; malarial fever 1.

From typhoid fever New York 5, St. Louis 4, Lowell 3, Brooklyn, Milwaukee and Nashville 2 each, Boston and Haverhill 1 each. From cerebro-spinal meningitis New York 7, Brooklyn 5, Milwaukee, Washington and Fitchburg 1 each. From whooping-cough Boston 7, Cincinnati and Washington 2 each, Brooklyn, Boston, Milwaukee and Fall River 1 each. From erysipelas New York 3, Boston and Cleveland 2 each, Brooklyn, Washington and Lowell 1 each. From typhus fever New York 2.

In the thirty-three greater towns of England and Wales with an estimated population of 10,185,736, for the week ending March 26th, the death-rate was 22.3. Deaths reported 4,348: acute diseases of the respiratory organs (London) 466; whooping-cough 102; measles 120; diphtheria 48; diarrhoea 32; scarlet fever 27; fever 10.

The death-rates ranged from 9.9 in Brighton to 37.2 in Huddersfield; Birmingham 22.4; Blackburn 18.8; Cardiff 24.5; Gateshead 19.4; Hull 16.3; Leeds 22.6; Leicester 20.6; Liverpool 26.8; London 21.3; Manchester 29.2; Newcastle-on-Tyne 17.9; Nottingham 23.0; Portsmouth 17.8; Sheffield 22.8; West Ham 19.9.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 9, 1892, TO APRIL 15, 1892.

FIRST-LIEUT. JAMES D. GLENAN, assistant surgeon, is relieved from duty at Camp Oklahoma, and ordered to Fort Sill, Oklahoma Territory, for duty at that station, relieving **CAPTAIN FRANCIS J. IVES**, assistant surgeon, who, on being so relieved, will report in person to the commanding officer at Fort Sheridan, Illinois, for duty at that post. S. O. 86, A. G. O. April 12, 1892.

Leave of absence for three months on surgeon's certificate of disability is granted **CAPTAIN ALONZO E. CHAPIN**, assistant surgeon, U. S. A.

Leave of absence for two months, to take effect on or about May 1, 1892, with permission to apply for an extension of one month, is granted **CAPTAIN WILLIAM C. GOBROS**, assistant surgeon, U. S. A.

CAPTAIN WILLIAM H. ARTHUR, assistant surgeon, is relieved from duty at Fort Grant, Ariz., and ordered to Vancouver Barracks, Washington, for duty as post surgeon at that station, relieving **CAPTAIN LOUIS BRECHERIN**, assistant surgeon. Captain Brecherin, upon being relieved by Captain Arthur, will return to his proper station, Presidio of San Francisco, Cal.

The resignation of **FIRST-LIEUT. WILLIAM N. SUTTER**, assistant surgeon, U. S. A., has been accepted by the President, to take effect July 28, 1892.

FIRST-LIEUT. MERRIT W. IRELAND, assistant surgeon, U. S. A., ordered to Fort Yates, N. D., for temporary duty during the absence of **CAPTAIN ALONZO E. CHAPIN**, assistant surgeon, U. S. A., on sick leave.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 16, 1892.

W. S. DIXON, surgeon, ordered to the Smithsonian Institution.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held on Monday, April 25, 1892, at the Medical Library, 19 Boylston Place, at 8 o'clock P. M.

Dr. M. H. Richardson: "A Case of Intestinal Obstruction, Laparotomy, Separation of Adhesions and Recovery."

Dr. G. L. Walton and Dr. F. E. Cheney: "The Importance of Correcting Ocular Defects in Functional Nervous Troubles."

G. G. SEARS, M.D., Secretary.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The annual meeting will be held at 19 Boylston Place, on Saturday, April 30, 1892, at 8 P. M.

Dr. G. W. Gay: "A Case of Nephrolithotomy; removal of a stone weighing five ounces; Recovery."

Dr. T. M. Rotch: "Improved Methods of Modifying Milk for Infant Feeding."

Dr. J. H. McCollum will show (by lantern slides) the various stages of the eruption of small-pox.

Dr. C. B. Belt, will read a circular of information in regard to the Pan-American Medical Congress: Dr. A. P. Clarke, of Cambridge, and Dr. Marcy will make remarks about it.

Electron of officers.

Supper after the meeting.

Members are requested to notify the Secretary at 188 Marlborough Street, of any error or change in address.

EDWARD N. WHITTIER, M.D., President.

JAMES J. MINOR, M.D., Secretary.

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION will hold its Eighteenth Annual Session at Cincinnati, Wednesday, Thursday and Friday, October 12, 13 and 14, 1892.

CHARLES A. L. REED, President, Cincinnati.
E. S. McKEE, M.D., Secretary, Cincinnati.

APPOINTMENT.

At a meeting of the Trustees of the Free Hospital for Women, held April 12th, it was voted to establish, in addition to the morning and afternoon out-patient clinics already existing, an evening out-patient clinic, to be held at 7 o'clock Mondays and Fridays. DR. CHARLES H. HARE was appointed Surgeon to Out-Patients in charge of this clinic.

RECENT DEATHS.

ORAMEL MARTIN, M.D. M.M.S.S., died in Worcester, April 15th, aged eighty-one years. During the war he served as surgeon of the third battalion of riders. He has been surgeon at the Worcester City Hospital, and was an honorary member of the Vermont Medical Society.

ELIJAH WHITNEY, M.D., died in New York, April 5th, aged ninety-three years. He was probably the oldest physician in the city. In early life he was a Presbyterian minister, but later graduated in medicine, and practised in New York from 1849, until a few years ago.

BOOKS AND PAMPHLETS RECEIVED.

The Year-Book of Treatment for 1892. Philadelphia: Lea Brothers & Co. 1892.

Aphasia and other Affections of Speech. By Charles K. Mills, M.D. Reprint. 1891.

Transactions of the American Association of Obstetricians and Gynecologists. Vol. iv. 1891.

Transactions of the American Surgical Association. Vol. ix. Edited by J. Ewing Mears, M.D. 1891.

The Pathology of Hip-joint Disease, with Illustrative Cases. By H. Augustus Wilson, M.D. Philadelphia.

Transactions of the New York State Medical Association, for the year 1891. Vol. viii. Edited by E. D. Ferguson, M.D.

A Text-book of Nursing. Compiled by Clara S. Weeks Shaw. Second edition. New York: D. Appleton & Co. 1892.

Transactions of the American Otological Society. Twenty-fourth Annual Meeting. Washington, D. C., September 22, 1891.

Tobacco, Insanity and Nervousness. By Dr. L. Bremer, late physician to the St. Vincent's Institution for the Insane, of St. Louis, Mo. 1892.

The Medical Annual and Practitioners' Index. A work of reference for medical practitioners. Tenth year. Bristol: John Wright & Co. 1892.

Concerning American Indian Womanhood: An Ethnological Study. By Wm. Thornton Parker, M.D. (Mass.). Beverly, Mass. Reprint. 1892.

Multiple Neuritis and Some of its Complications. Clinical Lecture delivered at the Philadelphia Hospital. By Charles K. Mills, M.D. Reprint. 1892.

ON RESECTION OF THE LIVER, ESPECIALLY FOR HEPATIC TUMORS.

WITH THE REPORT OF A SUCCESSFUL CASE OF RESECTION FOR AN ADENOMA OF THE BILE-DUCTS, AND A TABLE OF TWENTY RECORDED CASES OF HEPATIC OPERATIONS.¹

BY W. W. KEEN, M.D.,
Professor of the Principles of Surgery and of Clinical Surgery,
Jefferson Medical College, Philadelphia.

MRS. J. G., was sent to me by Dr. B. S. Erwin, of Mauch Chunk, October 2, 1891. Age thirty-one; married at fifteen; six living children; four miscarriages, the last one about the middle of August, 1891; weight January, 1891, 135 pounds; August, 1891, 125 pounds. She has been subject to malaria for six years, escaping it, however, in the past year. Otherwise her general health was good until three years ago, when she began to have pain, weakness, flushing, painful and irregular menstruation, and soon passed into a generally broken-down condition. She has had neither diarrhoea nor dysentery.

About two years ago she first noticed a lump on the right side of the abdomen. This remained for several weeks, and then was lost sight of. It reappeared a year ago, at first about the size of a walnut, but growing slowly. Her pregnancy, which ended in a miscarriage in August, 1891, seemed to cause a rapid increase in its size. There has been at times retention of urine, and of late the quantity has been very small. She has never had any jaundice or especial digestive troubles. Pain and excessive discomfort have caused her to seek relief; she is broken down in general health and utterly wretched.

On examination, an oval tumor, about the size of a fist, was found on the right side of the abdomen, in the situation of the kidney, separated from the liver dulness by an area three fingers broad, of distinct tympanitic resonance. By bi-manual examination pressure posteriorly is felt in front, and vice versa. The tumor was quite movable, moderately tender and of about the consistency of the kidney; no especially soft portion was found. The renal artery could not be detected. Vaginal examination showed no connection of the tumor with either uterus or ovaries. The perineum was somewhat torn posteriorly; the mouth of the uterus showed a moderate tear; and there was rather profuse leucorrhœa.

A microscopical examination of the urine was made by Dr. Kyle, who reports as follows: "Specific gravity 1,010; leucocytes single and in casts; blood-casts (many); blood-cupopuses; epithelium, squamous and ciliated; a few small renal epithelial cells; numerous crystals of uric acid, urate of ammonia, etc.; urea, 1.6%. Diagnosis probably a floating and diseased kidney. An exploratory operation was recommended.

Operation, October 9, 1891, assisted by Drs. Wm. J. Taylor and J. Chalmers DaCosta. Chloroform was used instead of ether, in view of the condition of the kidneys, as shown by the urine. I operated by a vertical incision in the right linea semilunaris, reaching nearly to the border of the ribs and nearly to the ilium. The incision was four and a half inches long. The moment the peritoneal cavity was reached a multi-

ple cystic tumor was seen. The surface was reticulated by partitions between the cysts, the cysts being on an average about the size of the little finger-nail, some larger and some smaller. The color was a light bluish-white (see Plate). The moment the hand was introduced into the abdomen it was discovered that the tumor had no connection with the kidney. The right kidney appeared to be somewhat smaller than normal but was in its right place. On drawing the tumor out of the abdomen, it was instantly seen to be connected with the liver, involving its extreme right border. In size it was three and a half inches vertically and nearly the same transversely. At its base, where it joined the liver substance, it was two and a half inches thick. It was evidently a localized tumor. Just at its internal border was the gall-bladder, which was normal, but so close to the tumor that I dissected it loose for half an inch in order to operate with greater ease. A few small vessels required ligation at this point.

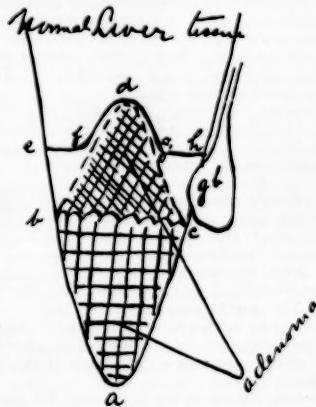

FIG. 1.

Diagrammatic Section of the Liver and the Adenoma. *a b c*, the limits of the tumor as seen externally; *e b c*, its wedge-like prolongation into the liver; *d e*, lines of section of liver substance by the cautery; *f g*, the portion enucleated by the finger-nail; *g b*, the gall-bladder; *d f c* and *d g h*, the "flaps" left after removal of the neoplasm.

Having gone so far as to open the abdomen and having found the source of the trouble, and the tumor appearing to me to be possibly, and I might even say probably, non-malignant, I determined to attempt its removal. My first idea was to ligate the thick border of attachment, where liver and tumor were continuous, and then to divide this pedicle, if it could properly be called a pedicle, by the Paquelin cautery. I therefore put one stitch directly through the liver-substance next the gall-bladder, induced especially to begin here by reason of a very large artery which had been exposed but not wounded during the separation of the gall-bladder from the liver. Having tied the liver here, I tried the effect of the Paquelin cautery, and was so well satisfied with it that I made no further attempt to ligate the liver-substance but continued cutting with the cautery. As I cut, four very large veins were laid bare, and were ligated before being burned through. When I had cut about half way through in depth, I

¹ Read before the Surgical Section of the Suffolk District Medical Society, March 2, 1892.

found that my cautery knife was cutting into cysts of the neoplasm, and that the latter extended as a wedge into the liver to a greater distance internally than was apparent from the outside (Fig. 1). Accordingly I made an attempt to strip the liver-substance from the tumor with my thumb nail, and found that I could do so with perfect ease and without serious hemorrhage. This enucleation left the tumor attached to the liver at its posterior border only. I then burned through the posterior attachments of the tumor with the cautery. A few points required extra touching with the dull red platinum point. The liver-stump, roughly speaking, resembled that of an amputation with its two flaps. These two edges or flaps were then approximated by five sutures passed deeply through the substance of the liver.

The intestines had been protected meanwhile by a large flat sponge. This had kept the most of the blood out of the belly cavity, and the amount lost I estimated at six to eight ounces. The belly cavity was flushed with hot water, and the wound closed after inserting a glass drainage-tube. A sublimated wood-wool dressing was now applied, and the patient put back in bed in very fair condition. Within fifteen minutes her lips had assumed a good, though pale, red color. The operation lasted about an hour.

December 10, 1891. After the operation, two doses of one-eighth of a grain of morphia hypodermically relieved her pain, and one of one-fourth of a grain of cocaine by the stomach checked her vomiting. From the drainage-tube in the first twenty-four hours about three ounces of bloody serum were removed, in the second twenty-four hours less than one ounce; and therefore at the end of forty-eight hours, the tube was removed. No bile or bile-stained fluid was seen at any time. The bowels were moved on the second day by drachm doses of sulphate of magnesia, the stools being then and afterward of a normal brown color, without any visible disturbance of the hepatic function.

The temperature on the night after the operation rose to 101.2°, on the two following days to 100°, and after that was not above 99°, excepting during what was apparently a malarial attack, which began eleven days after the operation and lasted four days. During this attack the temperature rose to 101.2° again. The stitches were removed at the end of a week. In fact, with the exception of the malarial attack, her recovery was an uninterrupted one. I kept her in bed for about three weeks in order to avoid any possibility of ventral hernia, and also, as I had no experience in such operations on the liver, I feared that either from the charred surfaces or from want of union of the tissues, followed by escape of bile into the peritoneal cavity, there might be some digestive or other abdominal difficulty. No such trouble, however, appeared, and she went home forty-two days after the operation, entirely well. I heard from her in February, 1892, and she has continued in the best of health, with no disturbances of either liver, stomach or bowels.

The tumor was entirely strange to me, and unlike anything I had ever seen before. Naturally my first idea was that it might be made up of echinococcus cysts, but certainly unlike any I had ever met with. I therefore gave it to Dr. W. M. L. Coplin, Adjunct Professor of Hygiene in the Jefferson Medical College, who

was assisted by Dr. D. Bevan in its examination. Upon receiving their report, I found that the tumor was exceedingly rare, and interesting pathologically as well as surgically. Accordingly I sent it to Prof. W. T. Councilman of the Johns Hopkins Hospital, who also has kindly sent me the results of his examination. I append both reports, as the examinations were made entirely independently of each other, and their concurrences are therefore the more valuable.

Professor Coplin has also, at my request, prepared a few remarks on the pathology of hepatic cysts of new formation, excluding hydatid cysts.

PATHOLOGICAL REPORT OF PROF. COPLIN AND DR. BEVAN.

"The tumor is ovoidal in outline, and measures 9 cm. (3½ in.) in width, 11.5 cm. (4½ in.) in length, 4.5 cm. (1¼ in.) in thickness. Weight, 113 grm. (3 oz., 255 gr.). Surface smooth, with slight tuberous elevations corresponding to cysts located beneath. The surface of removal irregular, showing at points attachment of liver-tissue. Several very large veins are to be seen entering at various points. Upon the external surface an incision has been made disclosing numerous cysts varying in diameter from 1 mm. or less to 20 mm., and containing a milky, flocculent fluid about the consistency of blood-serum. Under the microscope this contained white blood-corpuscles, and a few red, these probably having gained ingress in the opening of

FIG. 2.
Cells from the Cystic Fluid. The figure on the extreme right represents the size of red blood corpuscle.

the tumor. There was also present a much larger cell, at least three times the size of a white blood-corpuscle, irregular in outline for the most part, although a few could be seen with a sharply defined wall and round in outline (Fig. 2). Many of these bodies contained well defined nuclei, although these were by no means constantly present. When nuclei were present, the peri-nuclear protoplasm was always granular; those having no nuclei were finely granular, at points containing vacuoles. On the warm stage of the microscope these cells did not evince any movement; however, their varying contour is highly suggestive, and a more positive result might have been attained had the test been made early after removal.

"Many of the cysts communicate by small round openings through the thin part of the wall; these communications are not, however, universal, as the entire contents cannot be evacuated by the single incision, and fluid thrown in one cyst will not distend more than three or four other cysts. The walls of the cysts vary greatly, at points being extremely thin; elsewhere they may be found fully 6 mm. to 10 mm. in thickness. The density of the tissue between the cysts also varies, being for the most part firm and elastic.

"Microscopic examination reveals a cylindrical cell epithelial lining, at points projecting into the cyst cavity, and closely resembling dendritic growths, as seen in certain forms of papilloma (Fig. 3). It is, however, to be remembered that sections of gland acini would give exactly this appearance. The cylindrical cells are

high and not ciliated. They are arranged upon a fairly well defined basement membrane, back of which is found a varying thickness of connective tissue containing blood-vessels, unstriped muscular tissue and fibrous tissue, in varying amounts and stages of growth, at points still made up of embryonic cells. The sections do not show any hepatic cells present in the tumor itself.

FIG. 3.

a, Large cyst lined with columnar epithelium; b, small cysts; c, blood-vessel with greatly thickened walls; d, liver cells with dilated vessels between them.

Bacteriological Examination.—Sections stained by Gram's method, tissue stained by picro-carmine, show cocci present in large numbers. These are arranged for the most part in zoogaea around the blood-vessels and lymph-spaces; as single cocci and in short chains, they are also to be found between the epithelial cells and their basement membrane. The surface of the tumor being seared with cautery and a small cyst opened by a sterile needle, culture-tubes were inoculated. These gave a pure culture of cocci, growing rapidly on agar, as an ashen gray opaque growth, slightly elevated on the surface and penetrating the medium as a dense cloud and not liquefying the surface. They stained well both by Gram's method and Loeffler's alkaline stain. They measure 1 μ . in diameter, that is, they are slightly larger than the staphylococcus albus."

The patient had had neither attacks of dysentery nor of diarrhea from which any infection by these micro-organisms could be accounted for.

REPORT OF PROF. W. T. COUNCILMAN.

"The tumor is oval and somewhat flattened. The surface is smooth, but uneven from numerous rounded projections. The surface of removal is irregular, the edges here and there showing the marks of the cautery. This surface consists of liver-tissue with considerable connective-tissue. Several large vessels enter the tumor at this point.

"On section of the tumor, it consists of numerous cysts of varying size and of irregular shape. Many of these open into one another, and from the surface of one cyst there are deep projections into the sur-

rounding tissue. The cysts vary in size from 1 mm. (or smaller) to 3½ cm. They are relatively more frequent and larger in the periphery of the tumor. They contain (after hardening in alcohol) a soft, white, curdy mass. The wall is smooth and tolerably thick. The centre of the tumor and the tissue everywhere separating the cysts is dense and fibrous.

"On microscopic examination the cysts are lined with high, cylindrical epithelium, which in many places projects in small papillomatous formations within the cyst. None of the epithelial cells are ciliated. The tissue between the cysts, and forming the stroma of the tumor, is dense connective-tissue with numerous bands of non-striated muscular fibres. In the stroma there are some places rich in granulation cells.

"The tumor is one of the rare cystic tumors of the liver, and evidently originates from the bile-ducts, and most probably from the large vasa aberrantia found on the edge of the liver. The irregular shape of the cysts is due to their rupture into one another."

Professor Coplin has kindly furnished the following:

REMARKS ON ADENOMATA.

"Of the cystic adenomata of the liver we know very little, and the confusion is deepened by the fact that the German writers Ziegler, Klebs and others, consider cylindrical-celled carcinoma as adenoma, and draw little or no line of differentiation except that of infiltration. The earliest attainable literature is in Klebs who quotes E. Wagner² as having observed in the liver enlargements, the structure of which resembled the so-called glandular tumors of the mammary gland; Klebs is inclined to think that all adenomata of the liver are malignant, and does not refer to any that at all resemble the present case. Ziegler states that adenoma of the liver may be made up of tubular glands instead of lobules.³ Although he lays no stress on these tumors, save in their rarity, he gives a most typical cut presenting the exact histological structure of the present case, and designates the growth as papilliferous cystadenoma. As to the exact origin of these growths, nothing is known. Whether they arise from the ducts or from the liver-cells within the lobules, as Rindfleisch thinks, cannot be demonstrated. The reported cases do not appear at all like the present one; they are solitary cysts disseminated throughout the organ, lined for the most part by pavement epithelium, rarely by cylindrical cells, more rarely by ciliated cells.⁴ In the latter case, one can hardly call it an adenoma, or even a cyst."

Dr. David Bevan has kindly made an excellent drawing from a section (Fig. 3) and has furnished me with the following description of the microscopic appearance of the tumor:

"The stroma is composed of white fibrous connective-tissue, in which small openings are perceived, presumably (?) beginning cysts. Occupying the centre and extending to the right lower part of field, is observed a large cyst (a) lined with columnar epithelium. The margin of the cyst is very irregular, a number of small papillæ extending into it. In its extreme lower end is noted a papilla of considerable size; above the large cyst are two smaller ones (b), to the right of which is an artery with greatly thickened wall. Still further to the right is a bundle of unstriped muscular

² Arch. d. Heilk., 1861, S. 471.

³ Path. Anat. und Pathogenesis, Art. 167.

⁴ Friedreich: Virchow's Archiv.

tissue and a blood-vessel. To the left of the central cyst is another bundle of unstriped muscle. Just beyond this is the limit of the neoplasm where the fibrous tissue is very dense, sharply defining it from the liver proper (*d*). In the lower left of the field (*c*) is a large artery with enormously thickened coats. The lumen is greatly altered in form. The liver-cells (*d*) are changed in shape, and the capillaries between them much enlarged."

Dr. Thompson S. Westcott has kindly prepared the accompanying table, which, I believe, contains all the cases of resection or amputation of the liver which have been recorded up to this time. Based upon this and upon my personal experience in my own case, I shall add a few

REMARKS.

(1) *Date and locality of operation.*—Of the 20 cases two are American, and the others European, chiefly German and Italian. I have not found any English case. The first American case was reported by Tiffany, of Baltimore, in 1890 (No. 15). The first recorded case was by Langenbuch, in 1888, less than four years ago.

(2) *Age.*—This varied from twenty-one to fifty-eight years. The decade from twenty-one to thirty furnished six cases; that from thirty-one to forty, five cases; that from forty-one to fifty, three cases; and two were between fifty-one and sixty.

(3) *Sex.*—In striking contrast to age, sex is evidently a potential factor. Of the 19 cases in which this is given, three were men and 16 women. Taken in connection with the well recognized greater frequency of gall-stones in women, one can scarcely avoid attributing both affections to the pressure upon the liver, resulting from tight-lacing. In fact, Langenbuch's case (No. 1) was not really one of a tumor of new formation, but was a portion of the liver itself in process of gradual separation from the main organ, presumably by the pressure of the clothing; and Laueenstein's (No. 11) probably a similar one.

(4) *Size and weight.*—The tumors and portions of liver removed have varied in size from that of a small nut up to the "size of three fists," or of "a man's head." In weight, they have been as large as $3\frac{1}{2}$ oz., as in the present case, to $11\frac{1}{2}$ oz., and even 3 lbs.

(5) *Diagnosis.*—Of the twenty cases nearly all were incorrectly diagnosed. In three it was thought that there was a tumor connected with the liver, and in one with the gall-bladder. In others, the diagnosis had been a tumor of the pancreas, the mesentery, the omentum, the pylorus, the colon, the ovary, or the kidney. In my own case my diagnosis was a floating and probably diseased kidney. The reciprocal pressure, so easily felt in the loin and anteriorly, the mobility of the tumor, its apparent resemblance to the kidney in size, the blood-casts, leucocytes and renal epithelium in the urine, combined especially with the fact that there were over two inches of distinct tympany between the tumor and the border of the liver, all looked towards the kidney and away from the liver as the organ involved. I find that a similar tympany is distinctly stated to have intervened between the tumor and the liver in six cases of the twenty, and probably existed in some of the others.

While this physical sign should have its due weight, the presence of tympany must not be deemed to exclude tumor of the liver.

The symptoms, also, are not usually at all characteristic of the hepatic origin of the tumor. There has been no jaundice and no digestive symptoms other than those which would naturally arise from almost any abdominal tumor.

(6) *Variety of tumor.*—In two cases the part resected was a constricted and partly separated portion of the liver, and was not therefore, properly speaking, a tumor. Of the remaining eighteen, one-half (nine) were echinococcus and hydatid cysts; three were cases of cancer; three of syphilitic tumor; and one each of sarcoma, small calculi and adenoma of the bile-ducts.

But the chief interest naturally centres in the fact, the methods and the results of removal, since this constitutes an entirely new chapter in abdominal surgery.

(7) *Can any large portion of the liver be removed without a fatal result?*—The results of experiments upon animals rendered it probable, not only that in man also a portion of the liver could be removed without so seriously interfering with its function as to be incompatible with life, but that a very considerable portion could thus be removed without unreasonable danger. Ponfick⁵ showed that in the rabbit the removal of a quarter of the liver caused a slight deterioration in the general condition of the animal; removal of one-half was followed by much more serious results, which, however, passed off within a few days: even removal of three-quarters of the liver could be recovered from, though the prostration was very severe at first; but that removal of more than this amount (three-quarters) was always fatal. He showed, also, that not only could the animal bear the loss of a large part of the liver, but that there was a reparative power in that organ by which new hepatic tissue could be produced.

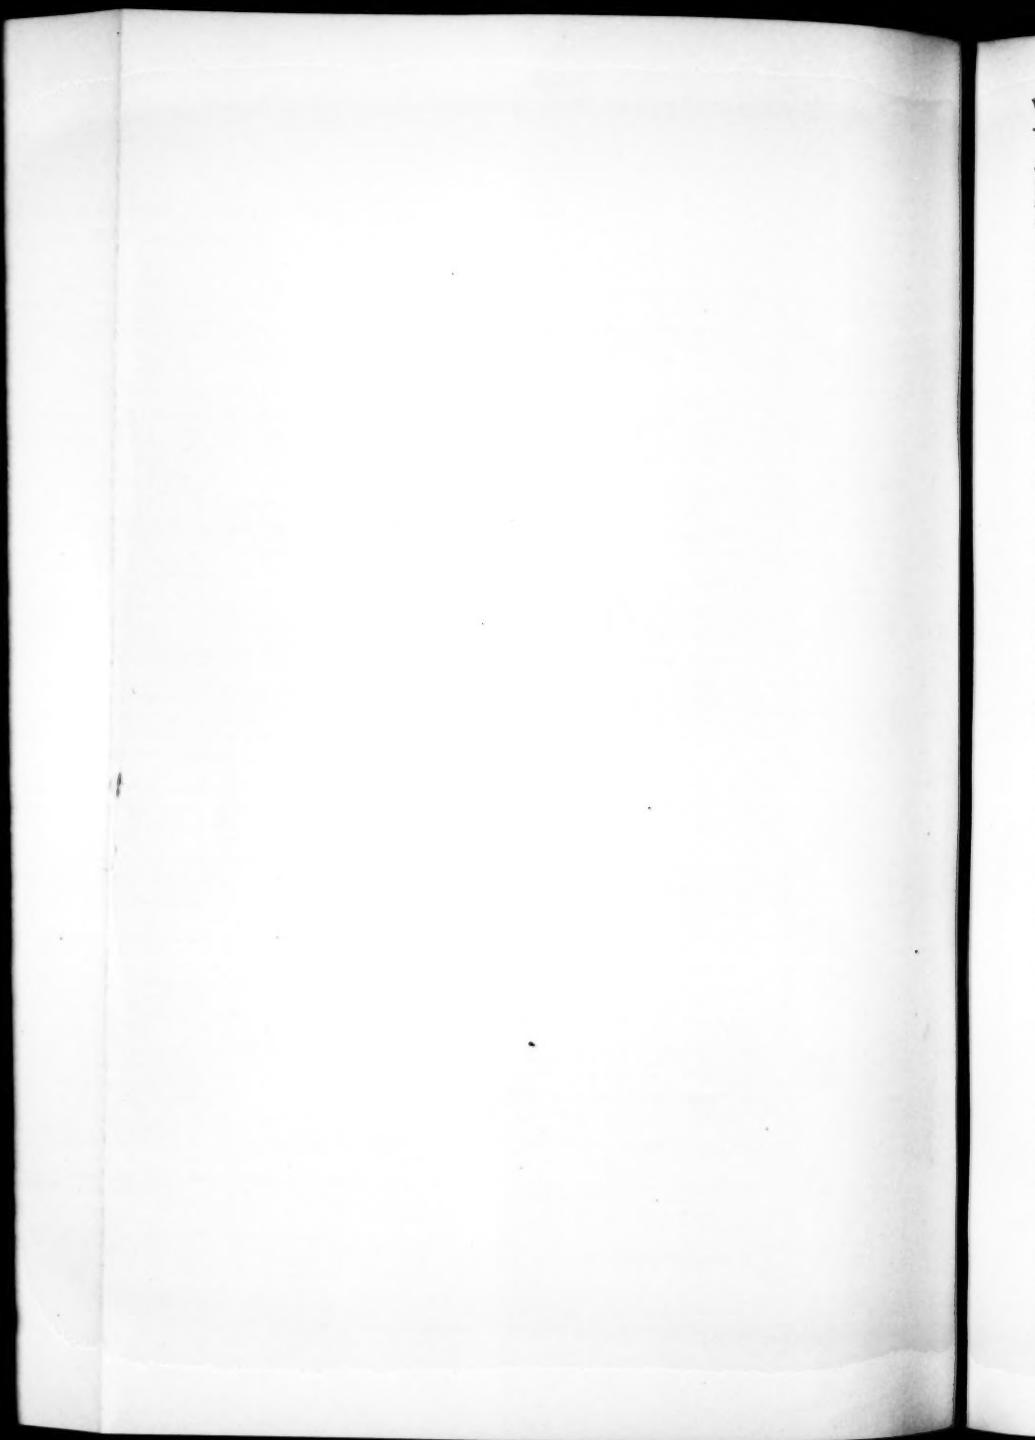

Later,⁶ Von Meister, from his own experimental observations has confirmed some of the results previously obtained by Ponfick, of the remarkable degree of reparative power exhibited by the liver, a power which may exist in other glands in greater or less degree, and he has even gone further. He found that in the dog and cat, as well as in the rabbit, the removal of even more than three-fourths of the liver was not followed by any serious consequences, and that within the space of thirty-six days repair had advanced to such an extent that the weight of the organ was regained. This regeneration is effected partly by hypertrophy of the hepatic cells, but mainly by their hyperplasia; but new lobules are not formed, and biliary ducts as well as blood-vessels share in the new formation. Observations were also made upon the effect of extirpation of such large portions of the liver upon the excretion of urea. It was found that the total quantity of nitrogen notably diminishes, but not in proportion to the nitrogen of the urea, so that the proportion of the latter to the whole nitrogenous excretion is decreased. On the other hand, the amount of extractive matters is increased, and their nitrogenous constituents appear in greater proportion than normal to the total nitrogen. The diminution in urea is proportional to the amount of liver substance removed, total extirpation of the organ leading to a very marked decrease in urea. It was further found that after partial extirpation — within a period of from eleven to fifteen days — the quantity of urea rises until it once more attains the normal degree.

TABLE OF TWENTY REPORTED CASES OF REMOVAL OF TUMORS OF THE LIVER.
COMPILED BY THOMPSON S. WESTCOTT, M.D., OF PHILADELPHIA.

No.	Reporter and Reference.	Sex.	Age.	Duration, Nature and Size.	Method of Removal.	Treatment of Liver Stump.	Result.	Remarks.
1	Langenbuch. Berlin klin. Woch., 1886, No. 3, p. 37.	F.	30	Eight years. A constricted part of left lobe supposedly due to carcinoma, until tumor began to be palpable and was first observed; weight, 370 grammes.	Ligamentous connection divided into several portions and ligated.	Returned to abdomen.	Recovery.	Abdomen reopened for internal hemorrhage a few hours after operation. Liver resected and stump returned. Exploration of abdomen revealed no signs of pancreatic tumor, movable tumor of mesentery or echinocoeum of liver. Possibility of a tumor of liver developed by hæmorrhage.
2	Loreta. Memorie della R. Accademia delle Scienze dell' Istituto di Bologna, 1886-1888, serie quarta, tomo viii, p. 581.	M.	40	Two years. Appeared externally the size of a fetal head. Echinocoeum cyst. Underlying tissue of left lobe infiltrated for an extent of 15 by 14 centimeters.	This area was included between an interlacing continuous suture, drawn tightly and tied. Removal by biopsy.	Hæmorrhage checked and edges of Gillson's capsule at edges of wound on convex and concave surfaces stitched together and to abdominal wall. Colloidion and iodiform dressing.	Recovery.	Diagnosis: Suspected echinocoeum.
3	Garré. Beiträge zur klin. Chir., 1888, Bd. iv, p. 181; abstr. in Annals of Surgery, xi, 1890, p. 127.	F.	44	Echinocoeum cyst, with pedicle.	Pedicle tied and touched with thermo-cautery.	Disinfected and returned to abdomen. No drain.	Recovery.	Tympanitis between liver and tumor; not believed to be connected with liver, but probably mesenteric or omental.
4	The same.	M.	50	Six months. Hazle-nut-sized cancerous nodule of right lobe, metastatic, from a larger tumor of abdomen.	Excision by knife.	Seared with thermo-cautery and returned.	Recovery.	Main tumor not removed, its point of origin not being determined. Diagnosis before operation: Carcinoma of mesentery.
5	Pozzi. Gazette Méd. de Paris, June 20, 1888; also Cong. Franc. de Chir., Proc. Verb., 1888, p. 945.	F.	34	Large echinocoeum cyst.	Scissors.	Ligation, thermo-cautery and suture, with suture of liver wound in abdominal wound, and drainage.	Recovery.	Discharge of bile and removed liver tissue through the drain. Fistula closed.
6	Ruggi. Dell' Epatectomia Parziale nella cura delle cisti d'echinococo, Bologna, 1889.	F.	22	Two years. Double echinocoeum cyst, in oblique diameter above 19 cms., springing from anterior surface a portion of liver 18 by 10 cms., excised 3 pounds.	Excision. Vessels tied with catgut.	Edges of cavities sutured to peritoneal edge of abdominal wound, and treated externally.	Recovery.	Diagnosis of echinocoeum of kidney, as the tumor was found in upper portion with liver, being separated by a tympanitic area (intestinal loop). Free discharge of bile through wound.
7	Boggi. Wiener med. Presse, No. 21, 1889; abstr. in Ann. Jour. Med. Sciences, Sept., 1889.	F.	--	Double echinocoeum cyst, weight 3 pounds.	Enucleated. Portion of liver parenchyma 3 in long resected.	Edges of liver cavity sutured in abdominal wound.	Recovery.	Free discharge of bile through wound.
8	Fohr. Handbuch Chirurgie, 1890, 22: 610-612; in Annals of Surgery, 1890, xi, p. 28.	F.	21	Tumor 9 years, rapidly increasing after confinement 11 mos. before. Echinocoeum cyst, size of child's head, extending below a line from one iliac spine to the other, and above the umbilicus with liver.	Excised with a portion of greatly atrophied liver tissue.	Wound united by a continuous suture so as to form a crest-like elevation. Abdominal wound closed.	Recovery.	
9	Wagner. Beilage zur Centralbl. f. Chirurg., 1890, p. 68; also Revue de Chir., 1890, x, p. 767.	F.	43	Four years. Right lobe, probably syphilitic. Three fistulae, with pedicle.	Division after ligation.	3 x 10 to 12 cms. Returned to abdominal cavity.	Death, same day.	Gall-bladder could not be found.
10	Déses. Union Médicale du Nord-est, 1890, No. 3, p. 91.	F.	23	Seven or eight years. Hydatid cyst, size of a large orange, broad, arising from the sharp border of left lobe, and enveloped by two folds of the gastro-hepatic omentum.	Pedicle at first incised by cautery, but part of hemorrhage ligated by two turns of catgut and removed by scissors.	Lavage. Abdominal incision closed.	Recovery.	Diagnosis of cyst of ovary, as it appeared attached in region of right ovary. It lay in front of stomach and behind transverse colon. Seemed independent of liver, and no hydatid fistulae felt.
11	Lauenstein. Beilage zur Centralbl. f. Chirurg., 1890, p. 73.	F.	--	Large freely-movable lobule attached to lobus Spigelii.	Operation in two stages. Thermo-cautery.	Extra-peritoneal.	Death, 12th day.	Diagnosis of liver tumor.
12	Tillmanns. Beilage zur Centralbl. f. Chirurg., 1890, p. 73.	?.	--	Large syphilitis.	Excision by knife.	Attempted suture, but sutures torn out. Stump fixed in abdominal wound.	Recovery.	Diagnosis: Cancer of pylorus or colon. Tympanite between tumor and liver. Gall-bladder removed.
13	Hochberg. Wiener klin. Woch., 1890, No. 23, in Centralbl. f. Chirurg., 1890, p. 751.	F.	58	Nine mos. Under surface of liver, 12 cm. in diameter, infiltrated, 3.5 by 4.5 cms., Carcinosomatous.	Isthmus tied, liver fixed to abdominal wall, and tumor amputated.	Stitched in abdominal wound.	Recovery.	Diagnosis: Probable tumor of omentum, not of liver, as note between liver and tumor was tympanitic.
14	Skilforsky. Wratch. No. 27, 1890, p. 594; in Annals of Surgery, xiii, 1891, p. 151.	F.	24	Seven mos. Fibro-myoma lipomatodes sarcomatoides. Size of man's head, with isthmus 23 fingers' breadth.	Excised with curved scissors, and surface cauterized. Abdominal incision of 5 in. in line of fibres of left rectus abdominis.	Cavity size of a walnut left, walls of which were cauterized.	Recovery.	Diagnosis not made. Operation exploratory.
15	Tiffany. Maryland Med. Journal, 1890, No. 23, p. 531, and International Med. Mag., April, 1892.	M.	25	Six mos. Tumor noticed to lie in middle line and slightly in epigastric region; nodule on convex surface of liver; contained a small amount of fluid, and was adherent to liver.	Contour of tumor burned through with cautery, and tumor enucleated. Hemorrhage stopped by gauze and pressure.	Fixed to abdominal wall.	Recovery.	
16	Hochberg. Wiener klin. Woch., 1890, No. 52, 1890; in Centralbl. f. Chirurg., 1891, No. 18, p. 365.	F.	27	Gumma 9 cms. Tumor imbedded in capsule, and covered with normal liver substance.	Total extirpation. Excision of a portion of liver.	Wound closed with sixteen sutures, partly silk and partly catgut.	Recovery.	
17	Tansini. Brit. Med. Journal, 1891, i, 81.	F.	--	Hydatid cyst.	Pedicle sutured to abdominal opening, tumor protruding.	Surrounded with iodiform gauze and tied with rubber drainage tube progressively tightened.	Recovery.	Free hemorrhage from cut surface controlled by esign ligature. Operation followed by no rise of temperature.
18	Lücke. Centralbl. f. Chir., 1891, No. 6, p. 115.	F.	31	Two years. Cancer left lobe size of fist, pedicle 20 centimeters in circumference.	Affected portion, clearly demarcated from healthy tissue, surrounded by rubber tube.	The artificial pedicle measured 24 cms. in circumference. Mass fixed to tip of incision by sutures. Iodiform dressing. Strangulated part withered; resected on seventh day. Edge of liver wound united by five silk sutures. Stump returned to abdomen.	Recovery.	Thermo-cautery used at first; abandoned on account of bleeding. Pedicle divided with cautery on ninth day. Diagnosis of distended gall bladder made by several other surgeons.
19	Terrillon. Rapport de Duplay. Bulletin de l'Académie de Médecine de Paris, 1891, xxv, p. 75.	F.	53	Six years. Following supposed injury. Multiple hydatid cysts, involving a portion of the liver about the volume of two fists.	Thermo-cautery and enucleation.		Recovery.	Diagnosis of flitting and probably diseased kidney. Tympanite between tumor and liver.
20	Keen. The present case.	F.	34	Two yrs. Increased during pregnancy. Size 9 by 111 cms., and 44 cms. thick at base; weight 113 grms. (31oz.); adenoma of bile-duets.	Pour very large vessels tied with catgut.			

(8) *Will not the escape of the bile produce dangerous or fatal peritonitis?* — Even the escape of bile into the peritoneal cavity, which would naturally excite great apprehension, seems to be more of a theoretical than a practical objection. In only two cases of the twenty was any such discharge of bile observed. This gave no trouble, as it escaped externally in both instances. Pavé has stated that no harm arose from such a free escape of the bile into the peritoneal cavity in his experiments in dogs; and Lane⁷ has reported a case of probable rupture of the gall-bladder, in which, after five weeks, he evacuated over three gallons of bile-stained fluid, yet the patient recovered. Moreover, there is probably a considerable escape of bile into the abdomen in some of the cases of cholecystotomy which recover; yet it is an accident that should be avoided if possible.

This fear of the escape of bile led me to insert a glass drain in the present case. Part of the tumor was removed by enucleation and part by the cautery; and I feared that either surface or both would allow of the escape of bile since the sutures did not, of course, accurately approximate the surfaces. The result showed that the precaution was needless, and after forty-eight hours the drain was removed, no bile or bile-stained fluid having been observed.

It being conceded, then, that more or less of the liver could be removed without sacrificing life, either primarily or by its after consequences, the next point is

(9) *The method of removal and especially the means for the prevention of hemorrhage.* — In my own case there was absolutely no trouble in this respect. The base of the tumor was severed by repeated small touches of the cautery-point; the large vessels were all seen and ligated before their division by the cautery; and the small ones either did not bleed or ceased bleeding upon slight touching with the dull red platinum point or after pressure with a sponge dipped in hot water. From the portion that was enucleated by the thumb-nail, absolutely no hemorrhage other than slight oozing took place, and I would especially commend this procedure. It was simple, easy and rapid. The methods adopted in the other nineteen reported cases have been various; and often, as in the present case, two or more have been combined with great advantage; thus the tumor has been excised; ligated and excised; ligated and cauterized; ligated, excised and cauterized; and in three cases was enucleated.

(10) *Treatment of the stump.* — In nine cases, after completion of the operation by the methods already named, the stump was returned to the abdominal cavity. In three cases the lips of the hepatic wound were first sutured, in one of them (No. 17) with as many as sixteen sutures. Of these nine all but one recovered. In six cases (Nos. 2, 5, 6, 7, 13, 16) the stump was sutured in the abdominal wound at the close of the operation. In two (Nos. 5, 7) there was a free discharge of bile through the wound. All of these recovered. In four cases (Nos. 12, 14, 18, 19) the liver was attached to edges of the abdominal wound before the removal of the tumor. In one case (No. 14) ligation of the pedicle, fixation to the abdominal wall and immediate amputation of the tumor was practised; but in the other three a true extra-peritoneal treatment was carried out. In one case (No. 12) it was done in two stages, that is, primary suture to the abdominal wall and a later amputation. Lücke (No. 18) sutured the pedicle to the abdominal

wall, surrounded the protruding tumor with iodoform gauze, and tied the pedicle with a rubber-tube, which was gradually tightened. Terrillon (No. 19) made an artificial pedicle (24 cm., [9½ in.] in circumference) by constricting the attachment by rubber-tubing and sutured it to the abdominal wound, the tumor protruding externally. Under an iodoform dressing this gradually withered, and was removed on the seventh day. All of these four extra-peritoneal cases recovered.

(11) *Results.* — In one case (No. 12) the result is not known. Of the other nineteen, seventeen recovered, and only two died, one on the day of the operation, presumably from shock, the other on the twelfth day, from sepsis.

(12) Conclusions:

a. Both experiments on animals and operation on man have shown that tumors of the liver, and even large portions of the liver itself, can be removed without undue disturbance of the function of the liver; the experimental evidence makes it probable that the liver tissue may be regenerated and the loss made good.

b. That the escape of bile into the peritoneal cavity is not a usual phenomenon after such an operation; that it may generally be prevented either by searing the raw surface of the liver, by ligation, or by securing the stump in the abdominal wound, and that, even if the bile so enters the peritoneal cavity, the result is not necessarily fatal.

c. Haemorrhage need not be greatly feared. The vessels can often be tied separately or in mass, or cut through by the cautery, or controlled by pressure, or by a combination of these means.

d. The resection or amputation is best done by enucleation, by the cautery or by the knife or scissors, preferably perhaps in the order named. In case of a tumor with a very large base of attachment, the operation may be done in two stages, the base being surrounded by an elastic ligature in the interval.

e. The mortality thus far has been only about ten per cent.

GALL-BLADDER SURGERY.

(a) ONE CASE OF IMPACTED GALL-STONES; PERFORATION; DEATH WITHOUT OPERATION. (b) FOUR EXPLORATORY OPERATIONS ON THE GALL-BLADDER. (c) SIX CHOLECYSTOMIES FOR GALL-STONES.

BY MAURICE H. RICHARDSON, M.D.

My attention was first called to the importance of gall-stones by a case which occurred in the practice of Dr. S. J. Mixter some ten years ago. He will remember a woman who passed a very large gall-stone, at least an inch and a half in diameter, by rectum. Later this patient died from acute intestinal obstruction caused by the lodgement of another stone so large as to obstruct entirely the lumen of the bowel. This condition must be considered infrequent if not unique; but it shows one of those rarer conditions which may occur after the dislodgement of an impacted stone and its escape into the intestine.

During the next six or eight years I saw occasionally cases of biliary colic, soon relieved by the escape of the stone. I have made it an invariable rule to examine the faecal discharges for at least a week after an attack of biliary colic. My method has been to pass the faces through a fine-meshed sieve, myself. Great care has to be taken in many cases not to crush the soft and recently-formed stone. The importance

⁷ Lancet, 1891, i, 1091.

of this procedure, I think, will appear in the cases which I have to report. Had such care been taken early in the history of my operative cases, the diagnosis would have been very clear indeed. So carelessly have these investigations been made, when they have been made at all, that I have not been willing to eliminate the existence of gall-stones from the fact that none have ever been discovered in the discharge. I recall one case very distinctly in which there was a clear history of biliary colic, and where at the end of a week I found a small, bright yellow stone of very recent formation, which without the most careful manipulation would have been crushed in passing the fecal discharges through the sieve.

Before reporting this evening those cases of prolonged and unnecessary suffering which have been entirely relieved by operative measures, I wish to report in considerable detail one of those lamentable occurrences which have not been infrequent in the history of medicine, and to avoid which is one of the chief objects of this paper. I refer to the case of a young woman, prominent in society, with a young family and with everything to live for, who died from the perforation of the common duct by an impacted stone, with all the symptoms of a general peritonitis. In this case, as in all other cases to be reported, the matter of diagnosis was of the first importance. It is very necessary for us to differentiate impacted gall-stones from malignant disease. The distinction between certain cases of gall-stone impaction and cancer or tumor pressing upon the duct and causing jaundice is at times very difficult. Some of the most skillful diagnosticians have erred in this respect. In most of the cases published herewith, some experienced man has been mistaken. In the majority of cases the symptoms are almost entirely subjective. There are no physical signs whatever on which we may depend for diagnosis, beyond jaundice and emaciation. The histories of the cases should therefore be taken with great care, and much reliance must be placed upon the patient's statements as to the origin, duration, character and direction of the pain. Believing firmly that the diagnosis must depend more upon the history than upon the physical examination, I shall report most of the following cases in some detail as to their subjective symptoms. The statements of the patients which have any bearing upon the diagnosis I have reproduced from my short-hand notes. As will be seen in all of them, whether simple exploratory incision or cholecystotomy for the removal of stones, with one or two exceptions, there have been no local physical signs whatever.

(a) GALL-STONE IMPACTED IN THE COMMON DUCT; PERFORATION; DEATH WITHOUT OPERATION.

CASE I. Mrs. T. D. P., aged thirty. First examined December 3, 1888. Married seven years; three children; two miscarriages; belongs to a family who have all died at about middle age or young. Father died of consumption; one brother died of appendicitis; a sister died at sixteen of some mesenteric trouble; another of Roman fever in Florence; one sister living and well; one brother living and well; one paternal uncle died of consumption; another lived until he was fifty and died of some brain trouble; grandmother now living.

Mrs. P. has been troubled with epilepsy. Has had post-partum hemorrhage twice. More or less womb difficulty. With the exception of the epilepsy and the

uterine trouble has always been well. About seven years ago there was cramp in the stomach and colic, just below the right breast. It was a pretty severe pain; would come on any time—night or day. No vomiting until recently. In the beginning she took sulphate of zinc to make her vomit. This would relieve the attacks. There seemed to be no connection between the food and the attacks of pain. Of late years the attacks have been of the same kind and constantly more severe. Between the attacks she would be perfectly well. Had a slight attack in July, and in the latter part of August another, which has persisted ever since. It was preceded by a miserable feeling. Jaundice has been present all the time since August. Movements of the bowels white, and urine very dark. The pain in this attack has been in the pit of the stomach, and it was so severe that she could not bear the bedclothes.

Physical Examination. — A large, strong, healthy-looking woman, considerably jaundiced. No evidence of disease in the heart or lungs. Urine dark-colored. Nothing in the abdomen. Liver somewhat enlarged. No distention of the gall-bladder could be made out. There was some tenderness in the region of the gall-bladder. Pulse and temperature normal.

This case was sent to me by Dr. Paddock, of Pittsfield, with diagnosis of gall-stones obstructing the common duct. I concurred in this diagnosis, and on November 14th wrote: "It seems to me that this is a case of gall-stones, which has resulted in obstruction of the common duct. I do not believe that anything can be done to relieve gall-stones except surgically. I should not advise operation in this case unless the symptoms are more severe than they are at present." December 24, 1888: "I am inclined to look upon the case as one of obstruction to the bile from gall-stones. During her visit here I think she has improved. Dr. — has seen her with me, and looks upon it as a case of neurasthenia, with gastralgia. As far as I am concerned I do not, and have not seen any indications for surgical interference." Early in March, 1889, Mrs. P. was taken with symptoms of violent peritonitis, and on the 5th I was sent for to open the abdomen. She died a few moments after my arrival in Pittsfield. At the autopsy, a large stone was found in the common duct. Perforation had taken place and the patient had died of peritonitis.

It is quite evident that this most unfortunate result might have been avoided had we known positively that there was a large stone impacted in the common duct. It was impossible to be sure of this, however, and it was the opinion of one eminent diagnostician that this condition did not exist. The symptoms at my last examination were improving, and it seemed after a deliberation of four weeks and a careful study of the case best to delay. In the light of the experience which I have acquired since, and from the gratifying results which have followed exploration in these cases, I should not now hesitate a moment in advising as strongly as possible the necessity of an exploration. While it is well known that stones, even of large size, make their way safely into the intestine, it is certainly not infrequent that a disaster like this results. In a case with a similar history I should not be willing now to take the responsibility of delay. Persistent localized pain with exacerbations accompanied by jaundice, if due to a stone at all, mean a large one hopelessly impacted, and demand interference.

(b) EXPLORATORY OPERATIONS ON THE GALL-BLADDER.

CASE I. Tumor of the gall-bladder, due probably to malignant disease; abdomen opened; gall-bladder emptied; cancer of the head of the pancreas pressing on the common duct; death at the end of ten days; autopsy; cancer of the head of the pancreas extending into the liver.

C. C. R., aged thirty-nine. Examined September 7, 1889, with Drs. Carlton and Peirson. Two years before, an attack of malarial fever lasting four or five weeks, followed by jaundice. Has had recurrence of the fever and the chills since. Eight weeks after the appearance of the jaundice a large tumor was noticed below the liver. The jaundice disappeared about a year ago, and he was perfectly well during the summer. In the spring of the present year the symptoms reappeared with a great deal of malaise. There was considerable loss of flesh; jaundice was present and persistent. Went to Clifton Springs, and in three weeks was much improved. At the end of that time had a gall-stone, which caused great pain for two hours and a half. The gall-stone passed and he felt better than he had for the previous six or eight months. The jaundice did not disappear, although he bleached out a little. The pain was very sharp when the stone passed. He never had had any such thing before. He looked for it in the first discharge, but did not find it. With the exception of these symptoms his general condition was good. Family history good. Loss of flesh excessive. Under the margin of the ribs on the right side, there was a round, fluctuating tumor extending down into the right iliac fossa. Two or three hard nodules could be felt at the upper part of the tumor. Very much jaundiced and very much emaciated. The tumor was apparently movable. Pulse good and general condition such as to justify interference. Probable diagnosis: malignant disease obstructing the common duct.

On careful consideration of this case it seemed to me probable that the man's disease was malignant, although there was a clear history of at least one gall-stone attack, and that the distention of the gall-bladder and jaundice were due to an obstruction somewhere in the common duct. Exploratory laparotomy was performed on the 9th of September, 1889. Incision was made over the right linea semilunaris, on the edge of the liver, about three inches in length. The liver was found with several small nodules on the under part of the great lobe. The gall-bladder was much distended and reached as far as the crest of the ileum. The gall-bladder was emptied through an aspirating needle and about a quart of fluid as clear as water was withdrawn. The hole made by the trocar was sewed up with fine silk. Exploration of the parts revealed malignant disease in the neighborhood of the common duct and the under surface of the liver. The patient died at the end of about ten days. Post-mortem examination showed that there was cancer of the liver with primary disease of the head of the pancreas.

In this case an operation was performed because I was not perfectly certain of the diagnosis. There was very little difference of opinion among those who saw the case that the cause was probably the pressure of a new growth. I did not feel, however, that it was absolutely certain that the cause could not be removed, and this in my opinion, then as now, justified the op-

erative interference. The fatal result was not due to peritonitis or any wound infection. The man died at the end of a few days, as, in my experience, so many do who are much reduced by long-standing malignant disease.

CASE II. S. L., aged fifty-eight, painter, married. Massachusetts General Hospital, July 22, 1890. Thirty-eight years ago had Panama fever — chills and fever. Dyspepsia at times. Eight months ago noticed that he was losing flesh and running down. At times troubled with colicky pains and flatus. No vomiting or pain after food. Since then has been losing flesh and appetite. Has lost forty-five pounds. Six weeks ago noticed lump in right hypochondrium, which patient thinks moves and feels like a bladder. Five weeks ago began to be jaundiced. This has increased, with clay-colored stools and intense itching.

No pain or other subjective symptoms. Examination showed marked general jaundice and emaciation. Skin was dry and harsh and covered with excoriations. The tongue was dry, with slight brown coat. There was a large mass in the epigastrum from enlarged liver, on which a small nodule could be felt. He vomited about a pint of brownish, muddy fluid on July 12th. No blood was found in the vomitus by the microscope. Stools were clay-colored. On July 22d, under ether, a vertical cut was made over the region of the gall-bladder. The abdominal wall was very thin and lax. The gall-bladder was found non-adherent, dilated. The hand introduced into the cavity of the abdomen could detect nothing suggesting neoplasm. There were no stones either in the gall-bladder or in the ducts. The bladder was aspirated and about a pint and a half of pure bile was withdrawn. The fundus of the gall-bladder was then stitched into the abdominal wound with interrupted silk sutures. The bladder was opened *in situ* by a one-inch incision. The mucous membrane was found thickened and injected. A probe was with difficulty passed into the common duct. The bladder was thoroughly washed out with warm water and a rubber drain left in it. The usual dressing, with swathe, was applied. There was a discharge of about one ounce of bile daily into the wound. On the 26th the bowels moved. Stools still clay-colored. Urine the same as before. He gradually failed, and died on 31st of July. The autopsy showed cancer of the head of the pancreas.

In this case, which was referred to me from the medical side as a case of probable gall-stone impaction, a fatal result followed the operation, as in the previous case, where the patient was subjected only to the slight danger of exploration. The wound healed well, and there was no peritonitis. If his disease had been less advanced, or if he had been brought to his state of weakness by a simple obstructive cholæmia, I think he would have recovered. The case, though fatal, was not so from the operation.

CASE III. Mrs. Robert H., aged forty-one, Lawrence. Seen with Dr. Chamberlain on April 9, 1891. A week or two before, Dr. George M. Garland, of Boston, had made a careful examination and advised an exploratory laparotomy. Had the grip about a year before, and has not been well since. Has suffered dreadful pain in the stomach during the past summer (indicating the region of the stomach on the left side.) The pain has continued more or less for a year. In the previous July fell on a chair striking the left side. The pain comes on suddenly. She be-

gan to be jaundiced on October 1st. In the beginning the pain was entirely on the left side, and did not go into the right until two months ago. There has been great loss of flesh, without vomiting. Used to have chills. Vomiting has come on within the last six weeks.

No abnormal appearance to the vomitus. Stools clay-colored; urine dark. She has complained of pain in the region of the right kidney, and there is great tenderness over the gall-bladder. No elevation of the temperature. On examination there was a tumor found in the region of the gall-bladder which shaded off in different directions. It seemed to me to be the liver. I thought at the same time I could feel one or two small nodules. Diagnosis: probably malignant disease of the liver. I concurred in the opinion of Dr. Garland as to the advisability of an exploratory laparotomy on the chance of finding something that an operation would remove. A longitudinal incision was made in the right linea semilunaris over the gall-bladder. The liver was immediately exposed, and, with the gall-bladder, came into view. The gall-bladder was normal, but there were numerous cancerous nodules in the liver. The wound was closed with interrupted wire sutures. The whole operation did not take over ten minutes. She made a good recovery, and her death, which took place some months later, was not hastened by the exploration, which satisfied physicians, patient and friends.

CASE IV. Mrs. L., aged sixty-two, a patient of Dr. Jackson, of Weston, was seen in consultation with Dr. Cutler, who advised an exploration of the gall-bladder. Mrs. L. said that she had had bilious attacks and pain, accompanied by chills, for some time. The pain was very sharp in the right side, running to the back and shoulder; also a burning, deep in the right hypochondriac region. No real dyspepsia. There is a burning in the side, and at times she cannot straighten up on this account. No loss of flesh; some loss of strength. A small, smooth mass, the size and shape of a kidney, slightly movable, in the region of the right kidney; an enlarged area of hepatic flatness, and an apparent enlargement in the region of the gall-bladder. Temperature persistently above normal daily for the past five months. Never more than 102° ; usually from 100° to 101° . Sleep good; bowels apt to be constipated. The diagnosis was necessarily obscure, but it seemed wise to us all to make an exploration. On November 17, 1891, I made the usual incision parallel with the ribs on the right side until the gall bladder was reached. The parts were much adherent to one another, and the omentum was very firmly fastened to the gall-bladder. There was an adhesion also to the hepatic flexure and the beginning of the transverse colon. These adhesions were very carefully separated from the gall-bladder, and, with the hand introduced into the abdomen, nothing could be felt in the common, hepatic or cystic duct. Nothing abnormal could be detected in the region of the pancreas. The gall-bladder was contracted, and evidently had been the seat of some trouble. The whole condition was very similar to that found in the cases of prolonged gall-stone impaction, where the gall-bladder has become contracted and its walls thickened. Mrs. L. made a very good recovery indeed from the operation, and at first was relieved of the dragging pain of which she complained before. Later she had a good deal of trouble in one shoulder, which had no connection whatever with the operation. I am

informed by Dr. Cutler that of late she is somewhat better than she was before the operation, but, up to quite recently, the attending physician, Dr. Jackson, states there has been no benefit whatever from the exploration.

(c) SIX CHOLECYSTOTOMIES FOR GALL-STONES.

CASE I. Mary W. This was the case which was reported in the JOURNAL, Vol. CXX, p. 414. She was referred to the hospital by Dr. Titcomb, of Concord. She had a history of pain in the side, associated with a very movable tumor on the right, just below the border of the ribs. The opinion was rather in favor of a movable and malignant kidney, though Dr. Titcomb had sent the case in as one of gall-stones. I found it to be an enlarged and distended gall-bladder, from which I removed six stones of moderate size. One was squeezed from the common duct into the duodenum. The sac was partially removed, and the body sewed into the abdominal wound. A fistula remained, which closed in a few weeks, and there has been no trouble since.

CASE II. Mrs. C. K., aged forty-eight, married, Massachusetts General Hospital, September 7, 1890. Has passed the menopause. At times has been subject to attacks of quinsy. Three years ago there were chills and fever. One year ago first noticed pain in the right side, coming on gradually. Afterwards the pain was in the epigastrum, and was not associated with ingestion of food. At the same time jaundice appeared. This has continued ever since, although at times less marked than at present. Since then there have been several similar attacks of pain, coming on rather quickly, and disappearing gradually. The pain is of a cutting, raw variety, beginning always in the right hypochondrium and radiating into the epigastrium. The attacks have always been associated with vomiting. Stools greenish. Nothing has ever been found by physicians in the contents of the stools. Ten days ago there was a very severe attack, requiring morphine. There had been none before for a month. Two days ago there was another severe attack. The itching at times is intense. Duration of attack eight to ten hours. There has been average loss of flesh. Fairly nourished; skin saffron yellow; pulse slow, and at times intermittent. There is a trace of albumen in the urine, with an occasional hyaline cast and renal cell. Tenderness at the edge of the liver, which can be felt, smooth and regular. Gall-bladder not made out.

On September 9th, under ether, an incision four inches in length was made in the right linea semilunaris from the level of the margin of the seventh rib. The abdominal wall was thick and vascular. Omentum firmly adherent along the lower margin of the liver. The adhesions were broken up with the finger, and the gall-bladder, which was atrophied and flaccid, exposed. A hard, round mass was felt by the finger in the region of the common duct. The bladder was drawn up and opened. With two fingers of the right hand down deep below the common duct and with the index-finger of the left hand in the gall-bladder, a stone could be felt as large as a walnut. After some difficulty it was withdrawn. This stone was in the common duct. Another stone was found in the hepatic duct, and was removed in fragments with long, common, polypus forceps. This stone was followed by a copious flow of bile, which was kept out

of the peritoneal cavity as much as possible with sponges and irrigation. The gall-bladder was too much retracted and tied down by adhesions to admit of its being stitched to the abdominal wall. The upper lip of the incision, however, was drawn up to the parietal peritoneum, while the lower was left loose. A glass drainage-tube was placed in the gall-bladder, and iodoform gauze packed about it. The abdominal cavity was thoroughly irrigated with warm water and the wound left partly open. The lower half was brought together with wire sutures and the upper half packed with gauze around the tube. A large absorbent dressing was applied with rubber pellets about the tube, and the whole fastened in place with plaster and flannel swathe. The operation lasted one hour and an eighth. In the evening the dressing was stained with bile, which escaped freely from the tube on its removal. A siphon was arranged to carry off the bile. Patient put upon liquid diet. Thirty-six ounces of bile were siphoned off in the next twenty-four hours.

The patient went on very well indeed for several weeks. The fistula became well established. Jaundice slowly began to disappear. Gauze was removed from the wound on the 13th. The wound was clean. On the 19th the feces were slightly stained with bile. On the 25th there was a discharge of very foul pus from the wound. The temperature had been up for some days. The pain in the back and right side, which had been constant for several days, gradually disappeared after the discharge of pus. Temperature became normal. Siphonage was omitted. Later the temperature kept rising, and the general condition was worse. There were chilly sensations and fever. The malarial history was thought to account for the chills. On the 29th an opening was made in the lower part of the wound communicating with a pus cavity which contained about half an ounce of pus. The opening was dilated and the cavity syringed out. Siphonage begun again. On October 2d there was a slight discharge of pus. The amount of bile was reduced to fifteen ounces. There was considerable vomiting. The temperature at times rose to 104°. She died on the 10th of October.

At the autopsy a gauze sponge was found at the bottom of the pus cavity, from which there had been an infiltration posteriorly, and from which the patient died septic.

In this case, at the time of the operation, it seemed to me that we had a most formidable condition of things. The gall-bladder was badly torn, and it was so contracted that it was out of the question to think of trying to sew it to the abdominal wound. The long obstruction to the flow of bile had dilated the liver-ducts to such a degree that large quantities of bile were stored there, ready to pour out over the wound and into the abdominal cavity the moment the obstruction should be removed. When the stone was removed from the hepatic duct, there was an abundant escape of bile, much of which covered the intestines and escaped into the peritoneal cavity. This formidable emergency could be met only by making anastomosis between the gall-bladder and intestine, or by closing entirely the bladder by suture, or by doing as I did at the time, putting a tube into the hepatic duct and tying the gall-bladder, or its remains, about the glass tube. In this case, as in several subsequent ones, this method has proved perfectly satisfactory and successful.

During the operation large quantities of bile escaped, in spite of all efforts to prevent it, and covered the surrounding parts. The immediate effect of the introduction of the tube with the gauze packing was to shut off the rest of the abdominal cavity. On removal of the gauze, the general cavity of the abdomen was entirely and firmly protected by the recent adhesions.

The method employed at that time to prevent the leaving of sponges in the abdominal cavity was to have a special nurse whose duty it was to count the sponges before and after the operation, to watch such as were introduced into the abdominal cavity, and to be responsible for them as far as possible by devoting her attention to nothing else. At this operation the nurse counted the sponges very carefully before and twice after the operation, and reported them all present. It seemed to me at the time that these precautions were ample, and as thorough as any taken elsewhere. The lesson which I have learned is to have more than one count made by at least two different persons, both before and after the operation.

CASE III. Harry K., aged twenty-four, detective, Massachusetts General Hospital, October 1, 1891. After leaving the hospital where he was in the spring of 1889, with similar symptoms, which were not treated surgically, he felt perfectly well until September 15th, when he had a severe attack, which lasted four weeks. Since then he has had six or seven attacks at intervals of from three to five months. The interval increased and the duration of the attacks diminished until the present one, which has continued since August 22, 1891. He has received all kinds of treatment, including massage. Morphin is the only thing that relieves him. Ether makes him crazy. When in pain he does not know what he is doing, though he can tell you afterward. The pain comes on suddenly. It starts in the pit of the stomach and travels through the right hypochondrium into the back. In some of the attacks he has been jaundiced. Bowels were constipated. There was blood in the dejections at times. He has lost considerable in weight the past two years. He has taken a great deal of morphin (nearly a grain, if not more) a day. When seen in the ward, the patient was very nervous and apparently in some pain. Attacks of pain came on about 3 P. M. This patient was examined by most of the physicians and surgeons in the hospital. Some advised operation, and others did not think it necessary. There was a good deal of doubt expressed as to the presence of any foreign body in the gall-bladder. Dr. F. C. Shattuck, who turned the case over to me, insisted that a stone was present, which proved to be so.

On October 6th an incision six inches in length was made parallel to the ribs and below the edge of the liver. It was carried well into the flank. The abdominal parieties were thick and muscular. The hand was introduced into the abdomen, and the gall-bladder found and drawn into view. The parts about the gall-bladder were slightly adherent to it. A small stone could be felt through its parieties. Over the stone the bladder wall was very thin and friable, and had every appearance of being about to be perforated. The bladder was incised, and a small, sharply angular stone removed. The wall was too friable to suture to the abdominal wall, and therefore a ligature was passed around the bladder near its base, and the whole removed. Previously a probe showed that the common

duct was patent. The lower end of the incision was closed with silk and wire. The upper end, about the stump of the gall-bladder, was packed with iodoform gauze, which was brought out of the wound. Dry dressing was applied. On the next day the dressing was stained with bile. The stitches were out on the 13th. The patient made a slow but gratifying recovery. He was very nervous, and seemed to suffer much for some weeks. The gauze was entirely removed on 23d. He was discharged from the hospital in November, and has remained well up to the present time (April 14, 1892).

In this case there was a good deal of difference of opinion, some thinking that there was nothing mechanical to cause the pain, and others being quite confident that a gall-stone was at the bottom of the trouble. The situation and impaction of the sharp stone, with the ulceration and inflammatory condition of the parts, seemed to me quite sufficient evidence that the whole trouble was caused by the calculus. His perfect recovery justifies the diagnosis and the operation. (Patient exhibited.)

CASE IV. George F., aged fifty-eight, gentleman. History of gall-stone extending over eight years, with occasional attacks of jaundice. Great suffering and almost complete disability. Referred to me by Dr. J. P. Oliver. Diagnosis confirmed by Dr. Fitz.

Operation on October 10, 1891, at St. Margaret's, assisted by Dr. Mumford. An incision parallel to the ribs was made just at the outer border of the rectus abdominis. Through a small space free from muscular tissue the gall-bladder was exposed by a small incision and the fingers introduced into the abdomen. A row of gall-stones could be felt in the cystic and common ducts. The base of the gall-bladder, which was in contact with the anterior abdominal wall, was united to the wound by numerous interrupted silk sutures. On opening the gall-bladder bile immediately escaped, and seven large stones, one after another, were removed from the cystic duct. By means of the polypus forceps the last stone, which projected into the common duct, was removed—the stone which had caused the jaundice in this case. After the operation a drainage-tube with siphonage was introduced into the gall-bladder. The patient made a rapid recovery, but a fistula still persists, and will probably require a secondary operation to close it. In this case, as in the first, the obviously safe method was to sew the bladder to the abdominal wall. There was nothing difficult about the operation.

CASE V. Mrs. E. L. W., aged thirty-seven, referred to me by Dr. George M. Garland, consulting physician, and Dr. Knight, of Milford, Mass., attending physician, December 15, 1891, entered the Massachusetts General Hospital. Present trouble began with pain in the stomach at the age of seventeen, which lasted about an hour. Had a few similar attacks, and then went two years without pain. From that time to the present there has not been a whole year without pain. First noticed jaundice a year ago. It was accompanied by pain and vomiting. No blood; urine dark. The pain was sharp and came on suddenly, lasted a few hours, and then went away. Jaundice came on a few days later. Has been jaundiced for the past year. Pain has been growing worse, so that she has been unable to work. Has had three or four attacks since last year. Diagnosis: gall-stones impacted in the common duct.

On December 29, 1891, an incision five inches in length was made, parallel to the ribs, on the right side. The incision was enlarged for the introduction of the hand. The gall-bladder was found with some difficulty, on account of the numerous adhesions. It was contracted and could not be brought in contact with the anterior abdominal wall. Stones could be felt in the common and hepatic ducts. An opening was made in the fundus of the bladder, and eight stones were removed from the common and hepatic ducts. One large stone was so firmly impacted in the common duct that it was impossible to stir it before it had been completely broken up by common polypus forceps, which in my opinion, is the best instrument for this purpose. The duodenum presented in the wound throughout the operation, and the manipulations of the stone with the right hand had to be made through the layers of the duodenum. During the manipulations large quantities of bile were discharged over the parts, which were washed off with warm water from time to time. The stones which were detached from the common duct would become lost in the dilated hepatic, and quite prolonged manipulations were necessary to recover them. A glass tube was placed in the hepatic duct, and iodoform gauze was placed about the tube down to the base of the gall-bladder, which had become much torn by the manipulations. A dry dressing was applied. There was considerable flow of bile. The stitches were removed on January 6th, and the gauze was out at the end of a week. January 9th the tube was out. A gauze drain was left in position. Bile was first noticed in the stools on January 18th. On February 10th the wound was entirely healed. Jaundice had then nearly disappeared and she was feeling as well as ever. She was discharged on the 16th of January, and has remained perfectly well ever since.

CASE VI. Elbridge B., aged fifty-two, referred to me by Dr. Fessenden, of Salem, and by Dr. C. F. Folsom, consultant, of Boston. Previous health good. Present trouble began with what he thought to be an attack of acute indigestion, after eating chestnuts, about eight years ago. The pain was described as "dreadful distress." A dose of morphine relieved him and he got up the next morning all right, that is, all right as far as the distress was concerned. He was very yellow for some days. The next attack was last July. He had jaundice, but no pain, nothing but "a miserable feeling all over." At other times it would be what he called a "horrible feeling." His weight was reduced from 170 to 125 pounds. The liver could easily be made out, but nothing else could be detected by examination of the abdomen. He was deeply jaundiced.

Operation was performed at St. Margaret's, on February 9, 1892, assisted by Dr. W. A. Brooks. An incision was made on the right side parallel with the margin of the ribs, at the outer border of the rectus abdominis. This brought me down upon a small muscular space at the outer border of the rectus just over the normal position of the gall-bladder. On cutting through this and exploring with the finger, I could feel gall-stones somewhere in the region of the common duct. The incision was enlarged downwards and outwards, and upwards along the outer border of the rectus, making a semilunar incision with the convexity downwards and to the left. The liver was distinctly enlarged and projected about two inches

below the border of the ribs. It was dark in color and had a congested appearance. In the sulcus where the gall-bladder was situated the omentum was firmly adherent, not only to the sulcus itself and to the under surface of the anterior border of the lobe, but to the fundus of the gall-bladder. There were no other adhesions. The gall-bladder was contracted and its walls were thickened. It was impossible to separate the adhesions of the omentum and the liver without tearing; I therefore clamped them and tied them off. This brought the fundus of the gall-bladder, from which the adhesions had just been cut, into view. An incision was then made into the fundus large enough to admit the finger. The whole lumen of the gall-bladder was not larger than the index finger. On dilating with the finger at the cystic duct, there was a sudden large flow of bile which pushed before it a large gall-stone three-quarters of an inch in diameter, faceted. This was followed in a few moments by another. I then dilated the cystic duct a little further and could feel another gall-stone, which I delivered with the forceps, having first crushed it. No other stones could be detected through the interior of the gall-bladder. I therefore inserted my right hand into the abdomen, and feeling through the stomach and duodenum detected a mass of gall-stones apparently lodged in the common duct. These, without much difficulty, were detached and pressed up into the hepatic duct, into the liver, beyond the opening of the cystic duct. With a great deal of difficulty I managed to squeeze them out through the cystic duct, and two more were delivered uninjured. The last one I caught with the common polypus forceps high up in the hepatic duct and removed. The operation, from the time of the ether until the end, occupied forty minutes. The wound was occasionally irrigated with warm water during the operation, and the parts were protected from the escape of bile, as well as possible, by packing with sterilized gauze. There was considerable hemorrhage from the liver at the point of the separation of adhesions. The patient's condition during the operation was excellent. It was impossible even to approximate the walls of the gall-bladder to the abdominal wound. I therefore put a glass drainage-tube through the gall-bladder into the hepatic duct, and packed around carefully with sterilized gauze and applied a rubber tube to the end of the glass tube for siphonage. This gentleman made an uninterrupted and rapid recovery, and was discharged from St. Margaret's, perfectly well, on the 25th of March. It took about three weeks to remove the gauze, little by little. At the end of that time the passage of bile through the common duct had become fully established. In a short time the abdominal wound was entirely closed by granulations, and the patient increased very rapidly in flesh and strength. The jaundice had almost entirely disappeared at the time of his discharge.

The most important factor in the diagnosis of gall-stones is the history. Physical examination adds very little, if anything, to it. Recurrent attacks of pain with transitory jaundice, persistent discomfort extending over a long period of time, accompanied even with a general cachexia, unless the anæmia is steadily progressive, are the most important diagnostic points in the distinction from cancer. Several patients upon whom I have operated, and others where I am considering the question at the present time, de-

scribe their discomfort as a "terrible distressed feeling," rather than actual pain. I have been struck by the similarity of the expressions used to give an idea of their sufferings. The presence of a dilated gall-bladder does not accompany the one condition any more frequently than the other. Patient examination of the discharges after an attack should be made, and all the feces should be passed through a fine sieve. Even the most experienced diagnosticians, however, may be mistaken. In most of my cases some one eminent medical man has been mistaken. I refer again to this fact to justify the opinion that in all cases where there is any doubt, the patient should be given the benefit of it, and an exploration should be made.

The prognosis in cases of long-continued impaction is certainly grave. In most of my cases I do not believe that Nature would ever have effected a cure, or not without great danger of some serious disaster, as in the first case reported. The prognosis after operation seems to me very encouraging indeed. With the exception of the second case of cholecystotomy, all have recovered, not only from the operation but from the symptoms demanding it. In the second case, I think I can claim recovery from the immediate dangers of the operation, and while the sponge was doubtless the direct cause of death, this accident could hardly have been provided against more carefully than it was at the time. I think that I can say that few men at that time took any more effective precautions than to have one experienced nurse whose duty it was to attend to the sponge and nothing else. The lesson I have already emphasized, is to confide that duty to no less than two individuals.

The best cut for operation, the extent of which is uncertain beforehand, is, in my opinion, that which starts a little to the left of the linea semilunaris, an inch from, and parallel to, the margin of the ribs, and carried across the fibres of the external oblique. At the outer border of the rectus there is a small space quite free from muscular fibre where the fundus of the gall-bladder is generally in contact with the peritoneum. At times the transversalis fibres intervene. Through this spot the bladder may be explored with one or two fingers. If necessary, the cut may be continued upwards along the outer border of the rectus, and downwards and outwards parallel to the margin of the ribs. In this manner a very satisfactory view of the parts may be obtained.

In most cases of long standing I have met with adhesions. At times it is very difficult to separate them. If it complicates or delays the operation there is the advantage of being less danger of bile escaping into the abdominal cavity. The fourth exploratory operation shows that a part of the discomfort, at least, may have been caused by the loaded colon dragging upon the gall-bladder.

If the bladder is loose and presenting, it should be sewed to the abdominal wound, once having completed the exploration of the common duct, and having become satisfied that in order to detach the stone it will not be necessary to have one hand in the abdominal cavity outside the gall-bladder. The line of suture having been completed the bladder may be opened.

Where the gall-bladder is contracted upon a stone, or is so inelastic that it cannot easily be drawn to the abdominal wall, or where it is necessary to open the common, hepatic of cystic duct, I believe there is no

method so rational or so successful as that employed in four of my cases (Fig. 1). A glass-tube fitted into the open duct and packed about with gauze, with the addition of siphonage, gives a most excellent and satisfactory drainage, with which I have as yet seen no bad results. This method may be applied to any condition of obstruction or impaction (Fig. 2).

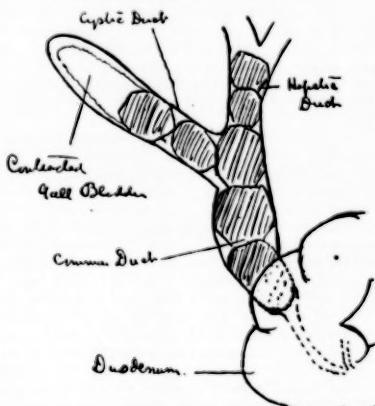

FIG. 1. Diagram showing position of stones in Cases II, V, VI.

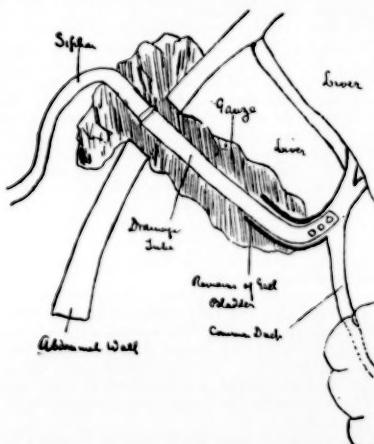

FIG. 2. Diagram showing position of drainage-tube and gauze.

The gauze should be removed gradually until all is out. I have seen most gratifying results follow this method of shutting off the general cavity of the peritoneum in operations for appendicitis and intestinal resections. The gauze, through its meshes, exercises an irritating effect which causes an almost immediate adhesive peritonitis.

The effect of bile escaping in large quantities into

the wound seems to be negative. In no case has there been any ill effect. It must have escaped in considerable amounts into the region of the gall-bladder in most of the operations. The anatomy of the parts, however, would tend to confine the fluid to the immediate vicinity of the foramen of Winslow. The transverse mesocolon and the hepatic flexures of the colon prevent bile escaping except in the right flank. The duodenum, pyloric end of the stomach, and the lesser cavity of the omentum through the foramen of Winslow, would be the only parts immediately invaded, and all these are apt to be shut off by adhesions in long-standing cases.

Patients suffering from symptoms of hepatic colic who have advanced into a profound cholelithia do not seem to offer as favorable prognosis as more recent cases, nor to be so favorable for operative interference. The stone is likely to be larger, and the danger of ulcerative processes greater, and the patient seems to run greater risks from attempts at relief; yet, so far as my observation and experience go, the most advanced cases have done as well as the most favorable ones, and I think the time has come when we should advise all patients, where a moderately certain diagnosis has been made, that after waiting a reasonable time for Nature to effect relief, the chances for recovery and usefulness are better when we resort to modern surgical art.

SECONDARY LAPAROTOMY FOR PISTOL WOUND OF THE LIVER, WITH A REPORT OF A CASE.¹

BY HOMER GAGE, A.M., M.D.
Surgeon to Worcester City Hospital and to Memorial Hospital.

THE natural history of wounds and injuries of the liver, aside from the interest which attaches to the subject of itself, is of interest because it illustrates the extent to which mutilation of the liver is possible without interference with its function, and because it illustrates the natural processes of repair. I desire, therefore, to present the following case with a few observations suggested by its occurrence.

On July 5, 1889, Frank M., aged fifteen, discharged a toy pistol, loaded with a blank metallic cartridge, with the nozzle held firmly against his jacket. It burnt a hole through his clothes and made a wound in the abdominal wall in the right hypochondrium, two inches from the median line and an inch below the margin of the ribs. There was but little hemorrhage from the external opening, and but little shock, and the wound, which was supposed to be purely superficial, was cleansed and closed. During the night he had very severe pain, and for ten days was confined to the bed. On getting up, it was found that he could neither stand nor sit upright, on account of pain in the region of the wound, but at no time was he regarded as very sick, and there was said to have been no rise of temperature. Within a few days the pain became more severe and he was obliged to return to bed. Then, for the first time, was noticed a decided fulness on the right side, with increased pain and tenderness, associated with progressive weakness and some rise of temperature.

I saw him first three weeks after the injury. He was decidedly undersized, pale, and much emaciated,

¹ Read before the Surgical Section of the Suffolk District Medical Society, March 2, 1892.

with a pinched, anxious expression. He complained of very severe pain in the left side, with inability to take a long breath. There was marked fulness over the right side of the abdomen in front, with lateral bulging of thoracic and abdominal walls. There was an area of flatness extending from the lower margin of the ribs on the right to the level of the umbilicus and across to the median line, and over this same area a feeling of elasticity with doubtful fluctuation. The wound had been healed, but its discolored site, surrounded by a red border, was still plainly marked. There was nothing abnormal in heart or lungs. His pulse was 120, temperature $99\frac{1}{2}$.

He was removed to the Memorial Hospital, where on July 29th I made a vertical incision two inches long, with the scar of original injury for its centre. The track of the wound was stained black, and was easily followed upwards and inwards to the peritoneum. A black stain on the peritoneum showed that it also had been perforated by the projectile, and a probe slipped easily through it at this point. Upon its withdrawal the opening was enlarged, and more than three pints of thin, dark greenish fluid withdrawn; the latter part of it was thick, almost like coffee grounds. The cavity in which it had been contained appeared to be shut off from the general peritoneal cavity, on its inner and lower sides, by firm adhesions. On the outer side was the parietal peritoneum, and above it extended around the margin of the liver to the diaphragm. A little more than one-half of the right lobe of the liver lay exposed. All the walls of the cavity, as well as the surface of the liver, were stained of a light green color.

The cavity was washed out with hot water, a counter opening made low in the right flank, and a dry gauze dressing applied. The contents of the cavity were sent to Dr. W. W. Gannett, of Boston, for examination, who reported that they consisted of "blood pigment and bile pigment in considerable quantity; much free fat in a finely divided form; fatty degenerated cells, probably liver cells, and a small amount of fibrin, but few leucocytes."

The patient rallied well from the operation. The wound was irrigated daily, and the profuse discharge, which resembled exactly the fluid removed at the operation, diminished slowly, becoming more and more yellow in color.

On September 7th, five weeks after entrance, he left the hospital with still some tenderness on deep pressure, and inability to maintain an erect position. During the subsequent two weeks he was treated as an out-patient, but with no improvement. The amount of discharge from the sinus increased very much and became of a dark brown color with large lumps of the consistency of putty, whose passage through the sinus caused severe pain. These lumps varied in size from that of a bean to that of a walnut, and were, under the microscope, found to consist of unorganized masses of free fat and fatty degenerated liver cells, stained with bile; no pus and no blood. One large piece firmer than the rest, was examined by Dr. Scribner, the pathologist of the hospital, and was found to consist of a fibrous stroma, similar to that of the liver, between the meshes of which were to be seen, in some places, liver cells in an advanced stage of fatty degeneration. In other places the meshwork showed where liver cells had dropped out and disappeared. On readmission to the hospital, his pulse was 100, temperature

$100\frac{1}{2}$. The area of hepatic dulness began at the fourth interspace on the right, and extended at least one and one-half fingers' breadths below the margin of the ribs. On the left side it was not increased. There was marked tenderness in the right hypochondrium, with induration between the sinus and line of incision. The sinus was irrigated daily with a double current catheter, and the amount of putty-like discharge steadily diminished, as did also the area of dulness and induration. The sinus closed October 10th, and by November 1st the area of hepatic dulness had receded to within normal limits, while there was no trace of induration and no tenderness. He could stand and walk erect, slept on either side indifferently, but still had occasional and unaccountable rises of temperature. On November 11th, four months after the injury, he was again discharged. His subsequent history, except for a small abscess which appeared at the site of incision, in December, 1889, has been uneventful, and he is now well, strong and at work.

The projectile was never discovered, and its nature must always remain unknown. But whatever it may have been, and however disposed of, the history of the case shows that it must have penetrated into the abdominal cavity and entered the liver, and probably near the lower margin of the anterior surface of the right lobe. From the hepatic wound had escaped the effusion of blood and bile which was subsequently found encysted, and around the wound had occurred a localized hepatitis with fatty degeneration and sloughing of some of the liver substance. The formation of the strong adhesions which protected the general abdominal cavity was due, I presume, to the smallness of the wound and the very gradual escape of the blood and bile. This view is supported by the absence of severe shock directly following the injury, and the time which elapsed before the swelling in the side was noticed.

This case is, I think, particularly interesting at this time, when the management of wounds of the larger viscera is receiving so much attention, because it illustrates the tolerance of the liver for injuries even of considerable severity, the absence of serious results after the loss of portions of its substance, and the natural tendency of wounds here, as in other tissues, if only they are given a chance, to heal of themselves.

In connection with this case, I have collected, with the assistance of Dr. R. Lorini, of Washington, the records of 272 cases of wounds and injuries of the liver, in which the relative frequency of the more important complications, and their fatality, are, I think, quite accurately portrayed.

In classifying these cases, we find that they divide themselves naturally into two groups, according to the manner in which the violence has been inflicted. We have the penetrating or direct wounds, which result from the passage of some foreign body through the abdominal parieties and into the liver, and the cases of rupture from indirect injury, that is, without perforation of the abdominal wall, such as from a blow, fall or crush. Of the direct injuries, we find 164 cases with 58 deaths, a mortality of 35.3%. Of the indirect, 108 cases with 92 deaths, a mortality of 85.2%. Dividing the former class again into two groups, we find that of 54 punctured or incised wounds, 24, or 44%, proved fatal, while of 110 gun-shot wounds only 34, or 30%, were mortal. Of the 272 cases, 150, or 55.5%, died. These figures correspond very closely

with the tables of Edler, which showed a mortality of 39.1% after shot wounds and 55% of all cases. It will be seen, therefore, that wounds of the liver are far from necessarily fatal, and that from penetrating wounds nearly two-thirds of all cases may be expected to recover.

As was to be expected, the most frequent, as well as the most fatal, complications were internal hemorrhage and peritonitis. Curiously enough, the presence or absence of these important factors is unnoticed in a majority of published reports, and the frequency of their occurrence after hepatic injury, as here indicated, is therefore only approximately correct. Of the 54 punctured and incised wounds, internal hemorrhage is mentioned as occurring in only eight, or about 15%. Of these eight, five, or 62½%, were fatal, so that of the 24 deaths from these injuries 20%, at least, were the result of internal hemorrhage. In the shot wounds, my records are too incomplete to enable me to draw any conclusion with regard to the frequency or fatality of internal hemorrhage. Of the 108 cases of rupture from indirect violence, internal hemorrhage is mentioned as occurring in 20, or 20%, and as being fatal in 18, or 90% of the cases in which it was noted.

Peritonitis occurred in 10, or 20% of the incised wounds, and in 10% of the shot wounds. Eight of the former died, or one-third of all the deaths in that class, and of the shot wounds in which peritonitis was developed, six proved fatal, or one-fifth of the total mortality. Its presence was noticed in 15% of the ruptures, and it was responsible for 14% of the deaths.

Abscess of the liver was observed four times as a sequence of incised wounds, with three deaths; five times after rupture, with four deaths, and three times after shot wounds, with one death. It is, therefore, one of the rarer sequels, having occurred in only 5% of all cases.

An escape of bile through the external wound seems to be a common accompaniment of gun-shot wounds, being present in 35% of all cases. Only five of the 37 cases in which it was observed, however, proved fatal, and in these the fatality cannot properly be attributed to the establishment of the biliary fistula.

One of the most interesting features in this collection of cases is the record of fifteen instances in which a penetrating wound of the liver was accompanied by loss of substance with but a single death. In twelve of these cases a piece of the liver was found projecting through the opening in the abdominal walls, and in nine it was ligatured and cut off; in the other three it was allowed to slough off, and in three cases pieces were washed out by irrigation during convalescence, as in the case which I have just reported. The amount removed is, in one instance, described as the size of an apple, in another as large as a goose egg, and in a third as weighing one and one-fourth ounces. In none of them were any ill effects observed.

These figures, though necessarily somewhat incomplete, indicate, I think, with sufficient clearness, the two great dangers which we must meet in these cases, namely, hemorrhage and peritonitis. Abscess, we have seen, is comparatively rare, and, when present, is a later complication to be dealt with, as if of entirely independent origin. The escape of bile is of consequence only when it takes place into the abdominal cavity, and then only as a cause of peritoneal inflammation. Even the loss of liver-substance may take place without serious danger. The problem is the

management of hemorrhage and the prevention of peritonitis.

In the case of punctured and incised wounds, or of bullet wounds, it would seem that exploratory incision, with a careful cleansing of the abdominal cavity, whenever necessary, was clearly indicated. Suture of an incised wound of the liver has already been performed three times, twice successfully; and if the nature of the injury were such that suture was impracticable, packing with gauze would do very much to control the hemorrhage, and would quickly exclude the general peritoneal cavity from contact with the wounded surface and its secretions. In the case of subcutaneous rupture of the liver, the problem is not so easily solved. For such cases no definite rule can be laid down. Whenever the manner in which the injury was inflicted, and the symptoms to which it has given rise, point distinctly to rupture of the liver as the probable lesion, incision and exploration are, at least, entitled to some consideration.

These injuries are apt to be so quickly fatal that there is no time for surgical interference. But when the primary shock is survived, and death seems imminent from a slow hemorrhage into the general abdominal cavity, exploratory incision is, I think, clearly applicable.

Clinical Department.

TWO CASES OF CHOLECYSTOTOMY.¹

BY A. T. CABOT, A.M., M.D.

THESE cases of operation on the gall-bladder illustrate two quite different conditions. The first is an example of dilated gall-bladder, due to a stoppage of the cystic duct by a calculus, the condition not being complicated by any considerable inflammation in or around the gall-bladder. In the second case, on the other hand, there was a very great amount of inflammation about the gall-bladder, and the stones which were the cause of the trouble had apparently led to a perforation of the cystic wall, and had escaped into an abscess cavity, lying probably behind the gall-bladder. As the diagnostic points of these conditions are of interest to the surgeon considering the question of operation, the clinical histories are given at some length.

CASE I. Mrs. P. was seen by me September 30, 1891, when I obtained the following history:

For ten years she had been subject to attacks of membranous enteritis, accompanied by nausea, griping pains in the abdomen and constipation. For the past six or seven years she had had frequent attacks of severe pain in the epigastrium which always required the subcutaneous injection of morphia for their relief. These epigastric attacks always occurred at times of especial fatigue, and came about four times a year; but since early last spring she had had none of them.

She had been feeling poorly, without appetite and listless, ever since the spring. In the summer she made a trip to the mountains and sea-shore without especial benefit. About the middle of August she had a severe lumbago; after three weeks the pain spread itself over the trunk as a severe general myalgia, and after persisting thus for a week, it gradually subsided, disappearing about ten days before my visit.

¹ Read before the Surgical Section of the Suffolk District Medical Society, March 2, 1892.

She was always of a constipated habit, had never had haematemesis nor had passed blood from the bowels. Had never been jaundiced nor had clay-colored stools.

After the subsidence of the myalgia, pain was still felt in the right hypochondrium; an examination made at this time revealed the presence of a tumor there. Mrs. P. was a well nourished woman of about thirty-eight, but somewhat pale. At the time of my visit there was still slight tenderness in the right hypochondrium, though I was told it was much less marked than it had been the week before. The abdomen was soft, and palpation was well borne and satisfactory. Below the liver was a smooth, globular tumor which reached downwards in the right side of the abdomen to a point below a horizontal line drawn across through the umbilicus. Upon long inspiration the tumor descended still lower into the abdomen, and when Mrs. P. turned on the left side, the tumor changed its position till it lay behind the umbilicus, part of it projecting over into the left side of the abdomen.

The opinion was expressed that the tumor was a distended gall-bladder, probably containing stones, and an operation was advised.

On October 7, 1891, the operation was done under ether. An incision parallel to the lower edge of the ribs was made, over the tumor. This was found to be the distended gall-bladder, and was easily lifted outside of the abdomen. A flat gauze sponge laid under it entirely shut off the wound, and the gall-bladder was then incised in its long diameter, making an opening about one inch long. Through this, considerable glairy mucus escaped, little, if at all, stained with bile. Four calculi were removed. One of the smaller ones lay in the opening of the cystic duct, but was easily dislodged. After this bile began to escape through the opening.

The gall-bladder was attached to the parietal peritoneum by a continuous cat-gut suture, and was also anchored to the skin by four silk stitches. The rest of the wound was closed with silk. A large absorbent dressing was then applied.

The patient made a good recovery, although her stomach at first was very delicate and intolerant of food. The opening slowly contracted, and closed without any drawbacks. Mrs. P. was not strong through the winter, and had some discomfort from dragging sensations about the cicatrix.

CASE II. The patient was a slight, delicate woman of twenty-nine, and was seen by me December 8, 1891, in consultation with Dr. A. L. Norris and Dr. J. T. G. Nichols. She had always been troubled with a very sensitive stomach that was easily and often upset. Married for a number of years, she had had but one child eight years before. Since that confinement she had always been subject to abdominal distress, and on two occasions had had attacks of what was thought to be pelvic cellulitis. She had also, during the previous two years, had occasional sudden attacks of pain in the lower part of the chest so severe as to take her breath away.

The present illness began four weeks before I saw her, and was characterized by abdominal pain so severe as to require the use of morphia for its relief, felt more in the right side than on the other. This was associated with much nausea and vomiting, and the breath was extremely fetid. There had been considerable fever with the illness, and Dr. Norris had detected a

tumor in the right side of the abdomen, which was very tender to the touch, and which he and Dr. Nichols believed to contain pus. The urine was scanty, high colored, and a specimen obtained at the time of our consultation was found to be stained with bile. There had never been any jaundice, and none was apparent to the eye at this time.

The abdomen was distended and tympanic, not very sensitive to pressure except in the right side where there was tenderness, both in the hypochondrium and in the right lumbar region.

This portion of the abdomen was occupied by a tumor continuous with the liver, and extending through the right lumbar region well round into that side; this did not move up and down with deep respirations. It being clear that suppuration was going on in the abdomen, probably connected with the gall-bladder, an operation was advised and accepted.

December 9, 1891, operation. Mrs. W. was etherized, and an incision was made over the tumor parallel to the margin of the ribs. This opened the peritoneum just inside of the point where the inflamed, thickened and considerably enlarged gall-bladder was adherent to the parieties. The gall-bladder could be clearly made out along its anterior edge, but outside and behind it was held fast in an inflammatory mass that masked its outlines. The gall-duct was thickened and enlarged to about the size of the little finger, but its walls were so resistant that palpation of it in search of impacted calculi was unsatisfactory. The most careful search failed to show any hard mass in it which suggested a stone.

The gall-bladder was opened, giving exit to about two ounces of thick, glairy muco-pus. The cavity was trabeculated and more or less diverticulated. A careful search was made in it for calculi, but none were found. A probe passed along the duct was arrested before it had gone half-way to the duodenum, but there was no hard body to be felt at the point of arrest.

The gall-bladder was stitched up tightly to the peritoneum, a drainage-tube was introduced through the opening, and the rest of the wound was closed.

The patient had a good deal of retching and vomiting following the etherization. The pain was considerable, but was kept under control by the moderate use of morphia.

During an attack of vomiting, the patient threw up three or four small biliary calculi, and a few days later several were passed in a movement of the bowels.

Improvement was slow but steady. She began to bear food well, and the mass in the right side slowly diminished in size. About a month and a half after the operation, a small biliary calculus escaped through the fistula. Two weeks later more calculi began to be discharged through the opening, and within the next month thirty-two little stones appeared in this way. All of these stones were small and much faceted.

At this time, while these stones were escaping, I was away, and Dr. Norris and Dr. Scudder, who were in attendance, found a hardness just to the outside of the fistula, which gave the feeling as if there were an accumulation of stones just under the abdominal wall; and the patient found that pressure over this spot forced the escape of the calculi. March 2d I etherized the patient for a thorough examination. After enlarging the fistula, it was found that the gall-bladder

had shrunk down to a very small size, and the inflammatory mass about it had almost wholly disappeared. Just outside of the fistula, at the point where the stones were thought to have lain, was a cavity between the gall-bladder and the parieties. During this examination the finger penetrated without force through what represented the lower wall of the gall-bladder, into the general cavity of the abdomen. Feeling through this opening in the direction of the gall duct, the parts were found a good deal tied up with adhesions, but there was no especial hardness or thickening to be made out.

It would seem probable that in this case, at the time of the first operation, the gall-bladder had already opened posteriorly and downwards, forming an abscess into which the stones escaped. Subsequently, as the abscess cavity contracted, the calculi were forced up to and through the fistula. The stones which were vomited and which passed through the bowels may have been in the cystic duct at the time of operation and have been masked by the swelling of the walls. In the absence of colic, however, at the time when they escaped into the duodenum, it seems quite as probable that they, too, were in the abscess cavity outside of the gall-bladder, and escaped into the bowel through some ulcerated opening.

RETENTION CYST OF THE GALL-BLADDER; OPERATION; RECOVERY.¹

BY S. J. MIXTER, M.D.

MRS. D., American, aged about thirty, married, has had six children. While carrying her last child, which was born in July, 1890, she had rather more pain than usual in the abdomen, especially in the right side. Delivery was somewhat difficult, and she was obliged to be up and about her work in nine days. When the baby was two weeks old, the patient had a severe attack of abdominal pain accompanied by nausea and vomiting, which required considerable doses of morphine for its relief. On the second day of this illness she noticed, for the first time, a tumor situated in the right side of the abdomen, tender on pressure, and somewhat movable. The general abdominal pain from which she was suffering was not referred especially to the position occupied by the tumor.

For several days after this attack she was unable to do her usual work on account of weakness and occasional pain; this, however, soon passed off and she was comparatively well again, but at times was troubled by tenderness in the right side. The tumor persisted, and she could move it from side to side and feel it, especially in the right loin. I first saw the patient early in September, 1891, at the Carney Hospital, about thirteen months after she first noticed the tumor, she having been referred to me by Dr. Munro, of the out-patient department, for examination. At this time she complained of increasing pain and tenderness in the right side, which almost prevented her from doing her usual work and taking care of her children, although she said that the tumor had not increased materially in size since she first noticed it.

On examination, a tumor, elastic, rounded, and occupying the right side of the abdomen, was found, ex-

tending from about the linea semilunaris back to the loin, and from the costal cartilages to a point about at the level of the umbilicus, slightly resonant in front of the lower part of the mass. It could easily be moved from side to side, in fact, to the left beyond the median line, and from its position, its mobility and shape, suggested most strongly a tumor or cyst of a floating kidney. This was the diagnosis at the time of the first examination, in which all the physicians and surgeons connected with the hospital who saw her until the time of the operation, agreed.

On October 2d, at the Carney Hospital, I opened the abdomen in the linea semilunaris, and found a cyst with smooth white walls, heart-shaped, and covered in its upper part by a very thin layer of liver-tissue; the right kidney normal in size and shape was found in its usual position. Careful search was made for a normal gall-bladder, but none could be found; neither could there be found any gall-stones or other cause of obstruction, though careful exploration was made by both finger and probe. The cyst was then drawn to the abdominal opening and securely stitched to the peritoneum and skin, and opened. A pint of clear fluid was drawn off, part of the cyst wall was excised, and a glass drainage-tube inserted and tied in, in the usual way. There was little shock, and recovery was uneventful — the cyst draining perfectly, the fluid gradually changing to a thickish, glue-like substance, and finally ceasing entirely.

The patient left the hospital in about five weeks, and soon after the sinus closed entirely. Since then she has regained her strength. There is only slight pain, no more than is usual after laparotomy, and she is able to do her regular work.

Dr. Whitney, who examined the contents of the cyst and the cyst-wall, reported that the wall consisted of fibrous tissue; that the inner lining, which was brownish in color, showed no signs of mucous membrane; and that the fluid was similar to that which would be found in any retention cyst. There was nothing that pointed to an echinococcus cyst. He was of the opinion that it was a greatly enlarged gall-bladder, the distention being due to a closure of the cystic duct in some manner.

This case is of special interest in connection with the other cases of cholecystotomy reported this evening, as in this case no gall-stones were found, the obstruction was in the cystic and not in the common duct, and the gall-bladder, as it probably was, contained only a clear fluid and no bile. It also shows how slight the symptoms may be from closure of the cystic duct compared with those of closure of the common duct. The attacks of pain in this case are better explained by some common form of gastric or intestinal disturbance than by any trouble of hepatic origin.

There was no jaundice at any time, and nothing which resembled biliary colic in character or severity. The obstruction of the duct and the growth of the cyst must have been of long standing, as when the patient first noticed the tumor, over a year before the operation, it was nearly as large as when it was seen and operated on by me. The cyst caused pain and discomfort simply from its size and pressure, and there were no symptoms of obstruction to the flow of bile, the history of the case throughout emphasizing the generally recognized fact that the gall-bladder is practically unnecessary to the animal economy.

¹ Read before the Surgical Section of the Suffolk District Medical Society, March 2, 1892.

CASES OF CHOLECYSTOTOMY.¹

BY GEORGE W. GAY, M.D.

MRS. C., aged thirty, was under Dr. Clement's care for about two months before she entered the City Hospital. Her symptoms were: severe pain, jaundice, obstinate vomiting, emaciation, debility, tenderness over the gall-bladder (but no distinct tumor), feces clay-colored, and urine dark brown, evidently due to bilirubin. A judicious trial of the usual remedies had failed to give any permanent relief.

The day after entering the hospital the gall-bladder was opened by an oblique incision four inches long, an inch below the ribs, and commencing about an inch to the right of the median line. The lower edge of the liver projected an inch below the ribs. The gall-bladder was readily found. It was not distended, and on being caught in a loop of silk and opened, was found to contain only a drachm or two of thick bile. No calculus could be detected by the finger outside the duct, nor by a long probe passed into it. After irrigating the cavity of the gall-bladder with warm water, a small stone was easily detected with the probe and removed. It was broken by the forceps during the extraction, but was estimated to be about the size of a large pea.

The gall-bladder was stitched to the abdominal walls, and the wound closed around the drainage-tube in the usual way.

The convalescence was uneventful. Jaundice was a good deal diminished in two weeks, and bile was apparent in the stools. In four weeks the discharge from the wound was very slight, and the skin was about normal. She was up about the ward in a short time, and was discharged nearly well in seven weeks.

At the end of three months the patient is well. The wound is entirely healed, and she is in her usual health. It should be stated that this patient had previously undergone laparotomy for the removal of "pus-tubes."²

Mrs. G., also a patient of Dr. Clement's, aged fifty-nine, was seen in consultation in July, 1891. The present attack was of nine months' duration, and was the fourth in as many years. The usual symptoms were present, to wit: jaundice, vomiting, pain, exhaustion, loss of appetite, high-colored urine, pale feces, and some emaciation. Being a very fat woman, no tumor nor area of dulness could be determined.

Operation July 5th. A vertical incision five inches long through very thick walls was carried down to the liver. Firm and extensive adhesions existed everywhere. In separating them with the finger below the liver, a profuse hemorrhage was brought on, which threatened to terminate her life upon the table. Nothing could be seen on account of the free bleeding, and no gall-bladder nor foreign body could be felt in the mass of fat omentum and adhesions. As the patient was failing the operation was reluctantly abandoned. The wound was packed with baked gauze, and covered with a large mass of the same material. Stimulants were freely given. She rallied somewhat for a few days, but never sufficiently to justify further efforts to find the gall-bladder and the obstruction. A low muttering delirium set in, and the patient died at the end of ten days.

¹ Read before the Surgical Section of the Suffolk District Medical Society, March 2, 1892.

² This woman has recently had an attack of biliary colic. She is now taking the Fluid Extract of Garden Celandine.

An autopsy revealed the presence of a calculus, about the size of a hazel-nut, in the common duct.

In the few cases of cholecystotomy that I have seen, the gall-bladder has not been distended, even though the jaundice has been most profound from the presence of gall-stones. On the contrary, in the case of a young lady upon whom I performed this operation several years ago, no stone was found, nor had she ever had jaundice. Yet the gall-bladder was enormously distended by about three pints of thick bile. She recovered, and remains well at the present time.

In one case of gall-stones, which was under my care many years ago, the ulceration extended in various directions. Calculi not only came through the opening in the skin, but several were coughed up. At the autopsy the gall-bladder was found to be entirely obliterated. —————

TWO CASES OF ABSCESS OF THE LIVER.¹

BY J. C. IRISH, M.D., OF LOWELL.

OCTOBER 17, 1891, I was asked by Dr. Edwards, of North Chelmsford, to do an operation for abscess of the liver. The patient, F. M., a man aged thirty, was just recovering from a moderately severe attack of typhoid fever, when Dr. Edwards, his attending physician, discovered upon the right side a tumor, with distinct fluctuation, extending from the free border of the ribs to the median line, and a short distance below the umbilicus, and nearly to the pelvis on the right. Dr. Edwards aspirated, and drew off about one quart of pus. Two weeks later, when I saw the patient, the tumor had regained its former size; the abdominal walls were evenly distended over it; there was no place showing any tendency of the abscess to point.

An incision, three inches long and about two inches to the right of the median line and below the border of the ribs, was made. A large quantity of pus, about one quart, was discharged.

The enormously enlarged liver was so completely adherent to the abdominal parieties that no precautions to prevent an escape of pus into the abdominal cavity were necessary. The abscess cavity was thoroughly irrigated, and a glass drainage-tube inserted. The patient made an excellent recovery.

A second case of liver-abscess I saw December 7, 1891. Mr. M., of Lowell, aged sixty, had had during the past ten years several attacks of icterus, which had speedily cleared up. He had never suffered from biliary colic. Previous to December 7th, he had, for two weeks, severe and continuous pain in the right shoulder. At the time I saw him his skin was but slightly tinged with bile. A large, fluctuating tumor occupied the upper and right side of the abdomen, extending nearly to the pelvis. As in the preceding case, a long incision was made and about three quarts of pus escaped. The abscess cavity was thoroughly drained; but a large amount of pus continued to discharge, and the patient died of exhaustion, February 27th. I am uncertain whether death was due to the continued formation of pus or to the extensive destruction of liver-tissue that had occurred.

In this case, too, the abscess wall was so closely attached to the abdominal as to prevent any escape of pus within the cavity of the abdomen.

¹ Read before the Surgical Section of the Suffolk District Medical Society, March 2, 1892.

Generally in the treatment of liver-abscesses, from whatever cause they arise, — dysentery, typhoid fever or gall-stones, — aspiration is valueless, except for purposes of diagnosis. As a curative means it fails here, as elsewhere, in dealing with an accumulation of pus. An incision through the abdominal walls, three or four inches in length, and a thorough drainage of the abscess cavity, I believe to be the only treatment. The operation is practically without danger. A long incision is especially mentioned, because with it we can more surely protect the abdominal cavity from the invasion of pus, when abscess and abdominal walls are not adherent. The fatalities of liver-abscess depend, not upon the operation, but upon the extent of the pus cavity and the relative amount of liver-substance that has been destroyed. Hence, the great importance of the earliest possible operation.

LARGE ECHINOCOCCUS CYST OF THE LIVER SUCCESSFULLY OBLITERATED BY LAPAROTOMY AND DRAINAGE.¹

BY MAURICE H. RICHARDSON, M.D.

ON Monday, August 3, 1891, Charles H., aged thirty-two, was sent into the Massachusetts General Hospital from East Boston. With good family antecedents, he had always enjoyed the best of health up to the present illness. At the age of twelve he went to sea, and for eighteen years was knocked about the world in the capacity of able seaman. Never was in Iceland. Always had a dog on board ship. On the 30th of June, about a month ago, was taken with what the doctor called inflammation of the bowels. He was greatly nauseated, but could not vomit. There was some pain in the abdomen. Last Friday noticed a "knob" on the right side of the abdomen close to the ribs. The next morning the lump had increased in size and he felt feverish and had chills. His condition rapidly grew worse, and on Monday afternoon he was brought to the hospital. The patient in appearance was very strong and robust and of great endurance. There was a large tumor in the right side of the abdomen, which, continuous with the liver dullness, extended downward to the crest of the ileum and ended in a broadly rounded margin. The whole right side of the abdomen was occupied by the mass. Toward the left, at the median line, the flatness gradually gave place to normal abdominal resonance. There was a distinct sensation of fluctuation and entire absence of resonance. There was nothing which suggested the peculiar thrill of an hydatid cyst. Over the region occupied by the tumor there was marked tenderness. The temperature was 102°, and pulse 120. There was no pain. All other signs were negative. It was impossible to make a diagnosis in this case. An abscess was not seriously thought of, for the operation was performed in Ward E. An echinococcus cyst was considered, but no diagnosis of such condition was made. It was impossible to eliminate dilated gall-bladder or hydronephrosis. Whatever the cause, it was quite evident from the severity of the symptoms that immediate exploration was imperative. No opportunity was therefore given us for that careful study and observation which obscure abdominal cases require.

¹ Read before the Surgical Section of the Suffolk District Medical Society, March 2, 1892.

The operation, under ether, was performed on Tuesday, August 4th. An incision three inches in length was made in the right flank, over the tumor, parallel with the fibres of the external oblique muscle. On cutting through the peritoneum a tumor presented which was very similar to liver in color and appearance. It was finely mottled, smooth and glistening, tense and fluctuating. The wall of the mass was sutured to the parietal wound with interrupted silk sutures, leaving an oblong space about an inch and a half in length and an inch in width occupied by uncovered tumor wall. At this point an aspirating needle showed the presence of pus. An incision was then made through about a quarter of an inch of normal liver substance until pus was reached. Large quantities escaped through the cut until the opening became clogged with a jelly-like substance, which, on being pulled out, was evidently the daughter cyst of an enormous echinococcus. At least five hundred cysts were removed by irrigation, varying from the size of an English walnut to a pin's head. The cyst was then thoroughly washed out with warm water. A large glass drainage-tube was left in the cavity, packed about with gauze. On the 5th the temperature was 99°. The discharge rapidly diminished under daily irrigation, and he was discharged on October 4th. At the present time he remains perfectly well.

This case shows the importance of early exploration in obscure abdominal cases which are accompanied by more or less severe constitutional disturbance — in all abdominal conditions where the symptoms are urgent and their cause not understood. This cyst was about ready to break into the abdominal cavity, and there was probably already existing a localized peritonitis, though none was discovered. As a safe and efficient method of treating echinococcus cysts encroaching upon the abdominal cavity, the case seems to be one of value, and the treatment may occasionally be imitated in the treatment of abscesses from other causes and in different regions of the abdomen. The appearance of what the patient called the "knob" in his side soon after the attack of inflammation of the bowels, together with its rapid growth, seems to me to indicate that the size of the cyst depended largely upon the accumulation of pus, and that previous to the inflammatory condition the tumor was so small as not to be noticeable.

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

CHARLES L. SCUDER, M.D., SECRETARY.

REGULAR Meeting, Wednesday, March 2, 1892,
Dr. A. T. CABOT, the President, in the chair.

DR. A. K. STONE, reported

BACTERIOLOGICAL AND CLINICAL INVESTIGATIONS INTO THE ACTION OF DERMATOL.

This wound-healing material was produced and first used in the laboratory and clinics of the University of Breslau. It is an odorless, astringent powder, aiding in the healing of fresh wounds and well-granulating surfaces, especially in all cases when primary union is threatened from the presence of much secretion. Its use is indicated wherever iodoform, aristol, or any

inert powder would be used, excepting in such cases as require stimulation; here dermatol not only does not act favorably, but tends to increase the condition. It is also of great value in moist eczemas, etc.

In the bacteriological laboratory it was found that when bacteria were grown in the presence of dermatol, their products entered into chemical combination with the dermatol and were modified; and quantitative experiments showed that the dermatol materially hindered bacterial growth.

DR. C. P. PUTNAM: In reference to dermatol, I have used it in the nostril in nose-bleed. One of the most disagreeable accompaniments of nose-bleed is the foul smell of the blood, which is difficult to remove afterwards without fear of starting the haemorrhage again. In one case I introduced dermatol abundantly on the end of a pad of cotton-wool, which did not cause irritation, and prevented the foul odor.

DR. J. E. GOLDFTHWAITE showed a patient suffering with

CHARCOT'S DISEASE OF BOTH HIP-JOINTS.

There is free play of the femur up and down for four inches, absolutely devoid of pain, and the attitude in standing is characteristic. There is a very marked rub of the two surfaces of the bone together. The reflexes are absent.

DR. WILLIAM W. KEEN, of Philadelphia, presented a paper on

RESECTION OF A LARGE PORTION OF THE LIVER FOR ADENOMA OF THE BILE-DUCTS: RECOVERY.¹

DR. GEORGE W. GAY reported

CASES OF CHOLECYSTOTOMY.²

DR. M. H. RICHARDSON reported cholecystotomy cases, together with

A CASE OF ECHINOCOCCUS CYST OF THE LIVER.³

DR. A. T. CABOT reported

TWO CASES OF CHOLECYSTOTOMY.⁴

DR. WILLIAM W. KEEN, of Philadelphia: There are two or three points which have occurred to me in connection with this subject. To illustrate one I will narrate a case I had recently, in which, if I had been aware of the method of drainage Dr. Richardson has spoken of, I think possibly the result might have been different. A lady came to me who had consulted a number of practitioners in Europe as well as in this country, in consequence of pain in the region of the gall-bladder with intolerable itching all over the body, but with very moderate, in fact, scarcely any jaundice. One might say she was a very sallow woman, but not distinctly jaundiced. Her body was covered with scratch-marks. The symptoms had continued about three years. No relief had followed any treatment. She declared she would rather die than live as she was. The diagnosis was one of probable gall-stones from symptoms and not from physical signs, for there was no gall-bladder, no tumor, nothing of the kind to be found, and no special tenderness in the region of the gall-bladder. I agreed to do an exploratory laparotomy, and it proved to be an excessively difficult one. I adopted, as I always have done in those cases, the

same incision as Dr. Richardson's. As soon as I opened the abdominal cavity, I examined the under surface of the liver, but could not find the gall-bladder. Directly posterior to the incision was a hard mass, evidently more or less agglutinated, in which I presumed that the gall-bladder lay, though it could not be recognized. The diagnosis lay between gall-stone and cancer, probably of the pancreas, and I was very uncertain as to which I had to deal with. However, I tore through the mesentery and came down upon the pancreas, and to my surprise found no cancer of the pancreas at all, but a perfectly normal one; but immediately back of the pancreas still this hard mass was to be felt. Her instructions being that if relief was to be had she wished to have it, I felt justified in searching further, and with my fingers and a pair of haemostatic forceps I bored through the pancreas, and back of it came upon a hard, nodulated mass, which I recognized as one or more gall-stones, presumably the gall-bladder, but lying directly across the spine. On opening this I removed one large and five or six small stones. I inserted a drainage-tube, but unfortunately I did not surround it with the gauze. I had the pleasure of seeing one of the operations. Dr. Richardson has so well described, and I was delighted with his method of drainage, and should have adopted it had I been familiar with it. The patient did very well for several hours; but in the middle of the night was suddenly taken with collapse, and died the next morning at seven o'clock. No post-mortem was allowed me. Only in one other case have I ever found the gall-bladder so entirely displaced. In that case also it lay transversely and immediately in front of the spine, but not behind the pancreas. I was therefore able to reach it readily without passing through any structure.

The cases he has referred to have thrown additional light on a point I raised in the paper I had the honor to read this evening, namely, the question of the escape of bile into the peritoneal cavity. Undoubtedly no glass drain, even if surrounded with gauze, will carry away, either through the tube or through the capillary attraction of the gauze, all of the bile. There must be more or less of it that will escape among the intestines during that period in which tubular drain is being established by agglutination of the intestines around the gauze that is placed outside of the tube. I think, therefore, we have here decidedly confirmatory proof of the fact I have mentioned, that the escape of bile into the peritoneal cavity is not necessarily a fatal occurrence.

Dr. Cabot's speaking of the case in which a number of gall-stones were passed, reminds me of a case of unsuspected gall-stones in an excessively fat woman on whom I did a laparotomy in consequence of pelvic abscesses. I made no examination of gall-bladder, for nothing had ever pointed in that direction. I paid attention exclusively to the conditions found in the pelvis, but after the operation the patient vomited continuously for a week. It was absolutely uncontrollable. Along with it, however, her temperature did not rise; and therefore I came to the conclusion that there must be some complication other than mere ether vomiting, and also that it had not to do with a peritonitis. About a week after the operation she began to pass gall-stones by the bowel. There was a perfect torrent of them for three days, during which time we obtained 101 of them. The vomiting then ceased entirely, and the patient never had a bad symptom afterward.

¹ See page 405 of the Journal.

² See page 411 of the Journal.

³ See page 422 of the Journal.

⁴ See page 416 of the Journal.

DR. ALBERT H. TUTTLE, of Cambridge: Having assisted at the last two operations of the seven successfully treated by Dr. Marcy, I am led to report the same, by the kind permission of that gentleman, on account of certain interesting features in both cases, which demonstrated the rationale of his method of treating this affection, and also show the advantages to be obtained by similar methods over some that have been practised during the last few years.

Mrs. H., aged sixty, when first seen, had been under the treatment of a physician for several days; her condition was critical and she took the ether badly. A tumor with faint outlines was present, just beyond the linea semilunaris, below the margin of the ribs, and an incision about three and one-half inches long was made across its centre, parallel to the border of the ribs and carried through into the abdominal cavity; the edge of the liver and a part of the considerably distended gall-bladder presented in the wound, the latter more or less mottled, with dull, grayish-yellow spots of necrotic tissue. The bladder was drawn well into the wound and stitched to the edge of the peritoneum, care being taken to pass the sutures (kangaroo tendon) only through the outer coat.

Three layers of stitches, passing in the form of a ring about the base of the bladder, were thus taken, and served to completely shut off the peritoneal cavity, a condition especially desired as it was anticipated the sac contained pus. An incision about one inch long was then made into the bladder, which allowed the escape of three or four ounces of slightly yellowish fluid, the modified secretion of the bladder wall, and one gall-stone.

The probe detected the presence of another of very considerable size; this could not be removed through the opening in the bladder wall, and an attempt was made to crush it with a pair of strong forceps, but without success; it was then seized between the points of a pair of tenaculum, or modified bullet-forceps, and broken, when it was easily removed. There was still another stone discovered in the common duct, the cause of the severe symptoms, — constant vomiting, temperature 104° and 105° , small pulse, scanty, high-colored urine, containing bile and albumen, — which was of considerable size, but easily removed.

The first stone removed was lozenge-shape, the diameters were three quarters and one-quarter of an inch, the flattened surfaces faceted; the second and largest was cylindrical in form, about one and three-quarter inches long, and one and one-quarter inch in diameter. One end was faceted.

The third stone removed from the duct was nearly spherical, one inch in diameter, the surface partly smooth, the whole mass weighing two ounces in the condition in which it was taken from the body. The wound was drained and packed with iodoform gauze, and an aseptic dressing applied. This patient made an uneventful recovery, the temperature after the operation never reached 100° , and at the end of four weeks the patient was out, and the wound entirely healed. This, I am informed, was a longer period than any of the other five preceding cases required, most of which healed by primary union.

The second case was Mr. G., aged twenty-nine, and operated upon March 2, 1892. Three years ago he was taken with sharp, colic pains, which confined him in bed for several days; jaundice was marked, urine became dark and the stools clay-colored, although

there was no local tenderness or swelling. There were two subsequent attacks with jaundice; the last, September, 1891, was called inflammation of the bowel, and followed a fall from his bicycle; it confined him to his bed three weeks, during which time he was badly jaundiced, and there was a great deal of soreness and pain over the region of the gall-bladder, but no local enlargement until about January 1, 1892. Since then the tumor has rapidly developed, until at the time of the operation it was about egg size, flattened and circumscribed, with distinct fluctuation in its centre, and firmly adherent to the abdominal wall. The general condition of the patient was fairly good, there was no jaundice, but his weight was from fifteen to twenty pounds below normal. The diagnosis was doubtful.

The tumor had been diagnosed as one of gall-bladder origin, but there was a superficial character about it, which pointed toward an abscess in the abdominal wall, and to help this opinion the tumor was firmly attached to the skin. It was in view of these facts that a straight incision was made through the skin over the centre of the tumor. The skin was thickened, and closely adherent to the parts below, and there was entire absence of muscular tissue.

The wall of the cyst was easily discriminated, and an incision three-quarters of an inch long made into it; some thick pus, containing a few small gall-stones, followed the withdrawal of the knife. Examination showed a contracted gall-bladder, the whole cavity of which was filled with a reticulated meshwork of tissue which was formed, evidently, from the inflamed mucous membrane, and containing strong bands of connective tissue which crossed the cavity in all directions. Firmly held in this web of tissue, were over one hundred stones of variable size, the largest being about three-eighths of an inch in diameter. These were slowly teased from their confinement by means of a dull curette, and the cavity packed with iodoform gauze, and an aseptic dressing applied.

DR. S. J. MIXTER read a paper on

RETENTION-CYST OF THE GALL-BLADDER.³

DR. WHITNEY: As regards the diagnosis of the situation, it was rather by exclusion than anything else. The examination of the wall of the cyst showed it to be of fibrous nature, and the contained fluid was thin, rather viscid, and such as I have seen often in cases where the gall-bladder has been cut off from the bile, and where there has been accumulation of thin, mucus-like fluid within the gall-bladder. There was nothing of the nature of an echinococcus cyst-wall, and from the situation, I think, with Dr. Mixter, there is no other supposition tenable except that it was a retention-cyst of the gall-bladder, the communication with the common duct having been cut off.

DR. M. H. RICHARDSON showed a

RETRO-PERITONEAL CONGENITAL CYST, removed eight days before from a baby of thirteen months, a patient of Dr. Bowers, of Clinton. When born the abdomen was abnormally enlarged, and the child was supposed to have something the matter with the liver. Later, as he developed, the swelling also increased in size. There was no interference with the general health of the baby. A few weeks ago it was decided, in consultation with Dr. F. C. Shattuck,

³ See page 429 of the Journal.

to make an exploratory incision. The diagnosis was necessarily obscure, but it seemed, on the whole, to be more probably a congenital hydrocephrosis than anything else. On opening the abdominal cavity in the median line, above the umbilicus, a large retro-peritoneal tumor was exposed. This contained about seven pounds of slightly opaque fluid. The cyst was attached just behind the pancreas. Over and in front of its neck the splenic vein passed, and it was necessary to tie and cut that vessel. The peritoneum was stripped from the tumor down to its base, and the pedicle ligated with catgut. The diagnosis made by Drs. R. H. Fitz and W. F. Whitney, after examination of the specimen, is retro-peritoneal cyst of congenital origin, and the case is apparently unique. The baby was discharged from the hospital well in about three weeks from the time of the operation.

Dr. WHITNEY: The specimen is quite unique, being a cyst developed behind the pancreas in the retro-peritoneal tissue, and is of interest from its point of origin, as cysts in this region are among the greatest rareties. In the ordinary literature of the subject I find no mention of it; and Dr. Fitz, who recently has given a great deal of attention to diseases of the pancreas tells me he has not come across any mention of a cyst occurring in this region.

As you look at the cyst you see on the upper surface the line where the peritoneum has been dissected off as sort of ridge. In the fresh condition this contained numerous gray, rather lobulated masses which attracted my attention at first, and which I thought to be simply minute masses of fat of the peritoneum. On section, you see that the upper part are really portions of the pancreatic tissue, a sinous gland-tissue. Under the microscope you see denser masses, masses of pancreatic tissue, then the wall of the cyst, which is of fibrous tissue. As regards the fluid which this contained, I am sorry that it was not received in a fresh enough condition to make a very satisfactory examination. From the report of the house-officers who examined it, it contained a certain amount of fatty, degenerated, granular corpuscles and fat crystals and a little free fat. In one point of the cyst wall there is also a little fatty-looking tissue. There is no epithelial lining of the cyst wall, and nitrate of silver staining failed to disclose a distinct endothelial lining, such as usually lines the serous surface of the abdomen. Being of congenital origin, as the history plainly shows, we probably have to do with something of developmental character, and at once attention would be called to the peritoneum as the probable source of origin.

Recent Literature.

A Manual of Hypodermatic Medication: the Treatment of Disease by the Hypodermatic or Subcutaneous Method. By ROBERTS BARTHOLOW, A.M., M.D., LL.D., Emeritus Professor of Materia Medica, General Therapeutics and Hygiene in the Jefferson Medical College of Philadelphia, etc. Fifth edition, revised and enlarged. J. B. Lippincott Company. 1891.

The fifth edition of this work has grown to a book of 540 pages, as many of the articles have been rewritten and new matter has been added.

An interesting historical sketch of the hypodermatic method begins the work. The author uses the term hypodermatic in place of hypodermic, as the term hypodermic is not sanctioned by scholars, but the use of the less exact word is now so firmly established that it will be difficult to substitute the more proper one for it.

Under the group of remedies affecting nutrition, there are given valuable suggestions about the subcutaneous use of mercury, of pilocarpine, of iron, and various methods of transfusion are briefly considered. Then follows a group which is classed as agents having the power to destroy pathogenic micro-organisms, among which are found a number of antiseptics and antipyretics.

A large portion of the work is devoted to morphine, the treatment of the opium habit and the antagonisms between atropine and other alkaloids. Following this, and also among the remedies which affect the nervous system, are strychnine, the digitalis group, cocaine, caffeine and ergot. The subcutaneous use of quinine is, of course, taken up; and the peculiar advantages of the subcutaneous method of administering it is insisted on. Of the remaining topics those of amylydrate, nitroglycerine and apomorphine are among the more important.

Besides a consideration of the subcutaneous use of the remedies, their history, properties and physiological action and uses are given. The work has many suggestions of practical value, but things of secondary importance are also included in a work which aims to be complete.

Dr. Bartholow recommends the hypodermatic use of atropine in asthma. Morphine is treated very fully; and the author takes the ground that it is not as much used as it deserves to be in relieving pain after operations and injuries, especially during the first few hours after fractures or dislocations.

So far as the reviewer is aware, this work is the largest and most comprehensive which has been written on this subject; and the well-known and distinguished author has evidently taken great pains to include all that has a bearing upon the subject of hypodermatic medication.

Therapeutics, its Principles and Practice. By H. C. WOOD, M.D., LL.D., Professor of Materia Medica and Therapeutics, and Clinical Professor of Diseases of the Nervous System, in the University of Pennsylvania. Eighth edition. J. B. Lippincott Company. 1891.

It is a satisfaction to see the editions of this standard work on therapeutics follow each other at short intervals. Only a few years ago the seventh edition was published; and we now have the eighth edition in a revised and enlarged form.

There is no work on this subject which is more reliable in its teachings. The many familiar excellencies of this valuable book are retained, and it is unsurpassed by any other treatise.

Essentials of Medical Electricity. By D. D. STEWART, M.D., and E. S. LAWRENCE, M.D. 16mo, pp. 158, with sixty-five illustrations. Philadelphia: W. B. Saunders. 1892.

This little manual is better than the average of such compilations. It is clearly written, and affords a fairly safe guide to the beginner in this subject.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, APRIL 28, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

THE REPORT OF THE MEDICAL OFFICER OF
THE LOCAL GOVERNMENT BOARD.

This valuable report contains the results of the investigations of the Local Government Board upon sanitary matters for the year 1890.¹

From this report it appears that the percentage of young children who had not been formally accounted for in the vaccination returns amounted to 10.3 in London, and 8.2 in the rest of the country, a somewhat larger percentage than that of the years immediately preceding. This increase may partly be attributed to the fact that no serious epidemic of small-pox has occurred in England for the past six years. The investigations made by the medical inspectors of the Board during the year comprised an inquiry by Dr. Barry relative to an epidemic of typhoid fever in the valley of the River Tees. The circumstances attending this epidemic are so much like those which recently prevailed at Lowell² and Lawrence on the Merrimack River, as to be worth repeating here for the purpose of comparison. The Tees Valley embraces a district of 746,000 acres, with an estimated population in 1890 of 520,000, the principal towns being Middlesbrough, Darlington, Stockton and Auckland. In the district there were 570 cases of enteric fever reported in the four weeks ending with October 4th. After describing the conditions which prevailed in the district, during the previous season, Dr. Barry concludes as follows:

"From a consideration of all the circumstances of the case, I have personally no hesitation in attributing the epidemic of enteric fever in the lower Tees Valley to the water pumped from the River Tees during the fortnight ending August 23d, at a time, namely, when the river was in flood, and when it must have contained abundance of excremental ma-

¹Twentieth Annual Report of the Local Government Board (1890-1891). Supplement containing the Report of the Medical Officer. Pp. xi, 296. London: Eyre & Spottiswoode, 1891.

²Journal, vol. xxiv, p. 397.

ter. And I consider that, so long as water for drinking purposes is drawn from the Tees, the condition of that river remaining as at present, so long will there be danger of the occurrence of similar epidemics to that described in this report, in the districts thus supplied with Tees water.

"There can be no question that if the sewage and excremental and other refuse of the various towns and villages above the pumping station were prevented from passing into the Tees, the danger of specific pollution of the water would be very greatly reduced; but even under these circumstances it is still doubtful whether a water, pumped from a river at a point forty miles from its source is, anywhere in this country, a desirable supply for drinking purposes.

"Until some very decided improvement is effected, either in the river conditions or in the source of the water-supply, it will be advisable for persons residing in the towns recently infected by enteric fever, to boil all water prior to its use for drinking purposes."

Other important investigations follow upon epidemics of diphtheria, scarlet-fever, cerebro-spinal meningitis, and pneumonia in different districts of England and Wales.

Dr. Parsons contributes a valuable inquiry as to the merits and demerits of water-closet construction, with special reference to the use of slop-closets and trough-closets. He is of the opinion that the slop-closet with automatic flushing is well-adapted for use at artisan's cottages, and that trough-closets might be introduced with advantage in common courts occupied by the lowest and roughest class of people, as well as at schools, mills, and other places where closets are used in common by large classes of people. Neither professes to be adapted for indoor use. One has for its object the economizing of rain and sink-water, where water is scarce; and the other, the prevention of injury to health by the misuse of water-closets. This advice would be better adapted for New England, if it were not for the liability of all outdoor fixtures to freeze during our rigorous winter weather.

Dr. Bullard contributes a summary of all the cases of food-poisoning which had been investigated by the Board during the previous twelve years, fourteen in number. Most of these resulted from eating pork, pork-pies, or tinned meats in some form or other. He describes the usual symptoms as follows:

"A person after eating the poisonous food, often and indeed usually without previous warning, is suddenly attacked by the initial symptoms, which may be rigors, or one or other of the following symptoms, faintness, muscular weakness and prostration, sometimes very severe, or giddiness, abdominal pain, vomiting and diarrhoea, followed by fever, thirst, and more or less violent headache, and pains in various parts, and a variety of nervous disturbances such as muscular twitchings, disturbances of vision, dilatation of the pupil, or drowsiness; there may be an eruption of the skin, and later on suppression of urine. Convalescence is apt to be prolonged and sometimes attended with desquamation of cuticle.

"Pathological conditions noticed after death in men and animals consist of inflammatory, hemorrhagic or destructive changes in the stomach and intestines, pneumonic engorgement or a hemorrhagic condition of the lung tissue, and inflammatory or destructive changes in the liver and kidneys. These are phenomena not of mere local irritation, but of a general disease. Both clinically and pathologically, therefore, the phenomena resemble those of our better-understood specific fevers, with which this form of malady must in future be classed."

In the special appendices at the close of the volume may be found a continuation of Dr. Klein's researches upon the etiology of diphtheria, in which he reaffirms, notwithstanding the doubts of Löffler, his statements relative to the inoculation of cats and cows with the bacillus of diphtheria.

Dr. Martin contributes a paper on the "Chemical Pathology of Anthrax"; Dr. Hamer presents a report on "Certain Conditions Determining Insusceptibility"; and Dr. Andrewes, a paper on "Pyogenic Organisms."

The report contains a memorandum which has much practical importance in connection with the management and control of infectious diseases. The subject included in the memorandum is, "The Circumstances under which the Closing of Public Elementary Schools or the Exclusion therefrom of Particular Children may be Required in order to Prevent the Spread of Disease."

THE HOSPITAL SATURDAY AND SUNDAY ASSOCIATION.

A MEETING of the New York Saturday and Sunday Association was held April 18th, at St. Luke's Hospital, to consider the annual report of collections for 1891. The report showed that the Association now embraces thirty-three hospitals. There are one hundred and fifty contributing churches, chapels and synagogues, while effective organizations for trade collections exist in all the principal business exchanges and trades of the city. During the last year a new impetus has been given to the work through the zeal and co-operation of women, who, through their Woman's Auxiliary, collected \$7,422.84 for the fund. The annual collection for the hospitals in New York amounted this year to \$60,263.91, which is \$1,921.68 more than that of last year.

The work of the Association has grown to such magnitude that a general agent has been permanently employed to foster interest and prepare the machinery for the annual collection, and to act as an intermediary between contributors and the hospitals with regard to the admission of patients.

Similar associations have been formed in some of the other cities of the country, and it is thought that the growth of interest in the cause may lead to the establishment of a National Hospital Saturday and Sunday Association. A committee that had been appointed in regard to awakening a more general interest

in the movement made a report, and it was decided to issue a circular letter, setting forth the objects of the Association, and the work accomplished by it in New York, and to send this to persons interested in philanthropic work in the various cities and large towns of the country.

SURGERY OF THE LIVER.

The present issue of the JOURNAL may be fairly termed an hepatic number. It opens with a paper by Dr. W. W. Keen, of Philadelphia, on resection of the liver, especially for hepatic tumors, which includes a report of a successful resection for a very rare cystic adenoma of the bile-ducts. This is followed by a paper by Dr. M. H. Richardson, of Boston, on gall-bladder surgery, illustrated by eleven different cases, and in addition he reports an echinococcus cyst of the liver. Dr. Homer Gage, of Worcester, Mass., contributes a case of secondary laparotomy for pistol-wound of the liver; Drs. Gay and Cabot, of Boston, cases of cholecystotomy; Dr. Irish, of Lowell, cases of hepatic abscess; and Dr. S. J. Mixter, of Boston, a retention-cyst of the liver.

This is an uncommon collection of cases presented by able surgeons, especially when one reflects how very recent the development of hepatic surgery is. We shall do no more, and we could do no less, than direct the attention of our readers to this interesting series, which we are fortunate enough to be able to lay before them simultaneously, and to the report of the Society before which it was presented.

The surgeon and the physician are prying into the liver as never before; hepatic tissues and processes which not long ago were dreadful and mysterious are rapidly becoming less so or ceasing to be so at all. Editorially we have had our say, not long ago, on the surgery of the liver,¹ and very recently on biliary infections,² and gladly leave the reader, without further comment on our part, in the good company in which he finds himself to-day.

MEDICAL NOTES.

THE PADDOCK PURE FOOD BILL. — This bill, the details of which were given on page 276 of the JOURNAL of March 17th, is now before the national house of representatives, and is being opposed by manufacturers of proprietary medicines, on the ground that it places undue restrictions upon an important and flourishing industry.

PHYSICIANS UNDER FIRE. — While two physicians in Brooklyn were endeavoring last week to have a child with small-pox removed to the hospital for contagious diseases at Flatbush the irate father of the child, in a fit of passion, fired two shots from a revolver at them. Fortunately no harm was done, and after the arrival of the police captain and several assistants, the

¹ November 19, 1891, p. 554.

² April 14 and 21, 1892, pp. 373, 387.

child went to the hospital and the father to the station-house.

MEDICAL DEGREES IN FRANCE.—During the academic year 1890-91, the number of persons admitted to the degree of Doctor of Medicine in all the French Faculties was 594, being three less than in the previous year. Of these degrees, Paris conferred 374, Lyons 71, Montpellier 60, Bordeaux 55, Lille 14, Nancy 11, and the newly-created faculty of Toulouse nine.

A MURDERER'S DEVOTION TO SCIENCE.—It is said that a French murderer, condemned to be guillotined, recently requested his brother, a medical student, to experiment with his head immediately after decapitation, in order to ascertain by a pre-arranged code of signals (winks and movements of the eye-balls), what he felt when the knife cut his head off, and how sensation and consciousness is retained.

THE SO-CALLED "PARROT EPIDEMIC" IN PARIS.—The Paris correspondent of the *British Medical Journal* notes the breaking out of a new epidemic of a hitherto unknown malady, which is supposed to have been transmitted by some parrots imported from Brazil. Professor Peter, of the Hôpital Necker, believes that it is often transmitted directly from the birds to the human subject than caught by one patient from another. One of the cases has come to autopsy. Professor Cornil says: "It is a new disease; this is the first time I have met with it." In this connection it is interesting to note that yellow fever is prevalent in Brazil.

FOOTBALL IN ENGLAND.—During the season in which the game of football is played in England, the record of accidents more or less serious, is practically continuous; and although many organs of public opinion from time to time contain articles remonstrating against the amount of injury suffered through the violence of the play indulged in at ordinary matches, still the frightful extent of it is not probably very generally realized. How widespread is the mischief, however, is forcibly brought out when the fatalities and injuries which occur within a single season are collected together and arrayed in a tabular fashion, as has recently been done in the pages of the *Pall Mall Gazette*. The result here shown is that during the football season of 1891-92 there died through accidents received on the field no fewer than eleven players, while more than seventy others received injuries, mostly in the shape of fractures, which would entail on them weeks of suffering and incapacity for work. The time has surely come when an attempt ought to be made in favor of arresting the annual tribute of lives to the craze for dangerous excitement, to which alone it is possible to attribute the popularity of the game.

BOSTON AND NEW ENGLAND.

THE WEST-END NURSERY AND INFANTS' HOSPITAL.—The directors of the West-End Nursery and Infants' Hospital, while acknowledging the receipt of generous contributions, regret that they must appeal to the pub-

lic again for aid in order that the work may be continued in its present manner until June 1st, and that arrangements may be made for caring for a number of babies during the summer months.

MASSACHUSETTS EMERGENCY AND HYGIENE ASSOCIATION.—The annual meeting was held April 21st at the house of Dr. Francis Minot. Mrs. Kate Ganett Wells read the report of the executive committee, Dr. O. H. Marion that of the militia work, and Miss Tower of the children's playgrounds. The financial statement showed that the association had not gone into debt, but that the public should be appealed to in aid of the funds to carry on the philanthropic work.

CASES OF TRICHINOSIS IN ROXBURY.—Cases of trichinosis have been recently reported in Roxbury (Boston). There were eight or ten cases in all, and one death. All the cases apparently originated from the ham of a four-year-old pig, brought up in the neighborhood. The meat was eaten uncooked, and the cases occurred in four families, all Germans from Saxony. Trichines were found in the ham and in the muscles of the man who died. Trichinosis has been very rare in or about Boston for many years.

CHILDREN'S ISLAND SANITARIUM.—The annual meeting of the Children's Island Sanitarium was held April 21st at the office of the treasurer. By the reports presented it appeared that 430 persons were admitted to the benefits of the institution last summer, and \$4,876 was expended in carrying on the work. With the exception of George Hayward, M.D., whose resignation was received and accepted with much regret, the old board of officers was re-elected as follows: President, C. E. Inches, M.D.; Treasurer, J. O. Shaw, Jr.; Secretary and Medical Superintendent, H. C. Haven, M.D.

NEWTON (MASS.) HOSPITAL AID ASSOCIATION.—A fund has been started by the Newton Hospital Aid Association, to establish what is to be known as the Palmer Memorial Home for Nurses in connection with the Cottage Hospital of Newton. The plan is to erect a suitable building with at least ten dormitories for the pupil nurses, and a large sitting and recreation room. It is to be named in honor of Miss Palmer, the former matron of the Cottage Hospital and the founder of the training-school.

NEW YORK.

CHANGES IN THE BOARD OF HEALTH.—A number of changes among the medical officers of the Board of Health were ordered at the meeting of the Board held April 19th. Dr. W. A. Ewing, who has been Sanitary Superintendent for three years, was discharged, and Dr. Cyrus Edson appointed in his place. Dr. Charles F. Roberts was promoted to the position of Chief Inspector of Contagious Diseases vacated by Dr. Edson. Dr. John T. Nagle was promoted to the position of Registrar of Records, and Dr. Roger F. Tracy, who had previously been Registrar, was given the position of Deputy Registrar, hitherto occupied by Dr. Nagle. Dr. F. R. Percival

was discharged from the post of resident physician at the hospital for contagious diseases on North Brother Island.

TIYPHUS FEVER AND SMALL-POX.—During the past week two or three new cases of typhus fever were reported. There were two deaths from small-pox, and a large number of new cases of the disease, as many as six being sometimes reported in one day. During the past month there have been more cases of small-pox in the city than for several years past, but the disease is apparently of a mild type, the mortality having been very small.

YELLOW FEVER.—The steamer *Alliance*, which arrived at quarantine from Brazilian ports on April 22d, had a number of cases of yellow fever on board before she finally left Brazil. One of the patients, a young man belonging to a wealthy New York family, who contracted the disease at Santos, died on the vessel. Two of the ship's crew were sent on shore at Santos, and six at Rio Janeiro, suffering with the fever.

Miscellan.

THE FIFTY-NINTH YEAR OF THE BOSTON LYING-IN HOSPITAL.

THIS admirable hospital has issued a handsome report for the year 1891, which includes a statement of its history, work, officers, staff, board of lady visitors and corporate members, the names of donors, statistics of its physicians, finances, and of its training-school for nurses.

It has judiciously provided itself with all the modern appendages for the successful working of a modern charitable institution.

The Boston Lying-in Hospital was originally established by the co-operation of the Massachusetts Humane Society and the Charitable Fire Society. What the hospital now is and what it does, cannot be better told than in the words of this report:

"During the past twenty years it has in various ways performed an important service to the city of Boston and to the larger community whose welfare it affects.

"The work which the institution accomplishes in caring for more than five hundred women annually in the hospital, and in extending its aid each year to more than seven hundred women in their own homes, fills a vital need, and at the same time relieves the public institutions of the city from the practice of a charity which can be far more effectively and properly exercised by private benevolence; but this is not the only and perhaps not the most valuable benefit which the hospital confers. It is only by a large hospital, where many and difficult cases are treated, and where the treatment is carried on systematically and under constant observation and record, that scientific advancement can be made, new discoveries achieved, and improved methods inaugurated.

"The Boston Lying-in Hospital has taken a leading place among the institutions of its kind; and the results which have been here attained have been

quoted both in this country and Europe, and have helped to form the basis upon which the wonderful progress in obstetrics has been founded. Considered in the light of the dangers and fatalities which in the immediate past have attended women at this critical period, it is a triumph of science and skill, as remarkable as it is gratifying, that of a thousand patients — many brought because of their exceptional difficulty and from exceptionally adverse circumstances — not a single death should occur fairly ascribable to child-birth. Such a fact appeals to every family; and it is owing to the work done in this and similar maternity hospitals that such facts are made possible.

"The hospital is not only thus adding to general medical knowledge and skill, but is at the same time doing a more immediately practical work for this community. Its wards make possible for medical students a clinical instruction which is invaluable, and indeed almost indispensable, to the young physician. Through its out-patient department more than a hundred student externes are annually afforded, under the hospital oversight, a practical experience in the homes of the poor, which inures to the benefit alike of practitioner and patient. Each year half-a-dozen young physicians, after four months' service, go from the hospital into active work with a knowledge and skill which physicians ordinarily are unable to gain by a lifetime of practice in obstetrics; and each year the hospital's training-school graduates nearly a score of nurses thoroughly equipped and instructed in the best methods for securing the care, comfort and safety of private patients. The hospital is, therefore, more than a charity, and there is no class to which its important benefits are limited."

The buildings have lately been much enlarged and extended; and, in order to properly accomplish its beneficent work in accordance with these increased facilities, the list of generous donors should also be greatly increased, as it undoubtedly easily will be, since the benefits which such a hospital confers upon a community are so patent.

THE LANGENBECKHAUS AT BERLIN.

PROF. ERNST VON BERGMANN has presented a report to the German Emperor in which he gives an interesting account of the foundation and progress towards completion of the Langenbeckhaus at Berlin. This institution, which is intended for the accommodation of the medical societies of the Prussian capital, owes its origin to a suggestion made by the late Empress Augusta, as far back as in 1878, while the seventh congress of German surgeons was in session. Von Langenbeck announced that such a building was in contemplation. It was not, however, till after his death that the proposal took practical shape, and the German Surgical Society and the Berlin Medical Society undertook to carry the suggestion into effect by making the institution a memorial to that surgeon. A committee was formed which set to work without delay collecting funds. At the head of the list of subscribers figure the names of the Empress Augusta, the Emperor Frederick, and the present Emperor, the latter giving 100,000 marks (£5,000). German practitioners in America contributed £500, Russian military surgeons £100. The profession in Germany also subscribed largely. The site is in the Ziegelstrasse,

close to the Royal Surgical Clinic, which was so long the scene of von Langenbeck's labors and triumphs. The building, which is now all but completed, is both architecturally imposing and excellently adapted for its purpose. It provides ample accommodation for meetings of several societies or for the different sections of a congress simultaneously. The largest room can seat 800 persons, and there are four others of somewhat smaller size, besides one, seating 100 persons, for smaller assemblies, one for microscopic and other demonstrations, a room for preparations, and two to be used as a library and reading-room.

INFLUENZA AT SEA AGAIN.

THE following note is of interest inasmuch as it adds another to the list of outbreaks occurring on shipboard, and like some of the other reported instances seems to show that something different from the mere association with people ill with influenza is in some instances responsible for an epidemic outbreak.

Dr. D. G. MacGowan, of Los Angeles, in a paper read before the Los Angeles County Medical Association on March 18th, in speaking of a recent trip to Japan, says: "We left San Francisco with every one well, excepting the doctor. Five days out every one on board was sneezing, and upon the sixth day nearly all of the white crew had well-developed attacks of influenza, which affected chiefly the nervous and respiratory systems. In about a week or ten days we suddenly seemed to sail out of the influenza belt, and every one rapidly recovered."

Such notes are of scientific value as an aid to the study of the etiology of the affection; and it is a pity that such observations are not more frequently reported in the medical journals.

PASSAGE OF TUBERCLE BACILLUS FROM THE MOTHER TO THE FETUS.

BIRCH-HIRSCHFELD AND SCHMAL¹ have recorded a case which they consider is the first in which it has been definitely shown that in the human subject tubercle bacilli can pass from the mother to the fetus. The patient was a young woman who, shortly after the commencement of her first pregnancy, began to exhibit symptoms of incipient phthisis; the disease assumed an acute form, and progressed so rapidly that the patient died during the seventh months of her pregnancy. Immediately after the death of the mother the child was removed by the operation of Cesarean section. A post-mortem examination was made on the body of the mother. Advanced tubercular changes were found in the lungs, and also some miliary tubercles in the liver and other organs. The child had been felt to move after the death of the mother, but by the time the operation had been performed it was found to be dead. The thorax was at once opened, but the lungs appeared to be quite healthy. The body was then removed to the laboratory, the surface of the abdomen washed with perchloride of mercury, and the cavity opened by means of sterilized knives. No evidences of tubercle could be found in any of the organs. Small pieces of the liver, spleen, and kidney were removed with steril-

ized instruments, and placed in the abdominal cavity of two guinea-pigs and a rabbit. One of the guinea-pigs died in fourteen days; miliary tubercles were found in the peritoneum and large omentum. The second one was killed about six weeks after inoculation, and the same appearances were noted. The animal had appeared ill, it was feverish, and emaciating rapidly. The rabbit lived considerably longer — three months; after death tubercles were found in the liver and lung. From these experiments it was evident that although no tubercular lesions could be found in the organs of the child, yet the latter were capable of infecting animals; and had the child survived, it would have undoubtedly developed tuberculosis at an early age. It is a point of great interest to read that tubercle bacilli were found in the umbilical cord and in the blood of the umbilical vein.

THERAPEUTIC NOTES.

STRICHNINE FOR SNAKE-BITE. — During the past year the *Australasian Medical Gazette* has been collecting evidence of the value of strichnine in snake-bite. This treatment, first suggested by Mueller, in Australia, consists in injecting subcutaneously liquor strichninae, B. P., in large doses, until symptoms of the action of strichninae appear. Persons suffering from snake-bite appear to be very tolerant of the drug, the total dosage sometimes reaching as much as a grain. The opinion is expressed that ammonia and alcohol are frequently, if not always, prejudicial in snake-bite poisoning.

THE ADMINISTRATION OF BROMOFORM. — Bedford² calls attention to the improper method in which bromoform is often prescribed, that is, in a mixture of alcohol, syrup and water. In this manner the bromoform is precipitated, and most of the drug may be taken in the last doses. The following formula is suggested:

Bromofom	:	:	:	:	:	m. vi.
Alcohol	:	:	:	:	:	150 c.c.
Glycerine	:	:	:	:	:	15 c.c.
Compound tincture of cardamom	:	:	:	:	:	3 v. s. M.

Each fluid drachm contains one minim of the bromoform in perfect solution. Syrup or water should not be used, as either will reduce the bromoform.

PRESCRIBING OF PEPSIN.³ — Dr. R. G. Eccles, in a paper recently read before the Chemical Section of the Brooklyn Institute, stated that one-half of all the prescriptions which came to the drug stores containing pepsin also contained an alkali, thus destroying the efficacy of the pepsin.

PALATABLE CASTOR OIL. — As the result of a series of experiments, Staadke⁴ believes that he has succeeded in removing the nauseous taste of castor oil. The best castor oil is repeatedly treated with hot water, then sweetened with sufficient saccharin to possess a syrupy taste. Minute quantities of the aldehyde of cinnamon oil and of vanilla flavoring suffice to completely cover whatever disagreeableness of taste remains. Oil so prepared has been found to be as efficacious and permanent as the ordinary oil.

¹ *Pharmaceutical Record*, February 11th.

² *Brooklyn Medical Journal*.

³ *Deutsche med. Woch.*, 1892, No. 4, p. 87.

⁴ *Beiträge zur Path. Anatomie und zur Allg. Path.*, 1891, p. 429.

THE SODIO-SALICYLATE OF THEOBROMINE, OR DIURETIN. — Dr. H. A. Hale⁴ reports his experience with this drug: Encouraged by the favorable results obtained by Keyes and Babcock in this country, by Gram and Hoffmann in Germany, and by Koritschoner in Vienna, he gave 120 grains daily, in divided doses, to four patients, — two of them with cardiac disease, one with general anasarca, and one with senile enlargement of the prostate. In these cases he failed to find any increase in the daily urinary flow — which could be justly attributed to the action of the diuretin. In one the urine did increase somewhat in amount; but he considered this due to the digitalis which it became necessary to administer. The diuretin (Knoll) and the sodio-salicylate of theobromine (Merck) were both employed, and no difference in result was noted. There is, however, a difference in the price of the two; diuretin (Knoll) costs two dollars and fifty cents an ounce, but sodio-salicylate of theobromine (Merck) costs fifty cents an ounce, or one-fifth as much.

Correspondence.

INTERNATIONAL PERIODICAL CONGRESS OF GYNAECOLOGY AND OBSTETRICS.

FIRST SESSION.—BRUSSELS, BELGIUM, SEPTEMBER 14 to 19, 1892.

CHICAGO, April 21, 1892.

MR. EDITOR:—The following named distinguished gentlemen have been delegated to represent the British Gynaecological Society at the International Congress of Gynecology and Obstetrics, next September: Robert Barnes, A. S. Simpson, Granville Bantock and Lawson Tait.

Great preparations are being made to entertain visiting physicians. His Majesty, King Leopold, will assist at the opening of the Congress. There will be a grand reception by the Belgian Gynaecological Society; gala performance at the Grand Opera; also a banquet by the Belgian Gynaecological Society; garden-party in the gardens of the royal family, etc.

For all information relating to the Congress, address,

DR. F. HENROTIN, American Secretary,
353 LA SALLE AVE., CHICAGO, ILL.

* Therapeutic Gazette, March 15th.

METEOROLOGICAL RECORD.

For the week ending April 16, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 3,431: under five years of age 1,235; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 438; acute lung diseases 387; consumption 373; diphtheria and croup 162; measles 156; small-pox 10; erysipelas 9; typhoid fever 41; cerebro-spinal meningitis 17; erysipelas 17; whooping-cough 16; malarial fever 7; puerperal fever 5; small-pox 1.

From typhoid fever Chicago 11, Pittsburgh and Washington 6 each; Philadelphia 5, Brooklyn and Boston 2 each; St. Louis, Cleveland, Lowell, New Bedford and Waltham 1 each. From measles New York 27, Philadelphia 5, Chicago 3, Brooklyn and Cleveland 2 each; Boston, Pittsburgh and Lawrence 1 each. From cerebro-spinal meningitis New York 7, Chicago and Lawrence 3 each; Worcester 2, Brooklyn and Cleveland 1 each. From erysipelas New York and St. Louis 4 each; Chicago 3, Philadelphia and Boston 2 each; Brooklyn and Cambridge 1 each. From whooping-cough New York 1, Pittsburgh 2, Chicago, Philadelphia and Cleveland; Nashville, Charlton and Haverhill 1 each. From malarial fever New York 4, Brooklyn 2, Philadelphia 1. From small-pox New York 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,183,736, for the week ending April 24, the death-rate was 22.2. Deaths reported 4,346: acute diseases of the respiratory organs (London) 430; whooping-cough 170; measles 134; diarrhea 42; scarlet fever 33; diphtheria 30; fever 16; small-pox (London) 2.

The death-rates ranged from 14.7 in Croydon to 28.1 in Manchester; Birmingham 21.9, Bolton 26.0, Bristol 23.2, Hull 18.8, Leeds 24.6, Leicester 21.8, Liverpool 25.0, London 21.4, Nottingham 23.2, Oldham 24.5, Sheffield 20.7, Sunderland 22.8, Wolverhampton 26.2.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE THREE WEEKS ENDING APRIL 16, 1892.

BAILHACHE, P. H., surgeon. Granted leave of absence for seven days. March 3, 1892.

BUXTON, GEORGE, surgeon. Detailed as chairman of Board for physical examination of officers, Revenue Marine Service. March 30, 1892.

GODFREY, JOHN, surgeon. Detailed as inspector of immigrants, port of New York. April 15, 1892.

HAMILTON, J. B., surgeon. Detailed as chairman of Board for physical examination of surfman, Life-Saving Service. March 31, 1892.

MEAD, F. W., surgeon. Detailed as chairman of Board for physical examination of officers of Revenue Marine Service. April 16, 1892.

BANKS, C. E., passed assistant surgeon. Ordered to examination for promotion. April 14, 1892.

CARMICHAEL, D. A., passed assistant surgeon. When relieved at Port Townsend, Wash., to proceed to San Francisco Quarantine for duty. April 8, 1892.

MCINTOSH, W. P., passed assistant surgeon. When relieved at San Francisco Quarantine to proceed to New Orleans, La., for duty. April 8, 1892.

PETTUS, W. J., passed assistant surgeon. Granted leave of absence for thirty days. April 12, 1892.

MAGRUDER, G. M., passed assistant surgeon. When relieved at Portland, Oregon, to proceed to Port Townsend, Wash., for duty. April 8, 1892.

KINTYOUN, J. J., passed assistant surgeon. Detailed as chairman of Board for physical examination of candidates and officers, Revenue Marine Service. March 30, 1892. Detailed as recorder of Board for physical examination of officers, Revenue Marine Service. April 16, 1892.

VAUGHAN, G. F., passed assistant surgeon. Detailed as recorder of Board for physical examination of candidates and officers, Revenue Marine Service. March 30, 1892.

GEDDINGS, H. D., assistant surgeon. Ordered to examination for promotion. March 29, 1892.

WERTHBAKER, C. F., assistant surgeon. Detailed as recorder of Board for physical examination of surfman, Life-Saving Service. March 31, 1892. Ordered to examination for promotion. April 5, 1892.

PERRY, J. C., assistant surgeon. To proceed to Gulf Quarantine for temporary duty. April 9, 1892.

YOUNG, G. B., assistant surgeon. When relieved at St. Louis, Mo., to proceed to Portland, Oregon, for duty. April 8, 1892.

STIMPSON, W. G., assistant surgeon. Detailed as recorder of Board for physical examination of officers, Revenue Marine Service. March 30, 1892.

BROWN, B. W., assistant surgeon. Detailed as chairman of Board for physical examination of officers, Revenue Marine Service. April 1, 1892. To proceed to Port Townsend, Wash., for temporary duty. April 8, 1892.

ROSENAN, M. J., assistant surgeon. When relieved at New Orleans, La., to proceed to St. Louis, Mo., for duty. April 8, 1892.

COFFEE, L. E., assistant surgeon. To proceed to Buffalo, N. Y., for temporary duty. April 8, 1892.

EAGER, J. M., assistant surgeon. To proceed to Gallipolis, Ohio, for temporary duty. April 8, 1892.

GARDNER, C. H., assistant surgeon. To proceed to San Francisco, Cal., for temporary duty. April 8, 1892.

AMERICAN PEDIATRIC SOCIETY.

PRELIMINARY PROGRAMME.

The American Pediatric Society will hold its fourth annual meeting in Boston, Mass., May 2, 3, and 4, 1892. The Sessions will be held in the Boston Medical Library Association Building, 19 Boylston Place.

MONDAY, MAY 2.

First Session (2 p. m.). — 1. The President's Annual Address. By William Osler, M.D., of Baltimore, Md. 2. "Experiments as to the Value of Nascent Ozone in certain Forms of Diseases of Children, with Demonstration of an Efficient Generator." Augustus Callie, M.D., New York City. 3. "Manifestations of La Grippe in Children." Chas. Warrington Earle, M.D., Chicago, Ill. 4. "An Epidemic of Alopecia in a School of Girls," Chas. P. Putnam, M.D., Boston, Mass.

TUESDAY, MAY 3.

Morning Session (10 a. m.). — 1. Discussion arranged by the Council on "The Relations of Rheumatism and Chorea." W. C. Townsend, M.D., Boston, Mass. M. Alice Starr, M.D., New York City. Samuel S. Adams, M.D., Washington, D. C. 2. "Nomenclature of Diseases of the Mouth." T. M. Rotch, M.D., Boston, Mass. 3. Report of the Committee on Nomenclature of Stomatitis. 4. "Pseudo-Diphtheritic Processes." W. D. Booker, M.D., Baltimore, Md. 5. "Treatment of Diphtheria by Sublimation of Mercury." Dillon Brown, M.D., New York City.

Afternoon Session (3 p. m.). — 1. "Typhoid Fever in Children under Two Years," W. P. Northrup, M.D., New York City. 2. "Typhoid Fever in Children," Chas. Warrington Earle, M.D., Chicago, Ill. 3. "Typhoid Fever in Infancy," W. S. Christopher, M.D., Chicago, Ill. 4. "Acute Emphysema in

Children, with Report of Cases," F. Forchheimer, M.D., Cincinnati, O. 5. "Pre-tubercular Anæmia," B. K. Bachford, M.D., Newport, Ky.

Evening Session (8 p. m.). — 1. Business Meeting at the residence of Dr. T. M. Rotch, No. 197 Commonwealth Avenue. 2. Report of the Council and election of officers.

Reception (9 p. m.). of the members of the American Pediatric Society, to be given by Dr. T. M. Rotch at his residence.

WEDNESDAY, MAY 4.

Morning Session (10 a. m.). — 1. "Prevention versus Medication in the Management of Diseases of Children." J. N. Love, M.D., St. Louis, Mo. 2. "Syphilitic Broncho-Stenosis," A. Seibert, M.D., New York City. 3. "A Simple Method for Clinical Examination of Breast Milk," L. Emmet Holt, M.D., New York City. 4. "Sacro-Coccygeal Tumor in a Child Three Weeks Old; Operation; Recovery," F. Huber, M.D., New York City. 5. (Title to be announced.) Henry Koplik, M.D., New York City.

Afternoon Session (3 p. m.). — 1. "Two Tracheal and Bronchial Casts," F. Huber, M.D., New York City. 2. "A Case of Death from Laryngismus Stridulus in Incipient Rachitis," Samuel S. Adams, M.D., Washington, D.C. 3. "The Value of Milk Laboratories for the Advancement of our Knowledge of Artificial Feeding," T. M. Rotch, M.D., Boston, Mass. 4. Action relative to the death of Dr. John Amory Jeffries, of Boston, Mass.

1632 K Street, Washington, D. C.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The annual meeting will be held at 19 Boylston Place, on Saturday, April 30, 1892, at 8 p. m.

Dr. G. W. Gay: "A Case of Nephrolithotomy; removal of a stone weighing five ounces; Recovery."

Dr. T. M. Rotch: "Improved Methods of Modifying Milk for Infant Feeding."

Dr. J. H. McCollum will show by (lantern slides) the various stages of the eruption of Small-pox.

Dr. C. B. Bell will read a circular of information in regard to the Pan-American Medical Congress; Dr. A. P. Clarke, of Cambridge, and Dr. Marcy will make remarks about it.

Selection of officers.

Supper after the meeting.

Members are requested to notify the Secretary at 188 Marlboro Street, of any error or change in address.

EDWARD N. WHITTIER, M.D., *President.*

JAMES J. MINOT, M.D., *Secretary.*

BOSTON SOCIETY FOR MEDICAL OBSERVATION. — A regular meeting will be held Monday, May 2, 1892, at 8 o'clock, at 19 Boylston Place.

Readers: Drs. M. H. Richardson and J. G. Mumford, "Surgical Methods in Private Practice, with Report of Cases."

Dr. F. H. Williams will report "A Case of Transfusion after Intestinal Hemorrhage in Typhoid Fever."

JOHN C. MUNRO, M.D., *Secretary.*

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY. — There will be a meeting of this Section at 19 Boylston Place on Wednesday evening, May 4, 1892, at 8 o'clock.

Dr. S. J. Mixter, "Median Abdominal Section for Removal of Tumor of the Kidney; Recovery."

Dr. H. W. Cushing, "A Case of Nephrectomy; Recovery."

Dr. John L. Morse, "Tracheotomy with Delayed Removal of the Tube."

Dr. C. L. Scudder, "Diphtheria; Tracheotomy, Curetting the Trachea; Recovery."

CHARLES L. SCUDDER, M.D., *Secretary,* 94 Charles Street.

—

THE MIDDLETON-GOLDSMITH LECTURE.

This lecture before the New York Pathological Society, will be delivered by Dr. Francis P. Kinnicut, Wednesday evening, May 11th, at the Academy of Medicine. Subject, "New Outlooks in the Prophylaxis and Treatment of Tuberculosis."

APPOINTMENT.

DR. W. S. HALSTED has been elevated to the full professorship of surgery in Johns Hopkins University. He was formerly assistant professor.

RECENT DEATHS.

SHELDON S. CLARK, M.D., of St. Albans, Vt., died April 21st, at the age of sixty-five years. He had been engaged in the active practice of his profession since 1849, he was a member of the Vermont State Medical Society and had been secretary and later the president of the Society.

¹ During the Sessions of the Society, the members are invited to visit and inspect the Milk Laboratory, 203 Clarendon Street.

Original Articles.

THE OPERATIVE TREATMENT OF GOITRE.¹

BY J. COLLINS WARREN, M.D.

TUMORS of the thyroid gland are not common in this country, and consequently the experience of American surgeons is small as compared with that of many on the continent of Europe, where within the last decade the operative treatment has received a considerable impetus.

The dangers of goitre appear to be due principally to dislocation and compression of the trachea and consequent interference with the respiration. There is also a certain amount of venous congestion in the cervical region, with consequent dilatation of the right heart, which may be followed by degenerative changes in the tissue of that organ. There may also exist some bronchiectasis and emphysema.

Pressure upon the trachea causes, in advanced cases of the disease, displacement and flattening of the tracheal canal, so that it presents an appearance known as the scabbard-like distortion. There is also, according to Rose, a softening of the tracheal rings, due to pressure, giving rise to a condition which favors the formation of a kink in the canal, following quick movements of the head, while the body is motionless. Sudden death may result under these circumstances. The disorders of respiration, seen in animals after removal of the thyroid gland, are regarded by Horsley as due to changes in the functional ability and activity of the respiratory centre, due to changes brought about in the nutrition of the tissues by the cessation of function of the gland.

The difficulties and dangers of thyroidectomy have usually been considered as objections to the operation. On this account many modes of treatment have been devised. It is not my purpose to give you this evening a complete summary of the various forms of treatment of goitre. I will, therefore, briefly refer only to one or two methods in which I have had some experience.

For clinical purposes the enlargement of the thyroid gland may be divided into three varieties — the vascular, the parenchymatous and the cystic. A favorite method of treating the vascular goitre is by electrolysis, and many of you are familiar with the monograph by Dr. Robert Amory. His results show that the operation is well suited to this variety, and if complete cure cannot be effected in all cases, considerable diminution in the size of the gland may be procured. Good results can also doubtless be attained in some of the parenchymatous types of the disease by this method.

The internal use of iodine may be of some use in young persons in diffuse forms of goitre; but, according to Bruns, if no change occurs in the size of the tumor very soon after the use of the drug, improvement is not to be looked for.

Parenchymatous injections of iodine have been employed, particularly in the cystic variety. A number of cases of sudden death are, however, reported as following the use of this remedy, although many favorable results have been obtained.

Death may be caused by embolism, and also by paralysis of the abductor muscles through reflex irri-

tation following an absorption of the iodine into the pneumogastric nerve or the recurrent laryngeal.

Wörner reports 75% of successful cases by this method, and in one case a single cyst, the size of a man's head, was cured in this way. It appears to be best adapted to single, thin-walled cysts. The possibility of suppuration following this mode of treatment should be considered, as well as the occurrence of hemorrhage from the interior of such cysts when once they have been opened.

The operation of thyroidectomy appears to be indicated in cases when the difficulty of breathing has become a prominent symptom, or when the tumor shows a tendency to grow rapidly and there is also some disturbance in the respiration. For cosmetic purposes solely, the operation should not be performed, except, perhaps, for a small nodule which can easily be enucleated.

The mortality of the operation has dropped, according to Bruns, from 41%, in 1850, to 5.8%, in 1884. Kocher reports 250 operations, with only six deaths.

The incisions recommended by different operators are either Y or V shaped, in the case of removal of both lateral lobes, or along the border of the sterno-mastoid if one lobe only is to be removed.

Several large subcutaneous veins are usually found running vertically over the front of the tumor. Their lumen is very capacious, and they retract quickly beneath the margins of the incision, and unless promptly secured with forceps are liable at any moment to give rise to troublesome bleeding. In order to reach the surface of the tumor, the edge of the sterno-mastoid must be sought for, and that muscle, which is thin and flattened, must be drawn aside. In two of my cases it was necessary to divide the sterno-thyroid and sterno-hyoïd muscles, but the omo-hyoïd, which frequently has to be divided in these operations, was not seen. On reaching the tumor, it is important to divide all layers of connective tissue until the capsule is reached. It is also important to avoid cutting into the tumor itself, owing to the difficulty in controlling the hemorrhage which ensues. Starting now from the median line the lobe should be slowly and cautiously separated from the surrounding tissues by the finger or some blunt instrument, and an effort made to reach its upper and outer border, beneath the margin of which the superior thyroid artery will be found. This should be clamped, as also a number of smaller vessels which have been divided in the meantime. The tumor is then drawn inwards and downwards until the inferior thyroid is reached, which must also be clamped and divided. Great care must be taken at this point to avoid clamping or cutting the recurrent laryngeal nerve, which lies close to and behind this vessel. The nerve is always hard to find, and in no case have I seen it. By keeping close to the surface of the tumor, and avoiding wandering between outlying layers of connective tissue, this mishap can be avoided probably in the great majority of cases. Large masses of tissues should not be hastily caught up with the forceps during this period of the operation. If the artery can be found and isolated, it would be well to pass a ligature around it with an aneurism needle. On approaching the trachea the knife has to be used more freely, as the tumor is usually quite adherent to its anterior surface.

In very large and adherent growths the operator may content himself with dividing the isthmus, as the

¹ Read before the Boston Society for Medical Improvement, February 8, 1892.

tumor may subsequently undergo atrophy after this operation. Pressure on the trachea will be relieved also in this way.

Whatever the method employed be, the bleeding is usually very free, and the operation more or less prolonged. Rose reports a case where 200 ligatures were applied, and the operation lasted several hours. The larger types of goitre, so familiar to the Swiss tourist, are fortunately rarely seen in this country. I am in the habit of using a small drainage-tube to avoid pressure on the trachea during the primary serous oozing.

The most important feature of the operation remains to be mentioned; that is, the necessity of leaving behind a portion of the thyroid gland, as myxedema is almost certain to develop if all the gland-tissue has been removed. It is true that quite a number of cases of "total extirpation" have been found without the occurrence of this unfortunate sequel, but it is probable either that a portion of gland-tissue has unwittingly been left behind, or that accessory glands existed. The presence of such glands is stated by one writer to be demonstrated in about one-half the cases examined. They lie in different places — near the arch of the aorta, at the side of the trachea, or between it and the oesophagus, or near the hyoid bone.

There are various theories still put forward as to the functions of this gland. By some it is supposed to be a blood-gland connected in some way with the development of the blood-corpuscle. It is also supposed to remove certain deleterious substances from the blood, or to prepare for the nerves certain substances which are necessary for their proper nutrition. It is also supposed to be a regulator of the circulation of the brain. It is probable, as shown from experiments on cats and dogs, all of which died after removal of these glands, that the organ plays an important part in the nutrition of the nervous system. Before this peculiar result of the removal of the gland was understood a large number of cases of total extirpation were performed. Kocher found a development of myxedema, or cachexia strumipriva, as it was originally called, in all but two of eighteen cases: as a recurrence of the growth took place in both of these cases it is probable that a portion of the gland was left behind in both instances. Reverdin in eleven cases of total removal had but five cases of cachexia.

In those cases where only a small fragment is left behind the symptoms of myxedema may develop to a certain extent and subsequently disappear after the fragment enlarges, as is usually the case. They may grow to considerable size, as the following case by Bircher shows:

A servant girl, twenty-seven years old, underwent the operation of total extirpation for a goitre accompanied with difficulty of breathing. The operation was followed by paralysis of both recurrent laryngeal nerves, the resulting hoarseness disappearing seven weeks later. Four weeks after the operation she became languid and sleepy, so as to be unfit for housework. Her mental condition deteriorated; her expression changed; and her complexion became pale and the skin wrinkled. This condition continued for two months, and gradually improved; and at the end of six months had entirely disappeared. In front of the larynx there was now to be seen a fragment of the thyroid gland, which had grown to the size of a fibert. It had evidently been left behind by accident.

Another case described by this author is of peculiar interest, as the symptoms of myxedema were temporarily relieved by the grafting of a fragment into the per-

itoneal cavity and apparently permanently removed by a second operation of the same kind.

A peasant woman, thirty-three years old, slightly affected by cretinism, was operated upon for partial removal of the thyroid gland. A small lobe, which it was intended to leave behind, came out accidentally with the rest of the tumor. The wound healed by first intention. Two months later she returned, and reported attacks of severe cramps. She was easily tired, and was always sleepy. Her appearance had changed entirely. Her face had become swollen under the eyes and about the cheeks and lips. Her gait was staggering. Her intellect was much deteriorated. Soon after entering the hospital she had an epileptic seizure. Six months later the marasmus had become so pronounced that she could not leave the bed. It was decided to try implantation of thyroid tissue into the abdominal cavity. Laparotomy was performed simultaneously with thyroidectomy in a case of partially cystic goitre. Two fragments, about the size of fiberts, were introduced through a small incision into the peritoneal cavity. A few days later improvement began to show itself, and in twelve days the patient was able to leave her bed and to walk about the ward. Her intelligence improved somewhat. At the end of two months, however, a relapse occurred; and the operation of implantation was repeated, about five times the amount of gland-tissue being introduced into the abdomen on this occasion. The myxedema swelling soon began to disappear; and, in the course of two months, the patient was able to do a good day's work as kitchen-maid. Six months after the second implantation the patient was still in good health.

The non-operative or atrophic myxedema is a rare disease and occurs sporadically, not being indigenous to any particular quarter of the globe. It is found more frequently in women than in men or children. It is supposed to have some connection with disturbed genital function, as it occurs frequently at the menopause. The disease develops slowly. The first symptoms are observed in the skin, which becomes rough and dry. The hair, sometimes the teeth, drop out, and the nails become brittle. The skin next becomes edematous, but there is not as in ordinary edema pitting on pressure. The face swells first, and loses its expression, later, the head, abdomen and extremities are affected; genuine edema may occur in the later stages of the disease when the internal organs have undergone extensive changes. The changes seen in the nervous system are more or less well marked. The reflexes are diminished; there is slowing of all movements and the gait is a rambling one. The power of co-ordination is somewhat disturbed. The intellect is at first intact, but later there are delusions, and sometimes delirium. The circulation is feeble; hemorrhages are often seen in the skin and mucous membranes, and the catamenia are irregular. The course of the disease is slow the duration varying from six to twenty years. Death occurs from exhaustion and visceral complications. The pathological changes consist in gelatinous hypertrophy of the connective tissue, particularly of the skin and subcutaneous adipose tissue, with enlargement of the lymphatic vessels. There is also a thickening of the walls of the arteries. The thyroid gland tissue atrophies and gradually disappears and the interstitial fibrous tissue becomes greatly increased in amount.

The operative myxedema or the cachexia strumipriva has become familiar since the general adoption of the total extirpation of the thyroid — an operation which has in consequence been abandoned. This type runs its course more rapidly. The cerebral irritation is more marked in consequence, and we find vertigo,

tetanic spasm and epilepsy in many cases. It may terminate fatally. It is interesting to note in this connection that after thyroidectomy in dogs the pituitary gland is swollen and the cells become vacuolated and ultimately disintegrated the longer the animal survives the operation. In sporadic cretinism when the thyroid gland is lost, the pituitary body has been found to be enlarged.² In this form, however, recovery may occasionally result either by the development of accessory lobes or fragment of gland tissue left behind, or by the implantation of portions of the gland. Those fragments left behind may grow to the size of a walnut, and it is only by the development of these fragments that the patient escapes the disease.

It is proved by experiment that dogs and cats cannot live without the thyroid gland—the animals become inert, sleepy and slow in movement. The sensibility is diminished and muscular twichings are frequent. Death occurs in four to twenty-seven days. At least one-third or in some cases one-fourth of the gland must be left to prevent the onset of the fatal cachexia. Shiff found that if a piece of gland was implanted into an animal the thyroid gland could be removed without injury. When animals thus treated were killed a few months later fragments of the original gland implanted were found still remaining. If the implanted gland becomes properly vascularized and resumes its functional activity the cachexia does not show itself, but if the gland undergoes atrophy and degeneration the cachexia supervenes. Colzi and Ewald found that the transfusion of the blood of healthy animals into the circulation of those which had been deprived of the gland delayed the cachexia. Improvement always followed subcutaneous injection of the juice of the gland. These observers conclude that the gland removes from the blood certain substances which are injurious to it if allowed to accumulate—a condition analogous to uremia after extirpation of both kidneys. Horsley found a diminution in the red corpuscles and an increase in the white corpuscles in experimental myxedema. There was a diminished power of coagulation and an increase in the amount of globulin and mucin in the serum, and also an increase of mucin in the parotid and submaxillary glands. Horsley holds that the "thyroid gland is a structure essentially connected with the metabolism of the blood and tissues; that in fulfilment of its functions it is haemopoietic both directly and indirectly, and that it forms, that is, secretes from the blood, a colloidal substance, which is transmitted via the lymphatics from the acini of the gland to the circulation."³

Cretinism is regarded by Bircher as essentially a different disease from myxedema. It occurs endemical and is found at an early period of life, and is associated with goitre. The change in the facial appearance, the motor disturbances and the alteration in speech and intelligence are common to both diseases, but we do not find the same changes in the hard skin and sensation as in myxedema. In the latter disease the pathological changes are found in the soft parts, but in cretinism the principal deformity is produced by alteration in the form and arrangement of the bones. These are particularly marked in the skull, which is much broader than in the normal state. The departure from the normal condition may be very slight in some forms, little being noticed beyond an enlargement

of the thyroid. In another class of cases deaf-mutism is the principal symptom. In the more prominent type the patients are idiotic. The speech is affected in the great majority of all cases, a symptom rarely noticed in myxedema. It is more common in male adults in its severest type.

The following series of four cases represent the extent of my experience upon the subject. They show that the milder forms can be easily removed by an operation apparently harmless, but one, at the same time, not without its dangers. When, however, we consider the great deformity and discomfort of a large bronchocoele and the danger of sudden death, we are hardly authorized in declining to perform the operation.

CASE I. Cyst of thyroid. H. M., seventeen years of age, a domestic, was born in New York, but has lived for many years in Wakefield, Mass. She entered the hospital November 10, 1891. Her father died of consumption and she herself has never been healthy. Seven years ago she first noticed a little tumor in the front of her neck which has grown steadily until two months ago a little additional nodule began to form below. On examination the thyroid gland appears to be symmetrically developed and a swelling about the size of a lemon occupies the median line of the neck, smaller growth appears to be attached to the tumor at the lower right-hand corner. There had been occasionally slight disturbance of respiration, but the patient was anxious for the removal of the tumor, partly on account of the deformity as it showed a tendency to increase in size. The operation was performed on November 15th. An incision was made in the median line about four inches long over the tumor, which, when exposed, was found to be cystic. When the cyst wall was reached it was enucleated without much difficulty from the normal gland-tissue. There was very little hemorrhage, a quill-drain was inserted and the edges of the incision were brought together by interrupted sutures and a light, dry dressing was applied.

The patient rallied well from the operation, but about five hours after the operation, while my assistant, Dr. Bartol, was in the ward, respiration suddenly ceased, the patient became cyanotic and the jaws were firmly closed. Tracheotomy was performed by Dr. Bartol immediately and an elastic catheter was introduced and retained until a tube could be obtained. The tube was allowed to remain for forty-eight hours. The patient made a rapid recovery and was discharged December 3d with the wound entirely healed. She visited me recently, about a year after the operation, and was in excellent health without any signs of thyroid enlargement.

The following report was made by Dr. Whitney:

"Cystic growth from region of thyroid. Section shows several cysts, the largest was the size of a small peach filled with dark, reddish-black fluid, showing blood-corpuscles, granular-corpuscles and cholesterol crystals. Section of wall shows normal thyroid tissue with here and there a tendency to cystic dilatation. Diagnosis: goitre with cystic degeneration."

CASE II. Cyst of thyroid. L. M., age twenty-seven, married; born in Massachusetts, lives in Quincy. Entered the hospital January 5, 1892. Her family history was negative. Was always well and has had five children. Four years ago the patient first noticed a small swelling in the neck which has grown very

² Horsley.

³ British Medical Journal, January 30, 1892.

slowly and has never pained her. She states that she has some difficulty in swallowing and that her breathing is somewhat impeded and that she suffers from dyspnoea on exertion. On examination a tumor the size of a large hen's-egg is seen just below the cricoid cartilage on the right of the median line. It is soft and movable and ascends and descends with the movements of the trachea during the act of swallowing. Pulse 90, strong and regular. The eyes are not prominent.

A laryngoscopic examination was made on January 6th, by Dr. J. P. Clark, who states that the rima glottidis was practically in the median line; motion of cords free, although in respiration the right cord does

laryngoscopic examination showed portions of the gland in the wall of the cyst. Cyst of thyroid."

CASE III. Parenchymatous growth of thyroid. C. M., forty years of age, was born in Canada but lives at present in Boston; is married and had one child eighteen years ago, two still-births since. Her mother and one sister are both the subjects of goitre. Her general health has been good. Eleven years ago the patient first noticed a small swelling corresponding to the right lobe of the gland followed later by a similar condition on the left side, eventually there was enlargement of the isthmus. The tumor has grown slowly and has varied considerably in size from time to time. During the past year there has been an in-

FIG. 1. Before Operation.

FIG. 2. Cleatrix Fourteen Days after Operation.

not move as far from the median line as the left. Some prominence below the right cord of the tracheal wall. No evident diminution of the calibre of the trachea.

Operation, January 9, 1892. An incision parallel to the anterior border of the sterno mastoid muscle was made over the tumor, exposing the wall of the cyst which was carefully dissected out with but little hemorrhage. It was found to contain a dark fluid. A small drainage-tube was inserted and the edges of the wound brought together by silk sutures.

The stitches were removed on the sixth day, and the wound healed promptly except at the point of drainage where a small sinus remained for two or three weeks.

Dr. W. F. Whitney made the following report of the microscopic examination: "A cystic growth of the size of a small peach in one lobe of the thyroid. Mic-

roscopic examination showed portions of the gland in the wall of the cyst. Cyst of thyroid."

On examination a tumor of dumb-bell shape is seen stretched across the trachea. The right lobe is about the size of an orange and the left lobe is the size of a goose-egg. There are numerous enlarged veins running over its surface. It is movable and rises with the larynx on swallowing. There is no pulsation.

Laryngoscopic examination by Dr. J. P. Clark: "Rima glottidis obliquely situated, being turned somewhat to the right. The trachea is bent to the left slightly. No constriction as far down as the fourth or fifth ring. Motion of cords apparently free and equal."

Operation, January 9, 1892. A curved incision with convexity downwards was made from the apex of left

lobe to that of the right lobe, and the operation performed as already described. Two small fragments of gland-tissue are left behind, one in the left lobe about the size of half a walnut, and one in the isthmus of the same dimensions. Two quill tubes were inserted to avoid pressure during the early oozing of the walls of the wound. The stitches and tubes were removed on the third day, and the wound dressed with collodion and cotton. A small collection of pus subsequently formed at the most dependent point of wound, and left a sinus which had not healed three months after the operation, when the patient left the convalescent home. There were at that time no signs of myxœdema.

Microscopical examination by Dr. W. F. Whitney: "Several large, dark, rounded growths from thyroid region. Section showed some small cystic cavities, the walls in places infiltrated with lime salts, but in general the growth was of the character of the thyroid, but with enlarged alveoli containing a colloid material. Bronchocelæ."

This patient suffered from aphonia for several weeks after the operation, and a laryngoscopic examination showed that the right vocal cord was paralyzed. The voice, however, was subsequently fully restored.

CASE IV. A. S., single, twenty-five years of age, entered the hospital February 1, 1892. She was born in Ireland, and lives at present in Dorchester. Her family history is good. She has always been healthy. Five years ago she first noticed a "bunch below the Adams apple." This has grown steadily since, although it varies at times somewhat in size (Fig. 1). There is no difficulty in swallowing and no change in voice or breathing.

On examination an enlargement of the thyroid gland is seen on both sides, that on the left being about the size of a large orange, and about twice as large as that on the right. The tumor is non-pulsatile and moves with deglutition. The larynx and trachea are displaced somewhat to the right of the median line. There is no protrusion of the eyes. Extirpation of the gland performed February 6th. A semilunar incision, about five inches in length, was made from the apex of the left lobe downwards and across the median line to a point considerably lower on the left (Fig. 2). A number of large veins were divided, but there was no great difficulty in controlling the bleeding as the capsule was separated from the surrounding tissues. A portion of the right lobe, about the size of a horse-chestnut, was allowed to remain. One quill drainage-tube was inserted, and the edges of the wound were brought together by silk sutures. The dressing was applied loosely, but sufficiently firm to prevent exposure of the wound.

The wound healed by first intention, the drain having been removed on the second day. The photograph (Fig. 2) was taken about ten days after the operation. A microscopical examination showed a growth similar to that found in Case III.

In a case of large cystic goitre, which recently came under my notice, where tapping and the injection of iodine had been tried, the swelling and signs of suppuration induced me to lay open the sac freely and pack it with iodoform gauze, which operation was successfully performed without any trouble from hemorrhage. The tumor was about the size of a cocoanut. I have not yet heard of the subsequent history of the case.

TUBERCULAR ULCERATION OF THE HARD PALATE AND GUMS.¹

BY A. COOLIDGE, JR., M.D.

The lesion to which I wish especially to call attention is a tubercular ulceration which occurs on the gums around the upper front teeth and on the hard palate just behind them. Its usual appearance is that of a coarse, granular ulceration, deep red, and often in places presenting a raspberry appearance. It is most active close to the teeth, and there is little or no swelling. The edges of the ulcer on the hard palate are not elevated, and often merge gradually into the healthy mucous membrane. The mucous membrane alone is attacked; there is no caries of bone. It is essentially chronic in its history, and shows no attempt to heal, at least, while the teeth remain. The gums may be slowly absorbed, leaving the roots of the teeth bare.

This appearance has been described as occurring secondarily, both in cases of primary lupus of the face and of the throat. It has also been seen in connection with more active tuberculosis of the lungs, pharynx and other organs.

The anterior palatine canal has been suspected as the channel through which the disease extended from the nose to the palate, or from the palate to the nose, and this seems to be borne out in two of the cases which I report. It surely seems possible that this lesion of the gums may be the bridge by which lupus or other tubercular disease may pass from the throat to the nose, or vice versa.

In the three cases which I report, the lesion of the gums and hard palate is the only symptom which occurs in all. In none of them has there been up to this time any disease of the lungs, larynx or epiglottis.

CASE I. The first case is a typical one of lupus. I. K., twenty-one years of age. Her grandmother died of phthisis, her family history otherwise negative, previous health good. In 1888, she noticed a sore spot on the gum above the right canine tooth, which in the course of two or three months had spread around the gums of the upper incisors on to the hard palate just back of the teeth, and appeared as a small spot inside the nostril, after which it appeared on the face. When the fauces became involved it is difficult to say. The patient noticed that she was growing deaf a year before the spot appeared on the gum, but did not notice any serious trouble in the throat until afterwards. The disease in the pharynx gave the patient so little discomfort that she did not realize that there was any serious trouble there until extensive cicatrices had formed. I suspect that the soft palate was the primary seat of the disease. I first saw her in August, 1890, she was, and still is, being treated by Dr. J. C. White for lupus of the nose and face. The gums round the upper incisors, and the mucous membrane of the hard palate, for an inch back of the incisor teeth, showed a granular ulceration of a deep red color. The pillars of the fauces and the velum had coalesced with the posterior pharyngeal wall leaving only a small opening into the nasal pharynx. The uvula had disappeared, the velum and back of the pharynx were white, cicatrical and hard, except that on the borders of the cicatrical tissue in some places were slightly elevated, inflamed nodules. From January until May, the patient was in the Massachusetts

¹ Read before the Boston Society for Medical Improvement, February 8, 1892.

General Hospital for treatment with tuberculin. While there, a small ulcer appeared on the tongue about an inch from the tip, which has slowly extended since, until it is now about the size of a quarter. The ulceration of the gums spread somewhat on to the mucous membrane of the lip. The treatment produced little or no permanent effect upon the local disease. On two or three occasions, the white cicatrical tissue of the pillars has become inflamed, and local ulcerations have temporarily appeared, a process which has often been noticed in lupus of the throat.

At present, the patient is in much the same condition as when first seen, except that the skin has improved very much under treatment and that the tongue is involved. The granulations of the gums have resulted in their contraction, so that the roots of the teeth are more exposed than formerly. The molar teeth are also surrounded by granulations. The mucous membrane of the hard palate is ulcerated in the vicinity of the teeth, and cicatrical in the centre.

CASE II. G. H., aged eighteen years. Her two grandmothers died of phthisis, other members of the family including the patient have always been delicate; family history otherwise negative. She has for some years been a patient of Dr White at the Massachusetts General Hospital. At the age of fourteen the patient had diphtheria followed by enlarged glands of the neck, which discharged externally for a short time. A year later a spot appeared on the leg, which increased to about the size of a silver dollar, ulcerated, and after a few months cicatrized. She subsequently had five or six similar patches on the leg and arm. In 1887, her throat began to be sore and to feel swollen, and she began to be deaf. The next year, she noticed a spot on the hard palate, which soon spread to the gums of the incisor teeth. I saw her first in September, 1889, there was then nothing on her skin but the cicatrices mentioned above. In the throat, the left anterior pillar was of a pale pink color and irregularly thickened. The right pillar was ulcerated, cicatrizing round the edges of the ulcer with very little infiltration, and there was some loss of substance. The uvula was nearly buried by the cicatrization of the pillars. The interior of the nostril was normal. On the hard palate for about an inch behind the front teeth and on the gums around the incisor teeth, there was a granulating ulcer. The patient was given full doses of mercury and iodide of potash for some time, but the local disturbances were apparently made worse by the treatment. For over a year different applications were made but without effect, except that after curing the ulcer of the hard palate it cicatrized, but broke down again in a few weeks. It spread very slowly on to the mucous membrane of the upper lip, and by the destruction of the gums the roots of the teeth became prominent. In the autumn of 1890, a small ulcer appeared on the floor of the right nostril. At the same time also the ulceration of the right pillar extended on to the pharyngeal wall, but later cicatrized, binding the pillar and wall of the pharynx together on that side. In January, 1891, she entered the City Hospital in the service of Dr. George B. Shattuck, for treatment with tuberculin. Examinations of scrapings from the gums failed to show any tubercle bacilli. After injections with tuberculin, the ulcerations round the teeth and in the nostril became inflamed, the pharynx was less actively affected. The ulceration in the nostril extended, being preceded by an in-

flammatory zone, which finally attacked the skin of the nose just above the ala, and also the septal cartilage. While in the hospital the destruction of the gums was more rapid, the incisor teeth were so loosened that they were removed. An interesting point is that after the removal of the teeth, the ulceration of the hard palate, gums and mucous membrane of the lip which had existed for three years, cicatrized speedily leaving only a slight ulceration around the canine teeth. This has continued since, and has already loosened the canine, and has attacked the molars. At present, the patient has upon the side and bridge of the nose an ulcer about the size of a five-cent piece, with elevated edges, a destruction not only of the skin, but also of the septal cartilage. The patient's general condition is much better than it was a year ago.

CASE III. M. F., twenty-seven years old, family history negative, previous health excellent, except that she had frequent headaches, which disappeared entirely while the mouth was sore, but have now returned. Five years ago, her brother noticed an ulceration, apparently tuberculous, on the edge of his left nostril, which has been under treatment, and which has, up to this time, involved only the skin around the nostril. Two years ago, the patient first noticed a sore spot on the gum over the left canine tooth, which slowly spread during a year and a half around the incisor teeth and on to the hard palate. I first saw her in the out-patient department last May. The gums around the front teeth and on the hard palate for half an inch behind them were ulcerated, deep red and coarsely granular. The patient complained of a tender spot on the floor of the left nostril, but nothing could be seen there. Except for this ulceration, the patient presented no signs of disease. She had felt run down for a few months, but was otherwise in good health. A month later, the disease had spread slightly. She was then sent into the hospital where, on July 25th, Dr. F. B. Harrington resected the upper jaw, removing all trace of the disease. The patient made a good recovery, and in three months had gained fifteen pounds. There has up to this time been no return of the disease. The part removed contained the alveolar process as far back as the first molar teeth and the anterior part of the palatal process. The teeth although well-cared for had been very subject to caries as is seen by the number of fillings which they contain.

In reviewing these cases, we find a very similar lesion of the gums and hard palate in three cases presenting very different clinical histories; and this I have found to accord with previous reports. The granular ulceration of the gums has been most frequently seen in connection with lupus of the nose, especially where the soft palate or the larynx is also involved. The first of my cases belongs to this class. In the second case it appeared with a condition of the throat which has been described as scrofulous. In the third case the lesion on the gums and hard palate and a small spot in the nostril are the only evidence of disease.

Lennox Brown, in his book on diseases of the throat, puts under the head of tuberculosis only the more malignant form seen in connection with tuberculosis of the lungs and other organs. Lupus he considers a distinct disease, clinically at least. There is surely a great difference between the more malignant tuberculosis and the very slow progress often seen in lupus of the pharynx which tends to form hard cicatrices and which may lose all activity, at least temporarily.

There are, however, certain cases which are slow in their course and in which the diagnosis of lupus from the appearance in the throat alone is hard to make. That lupus may be primarily in the throat is not now doubted. Such a case was reported by Dr. F. I. Knight,² in 1881, before the American Laryngological Association, and similar cases have been reported since. The differential diagnosis between lupus and other tubercular lesions in the throat is often difficult. In the mouth, and especially around the teeth the distinction is even more difficult to make. Clutton³ prefers to call it tubercular ulceration, and the same view is taken by Michelson⁴ in a review of the literature of the subject. Tuberculosis of the mouth is generally secondary to tuberculosis of the lungs, pharynx or other organs, or to lupus. Primary tuberculosis of the mouth is not common. Some cases have, however, been reported, in most of which the disease has soon appeared in other parts of the body.

Tubercular ulceration of the gums and of the hard palate just behind the gums generally shows no tendency to heal, at least while the teeth remain. It tends to destroy the gums and loosen the teeth, and altogether acts as if the tissue immediately around the teeth were a favorable seat for the disease. It has been suggested that when the disease spreads from the gums to the nose, or from the nose to the gums, it does so through the anterior palatine canal. The lip is seldom involved, and the bone never.

I think that it is important to recognize the malignant character of this form of ulceration around the front teeth, and in cases in which both the nose and

the soft palate, or pharynx, or larynx are not already involved, to take active measures to check the disease, and if possible to prevent it crossing by this bridge from the nose to the throat or vice versa. Of primary importance in the treatment is the removal of the teeth, the gums of which are attacked. While the teeth remain, the gums show no tendency to heal; after the teeth are out the gums are much more amenable to treatment. In my second case, by using the curette and galvano-cautery, the ulcer on the hard palate cicatrized, but the disease could not be got at around the teeth, and the cicatrization was only temporary. After the teeth had been removed the ulcer cicatrized readily; but by that time the nose was involved, apparently by direct extension. In the third case the unhealthy tissue was entirely removed, and I hope that the patient has been saved from tuberculous disease in other places. I have not been able to find a report of a similar operation for this trouble.

Microscopic examination of the mucous membrane, from Case III, after hardening in alcohol and imbedding in celloidin, showed a granulation tissue resembling in every respect that seen in tuberculosis, namely, very numerous Langhans giant-cells, intermingled with epithelioid and small round cells. The number of Langhans cells corresponded to those found in lupus, as distinguished from some of the other forms of tuberculosis. There was very little "cheesy degeneration" seen. A few sections stained by the Ziehl method failed to reveal the presence of tubercle bacilli, but the bacteriological examination was not sufficiently thorough to warrant any deductions.

SEASON AND DISEASE-PREVALENCE IN CAMBRIDGE, 1880-1889 INCLUSIVE.

BY EDWIN FARNHAM, M.D., CAMBRIDGE, MASS.

Max. ±, min. =, above average +, below average -.

The diseases contained in the accompanying table were selected on account of the large contingent sup-

plied by them to the deaths from all causes, and because some of them belong to the class of diseases it is customary to call preventable, while others are ones which we hope to see hereafter included in that class.

¹ Archives of Laryngology, vol. II, 1881, p. 273.

² Clinical Society Transactions, vol. xii, 1886, and vol. xx, 1887.

³ Zeitschrift für Klin. Med., 1890, xvi, p. 202.

In the period considered, the total number of deaths was 11,541, to which those here given contributed 5,434 (47%). The signs used are of little absolute value apart from the figures; for instance, in October scarlet fever has the sign —, in February and March the sign +, while the figures are 11 and 12.

In comparing individual months it must be borne in mind that February contains 283 days, the longest months 310 and the others 300 each. So also with the quarters: the third and fourth are equal, 220 days each, while the second has 910, and the first 903.

Diphtheria, scarlet fever and typhoid fever are notification diseases. In them the maximum number of deaths fell in the months immediately following those during which the maximum number of cases were reported.

Measles. — Not a notification disease during this period. No death from it in October. Out of 71 deaths, 38, or 53%, occurred in May and June. In the last four months only five deaths.

Whooping-Cough. — Not a notification disease. Of 102 deaths, 47 occurred in third quarter, 46% of the total. January had a large number, while June and December contained respectively two and three deaths.

Diarrhoeal Diseases. — Includes diseases certified under the following names: diarrhoea, summer diarrhoea, infantile diarrhoea, inflammatory diarrhoea, summer complaint, enteritis, gastro-enteritis, entero-colitis, colo-enteritis, colitis, cholera infantum. The third quarter contains 84% of all the deaths from these diseases.

The greatest incidence and largest number of deaths in these diseases probably coincide pretty closely.

Bronchitis and Pneumonia. — Beginning with the third quarter, the minimum one for both, they rise in the second, with a further rise in the fourth, to reach their maximum in the first quarter.

In bronchitis, the rise from the minimum month, August, to the maximum month, January, is an unbroken one, while in the decline April appears to break the regularity.

In pneumonia, the rise from August, the minimum month, to April, the maximum month, has its regularity broken in February and March. In February, we are, of course, dealing with a shorter period than in the other months.

In bronchitis, the fourth plus the first quarter contains 62% of the total deaths. In pneumonia the same period contains 61%. In bronchitis, the minimum month, August, is to the maximum month, January, as 1 is to 3.6. In pneumonia the proportion is as 1 to 4.7.

Phthisis. — During the period considered this disease caused 16% of all the deaths. Its maximum month coincides with the maximum month of pneumonia. While the signs represent phthisis, pneumonia and bronchitis as above the average during January, February, March and April, the figures show the percentage of deaths from those diseases respectively during these three months to have been as follows: bronchitis 45%, pneumonia 46%, phthisis 35%. If we take July, August, September and October, it will be seen that bronchitis has fallen to 18%, pneumonia to 17%, while the phthisis deaths are 30% of the total.

Typhoid Fever. — In August, September, October and November, 819 cases, 72% of the total, occurred.

Diphtheria. — Though prevailing at all times there is between its maximum and minimum months a difference of more than 100%. It rises abruptly from Sep-

tember to October, and falls abruptly from January to February. From February to September it seems to oscillate irregularly.

Scarlet Fever. — The proportion of the minimum to the maximum months is as 1 to 3.6. The rise from the minimum to the maximum month is more regular and shorter than the decline, the former comprising four monthly waves, the latter eight. The fourth and first quarters contain 65% of all the cases.

NOMENCLATURE OF PEDICULOSIS.¹

BY CHARLES W. ALLEN, M.D., NEW YORK,
Surgeon to the Charity Hospital, etc.

MOST of the text-books, in this country at least, treat the subject of pediculosis into the three general varieties: *pediculosis capititis*, *pediculosis corporis* and *pediculosis pubis*.

Against the designation of the first variety I have no objections to offer. The pediculus which inhabits the hairy-scalp confines his entire attention to this region and it is only by accident that he is found upon any other portion of the surface. The pediculus which habitually goes by the name of the body-louse or pediculus corporis does not however live upon the body as the head-louse lives upon the scalp. His habitat is in the clothing; and it is only for purposes of feeding, and possibly of exercise and recreation, that he makes excursions upon the skin's surface. If you strip a subject affected with this variety, only a laggard who has been caught unawares can be found upon the skin, and he will make all haste to rejoin those remaining upon the clothing. Instead of laying their eggs upon the hair-shafts as do both the other varieties, these like deposit their ova along the seams of the garments. For these reasons, it seems to me, this variety should be called only by its other name, pediculus vestimenti, and the term pediculus corporis be given up exclusively to designate what is now universally known as the pediculus pubis or crab-louse. From the extensive migrations of this last mentioned pest, wandering, as it does, wherever hairs abound, and not even sparing the scalp in rare instances, as in a case of an infant of five months reported by Trouessart,² it has come to be variously called according to the situation in which its presence is most prominently made known; *pediculus inguinalis*, *pediculus axillaris*, *pediculus palpebrarum*, *pediculus ciliorum* and *pediculus barbe*.

Now, all this leads to confusion, and explanations have to be entered into whenever we speak or write of the *phtheirus inginalis* as occurring in locations other than the genital regions, and if pediculosis ciliarum or axillarum is mentioned, one must explain, to students at least, that the particular louse in question is the so-called pediculus pubis.

There is another reason why the latter should be distinguished as the body-louse and that is its decidedly great prevalence in many quarters over the pediculus vestimenti. In my office I see frequent instances of the former in both sexes, and rarely if ever one of the latter. In the report of the Good Samaritan Dispensary for 1891 we find that, in the two principal classes, 232 phtheirus cases were treated. Of these 185 were of the head, 36 were due to the pediculus pubis,

¹ Read at the New York Dermatological Society, February 23, 1892.

² Le Bulletin Medical, January 6, 1892.

and only 11 to the pediculus vestimenti. Beside this, in the eye class, where of necessity only the one kind would be found, there were no less than 85 instances of phtheiriasis ciliorum out of a total of 5,974 eye cases treated. The same proportion is found to obtain in former years; thus in 1889, out of 202 instances of pediculosus, 135 were put down to the credit of the head louse, 56 to that of the pediculus pubis affecting various regions, and again only 11 to the pediculus vestimenti. Here, too, the proportion is increased by 68 cases of pediculosus of the lids in the eye department.

At the Charity Hospital we naturally have more phtheiriasis in the skin wards, due to the irritation of the pediculus vestimenti, than to that of the crab-louse; but this is simply because the latter does not, as a rule, cause that amount of scratching and consequent alteration in the skin which would call for hospital treatment. The prevalence of the crab-louse among the patients at large is, however, very great; and as it is so often found in the armpits, upon the chest, down upon the thighs and legs, in the beard, and upon the margins of the eyelids, it is only due to its enterprise to give it the more dignified and comprehensive name, *pediculus corporis*.

Clinical Department.

PANCREATIC CYST APPARENTLY CURED BY INCISION AND DRAINAGE; RECURRENCE, PERFORATION OF THE STOMACH, DEATH, AUTOPSY.¹

BY MAURICE H. RICHARDSON, M.D.

THE case of D. C. L. was reported in the *Boston Medical and Surgical Journal* for January 29, 1891. He had been admitted to the Massachusetts General Hospital on October 10, 1890. A diagnosis of pancreatic cyst was made and operation advised. On October 24, 1890, the cyst was exposed and drained. The tumor, everywhere adherent, was found and drained without any difficulty. He made a good recovery and was discharged from the hospital, wearing a drainage-tube, on the 26th day of November, 1890.

February 3, 1891. Mr. L. reported to me that he felt very well indeed, that he had grown stronger and fleshier. He had, from time to time, attacks of dizziness in the head. He still wore the tube. There was no change in the character of the clear white fluid discharged from the sinus, and its amount was considerable.

May 26, 1891, he said: "There seems to be less discharge. There is something about four inches deep which hinders the tube going in. It is just before it strikes the water." General health and appearance very good.

July 9, 1891. "The discharge has ceased almost entirely, but it is sore in the region of the tube, and there has been, for a week, some matter." I removed the tube and the sinus became closed in a few weeks. During the fall the patient called occasionally and I had the opportunity often to examine the abdomen. Nothing abnormal could be detected by physical examination, and I looked upon the case as one of perfect and permanent cure.

On Saturday evening, January 23, 1892, I was

¹ Read before the Boston Society for Medical Improvement, February 8, 1892.

asked by Dr. Cowdrey, of Stoneham, to go out early the following morning prepared to operate upon Mr. L., because it was thought that he was suffering from acute obstruction of the bowels. I found him in great pain, vomiting constantly large quantities of greenish-black fluid. The abdomen was distended and everywhere tympanitic.

History. — Dr. Cowdrey gave the following history: Some two weeks ago, Mr. L. was taken with a cold, to which he was subject. With the cold he had quite a severe attack of diarrhoea. The cough which accompanied the cold, and seemed like asthma, left him. Then, a week ago Friday, he said that he had been sick all day, and that he could feel a lump in his stomach. That night he was quite restless. Two weeks before that time — that is, between three and four weeks ago — he said that he never felt better in his life, that the old trouble had entirely disappeared. There was nothing in the stomach which he complained of. During the last three or four weeks his appetite has been poor, although otherwise he has been about the same as before. On Saturday he stayed at home all day, and there was no vomiting and no pain. On the Monday previous to my visit he felt no better. He referred his trouble to his stomach. On Monday night he took a pill, which produced free operation some time towards morning. There was no fever. On Tuesday he said that his stomach did not feel right, although he had no pain. He could not get rid of that lump in his stomach. He was nervous and restless and has a feeling of distress. On Tuesday night he was taken with the same distress, and we sent him to bed and put on hot flannels. At this time he began to vomit, which was the first attack of vomiting that he had. I found him, on Wednesday, vomiting what seemed to be bilious matter. Temperature was normal, pulse was about 80. I gave him morphia subcutaneously, on account of the distress. I found the epigastrium full, but there was no fulness in the abdomen. There was this prominence below the ensiform cartilage. There was some nausea and some pain all over him. Tongue was furred. Since my visit nothing has passed him, except some gas this (Sunday) morning. He is terribly thirsty, but he vomits whatever water he drinks immediately.

Physical Examination. — General appearance fair. Tongue coated slightly. There is incessant vomiting of very dark, greenish fluid, almost black, and odorless. Over the scar of the original operation there is a slight hernia. The abdomen is everywhere tympanitic. Deep pressure reveals a tumor which fills the epigastrum and extends from the region of the liver to that of the spleen. In front of the tumor it is everywhere tympanitic. There is no tenderness.

I could not satisfy myself that there was any fluctuation. His condition was not good. Pulse was 120, and of poor quality; face flushed, and expression anxious. He said he preferred to die rather than to be obliged to wear a tube all his life. It seemed to me that, on the chances, the tumor had refilled, and that the obstruction which apparently existed was due to the pressure of the mass upon the duodenum, or the upper intestine somewhere. I advised immediate interference with the hope of finding something which could be relieved by a very short operation.

Assisted by Dr. J. H. Swasey, of New York, I opened the abdomen through the scar of the former operation. On separating the adhesions, I found the

anterior wall of the stomach presenting, pushed well forward by a tumor behind. I separated the adhesions in the region of the duodenum, where there seemed to be a hard mass about the size of an egg, with one or two nodules like lymph-glands. To the left the tumor was quite well defined. The mass in the region of the duodenum seemed to be malignant, and not to admit of any permanent relief. The patient's condition was very bad, and I abandoned the operation, closing the wound with interrupted sutures in the usual manner. During the operation, which was very brief, not lasting more than fifteen minutes in all, the pulse became very feeble and respiration alarming. It seemed impossible for him to recover under any circumstances. I was much surprised by his rapid recovery from the operation and the ether. On the following day I aspirated the tumor through both walls of the stomach, and withdrew about two quarts of dark fluid in gross appearances precisely like that vomited the days before the operation. He was much relieved by this, and vomiting ceased immediately. He said, "I feel as though five hundred pounds were taken off of me." He suffered no more pain that afternoon and vomited none. His nourishment was increased until he took about four ounces every hour and a half. He continued in this way about seven days, and on the following Saturday began to have movements of the bowels. On Sunday he began to fail, the pulse became intermittent and more rapid, and he refused to take his nourishment. From that time he gradually grew weaker, and died Friday morning, February 5th. He had no pain from the time of the operation until his death.

Autopsy., by Dr. W. F. Whitney on February 5th, at twelve o'clock, five hours after death. After opening the abdomen I made an examination of the cyst which had become refilled, but which was not as tense as at the time of the exploration on the preceding Sunday. On examining in the region where I felt the hard mass before, my finger accidentally passed into the cyst. This showed the friable nature of the cyst at this part. It was very difficult, and even impossible, at the time of the autopsy to dissect the cyst out from the parts to which it was adherent.

Dr. Whitney's report is as follows: "Lying between the stomach and the transverse colon, covered by the omentum and adherent to the stomach wall, was a cyst almost the size of the stomach, lined with a membrane looking like a mucous one. Dissection revealed a normal head of the pancreas in connection with the duodenum. A small probe could be passed through the pancreatic duct directly into the cyst. At the opening into the cyst was a minute white thickening, suggesting connective tissue. About two inches of normal pancreatic tissue was found lying between the cyst and the spleen. From this also a duct could be traced into the cyst. At the point of attachment of the cyst, near the pylorus, was a perforation into the stomach, the mucous membrane of which was dissected up in various directions. Although not absolutely proved, the appearances were highly suggestive of an ante-mortem perforation. The gall-bladder was dilated and thickened. The other organs were normal."

There was no peritonitis from the second operation. The hard mass and the nodules found at the operation proved to be the head of the pancreas. There was no evident of malignant disease whatever. Clinically this case would seem to show that communication existed between the stomach and the cyst at the time he

was vomiting the peculiar fluid described. It was impossible to distinguish the vomitus from the aspirated fluid by color, odor, or other gross appearances. Why this communication, if it did exist, should have caused his uncontrollable vomiting seems to me inexplicable, nor can I understand why the vomiting ceased immediately upon relieving the tension, unless it was caused by pressure upon the stomach or duodenum or an actual mechanical obstruction. Another possibility was suggested by Dr. Whitney, that the tumor caused an irritation of the solar plexus. It is very evident from the appearance of this cyst and from its intimate connections with other organs, from its great size and its thick walls, that drainage would never have been followed by a complete obliteration. It is apparent that the cyst wall could not have been dissected out.

The conclusion, therefore, must be reached that this was essentially an incurable case and that the permanent use of a tube would have been necessary. Nothing was found at the autopsy to account for the sac which occupied the body of the pancreas, and was probably a dilatation of the canal of Wirsung. A prominent feature in the history of the case is the rapidity with which the sinus closed after the removal of the tube. This has suggested to my mind the possibility, or the probability, that, in cases of pancreatic cyst previously reported as cured, the same condition has existed as in this case, and that the apparent cure was not real. The rapid healing of the sinus after the removal of the tube leads us to think that the cyst has been permanently obliterated.

It would be very interesting to follow the cases hitherto reported and to know whether there ever had been any recurrence. In the case reported a few weeks ago in the JOURNAL² there was still considerable discharge, and at my last visit, the very day I was called to Stoneham, I recommended the removal of the tube. In the light of my recent experience, I have advised the re-establishment of drainage.

One other point of interest in the surgical management of this case is the question of drainage at the second operation. I should have done this at the time if it had not been necessary to separate extensive adhesions between the colon, stomach and the omentum. It was not possible to do this without spending a good deal of time and without making a careful suture through the abdominal wall. This I should have done at the time had the patient's condition justified it. I thought it much better to abandon the operation and to drain the cyst by aspiration on the following day, if he survived the exploration, which did not seem likely. The drainage of the cyst with the needle, and the immediate subsidence of grave symptoms, seemed to me to show that they were due, probably, to pressure. The fact, however, that the relief of pressure was not followed by recovery seems to me sufficient evidence that the case was essentially an incurable one, and that the conditions then existing could not have been relieved by any operative method whatever.

THE NEW UNITED STATES COINS.—It may be useful to know that the new coins are made to weigh definite amounts according to the metric system, and may consequently be used in one side of the scales. The half-dollar weighs twelve and one-half grammes, and the dime two and one-half grammes.

² Vol. xxvi, No. 4, p. 28.

FORCIBLE STRAIGHTENING FOR PERMANENT FLEXION OF THE KNEE.

URETHRAL STRICTURE, WITH A COMBINED INTERNAL AND EXTERNAL URETHROTOMY IN THE SAME CASE.

REPORTED BY JOEL E. GOLDFWAIT, M.D.,
Former House-Surgeon at Boston City Hospital.

THE following case is of interest, particularly, as it illustrates a new and very satisfactory mode of treatment for deformities of the leg resulting from chronic rheumatism. The patient was treated at the Boston City Hospital, and was under the care of Dr. E. H. Bradford and Dr. Abner Post. I am indebted to these gentlemen for permission to report the case.

P. C., thirty-four years of age, entered the Boston City Hospital March 18, 1890, upon Dr. Bradford's service. He gave the following history: Since boyhood he had been subject to attacks of acute articular rheumatism; at the age of seventeen, after an attack of gonorrhœa, the rheumatism, which had been quiescent for two or three years, became more severe; and from this time on he has had frequent attacks of gonorrhœa, each time followed by an exacerbation of the "rheumatism." Five years ago, after a fresh attack of the urethral trouble, the pain and swelling in the knee became unusually severe. From this he was a year in recovering, and at this time the deformity of the leg, which is present, occurred.

At the time of entrance to the hospital, the left knee was flexed to nearly a right angle, the tibia was subluxated backwards and rotated outwards. There was very little motion possible, and this was very painful. The foot of the same side was fixed in the position of extreme valgus. There were also strictures in both the deep and the anterior urethra.

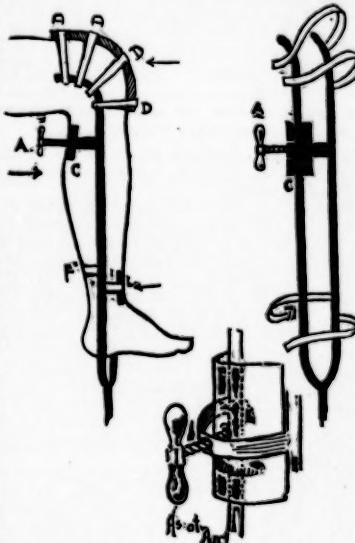

One week later Dr. Bradford operated. (In the interval the patient had been kept in bed, with extension to the leg.) The adhesions in both knee and ankle were broken up, and the leg brought into as good position as was possible by manual force. The subluxation of the tibia, however, could not be corrected. A plaster-of-Paris bandage was applied. Following this, the patient had a great deal of pain in the knee; he was obliged to remain in bed for four weeks, and even then could move about but little with the aid of crutches and the plaster bandage.

On the 23d of May a combined internal and external urethrotomy was done by Dr. Post, who was then on duty. From this the patient made a good recovery; the catheter was removed on the next day and the urine came in drops from the wound for about two weeks. At this time the pain in the knee became much more severe than usual.

Two months later, the pain in the knee still remaining, more radical operative procedure became necessary. He himself demanded amputation if relief from the incessant pain could not be obtained in any other way. On July 29th Dr. Post operated. After the adhesions were broken up, the genuclast devised by Dr. Bradford was applied; and, with the use of a great deal of force, the subluxation was corrected, the leg straightened and done up in plaster-of-Paris. (This apparatus which was not to be had at the time of the first operation is shown in the following illustration.)

Its construction and mechanical principles are apparent. When it is applied and the leg straightened, the straps D press the femur back while the screw-pad C forces the tibia forward.

After this operation, or after the bones were once in place, the pain ceased, only one dose of morphia being necessary, whereas formerly it had been used very freely. In one week the patient was up about the ward; and on the tenth day he was discharged, using crutches and wearing the plaster bandage.

Since then he has done well. When last seen, about six months ago or over a year from the time of operation, he was at work, wearing a Thomas caliper brace-splint, with a strap over the knee to prevent a recurrence of the deformity. Even without this splint he is able to walk very well, and is free from pain.

The case is of interest particularly, aside from the history in which gonorrhœa is so mixed up with the joint condition and urethral trouble, as it shows the possibility, by means of such an apparatus, of offering the patient a useful leg, whereas otherwise amputation would have been the alternative. The cessation of the pain is also noticeable, immediately after breaking up the adhesions and restoring the bones to their proper positions.

Medical Progress.

RECENT PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

STATISTICS OF ANESTHESIA.

GURLL'S¹ report is an analysis of the observations of the members of the Deutsche Gesellschaft für Chirurgie made between July 1 and December 31, 1891, and are founded on the data contributed by sixty-

¹ Arch. f. Klin. Chir., 1891, Bd. xlii, 2, p. 282.

six members. The total number of cases where anesthesia was produced was 24,625.

22,636 Cases Chloroform	71 Cases Asphyxia	6 Deaths
476 Cases Ether	0 "	0 "
1,035 Cases Chloroform and Ether	5 "	0 "
417 Cases A. C. E. Mixture	4 "	0 "
27 Cases Bromo-ethyl	0 "	0 "

These figures show one death from chloroform in each 3,776 cases, and severe asphyxiation once in every 319 cases. It is difficult to form an opinion from them of the comparative fatality of ether, but a good knowledge of the death-rate from chloroform is shown by this investigation.

THE ADMINISTRATION OF ANÆSTHETICS IN ORAL AND NASAL SURGERY.

As anæsthetist, Frederick Hewitt of the Charing Cross and Dental Hospitals, London,² has developed the following points:

Ordinarily, it is best to anæsthetize the patient with ether and to continue the anæsthesia with chloroform, care being taken not to make the substitution until the patient begins to show signs of emerging from the ether narcosis. The advantages of the ether are: (1) It is possible to fill the patient with such a quantity that for many operations it is not necessary to add more than to produce profound narcosis. (2) There is no objection to having the patient's head elevated or even to the sitting posture. (3) Should any difficulties dependent upon the presence of morbid growths, etc., in the nose or mouth arise during the administration of ether, there is not that liability to circulatory depression which exists during the use of chloroform under similar circumstances.

When considerable bleeding is anticipated, one of two positions should be chosen, if possible: (1) The etherized patient should be slowly raised into the sitting posture and his head and shoulders thrown well forward; or (2) he should lie on his side with arm under him and, his head being near the edge of the table, his face should be directed downward, the mouth being well opened by some form of gag in either case.

ASEPSIS IN THE BERGMANN KLINIK.

A recent report by Schimmelbusch³ describes the methods used at Berlin for aseptic work. Among the statements made, the importance given to cleanliness by mechanical means that is, scrubbing, washing, etc., is striking. It is sufficient for the most obstinate hardened spore or coccus. Physical sterilization, that is, by steam, hot air, or boiling water, is preferred to chemical antiseptics. For instruments, boiling for five minutes in a one per cent. soda solution is claimed to prevent rusting and to be perfectly effectual. The soda increases the disinfecting power of the boiling water, and the boiling soda solution is the most powerful disinfecting agent which one can use in practical work. For detail the reader is referred to the original article. Brushes are disinfected by soaking in a one-half per cent. aqueous sublimate solution, unless strongly infected, in which case they are boiled.

THE TREATMENT OF ERYSPIELAS.

From an interesting paper by Charles W. Allen⁴ of a personal experience in fifty cases of erysipelas, he suggests the following plan of treatment:

¹ London Lancet, and Annals of Surgery, vol. xiv, No. 5, November, 1891.

² Arch. f. Klin. Chir., 1891, xlii, 1, p. 123.

³ American Journal of Medical Sciences, July, 1891, p. 51.

First, internally, such systematic treatment as the nature of the case seems to require. Antipyretics only in case of high or persistent fever (over 103.5° to 104°). Then antipyrine in doses of at least fifteen to twenty grains, for an adult, guarded by alcohol. Cooling drinks. Calomel or saline aperients in full dose if constipation. If much weakness, alcoholic drinks given freely, especially at critical periods, and iron or iron and quinine; digitalis, if much fever and prostration; bromides for delirium; antipyrine or phenacetin for headache, with cold applications to the head, and as concentrated and nutritious a diet as possible.

Second, locally, I would paint the patch and surrounding margin of healthy skin thickly with ichthyol in collodion, one drachm to two drachms to one ounce. If the scalp is the region affected, a watery solution or ointment of ichthyol can be employed. To arrest the spread I should in every case make an attempt, either with the band of adhesive plaster, or scarification, or both, the latter to follow the former, in case the disease spreads beyond the adhesive strips. In erysipelas of the face which had not yet reached the forehead, or at least its upper part, I would apply a band tightly about the forehead and just above the ears, cutting the hair in a strip around if necessary to secure firm pressure. The chances of arresting the process here should be at least equal to those of checking the spread upon an extremity, for we have a hard, bony base over which to make our compression. If the boundary is passed, then I should at once have the scalp shaved and apply another band higher up. The hair should be cut in any case in which the scalp is invaded or threatened. Then the same application of ichthyol in collodion can be made, as to the face or other part. If there be much tension, swelling, heat and discomfort (which is not apt to be the case under collodion) any oily substance can be applied over it.

DIAGNOSTIC VALUE OF PUS COCCI IN THE BLOOD.

A. von Eiselsberg claims that the demonstration of the presence of pus microbes in the blood by culture (*streptococci pyogenes*, *staphylococci pyogenes aureus*, *staphylococci pyogenes albus*) indicates also the presence of a suppurative process; and that in doubtful cases he has thus made the diagnosis of septic infection of operation wounds, osteomyelitis, hip-abscess, etc.⁵ He does not think that failure to find such pathogenic microorganisms by culture, proves the absence of suppurative processes.

THE PULSE AS AN INDICATION FOR LAPAROTOMY.

G. H. Burrell's article⁶ on the value of the pulse-rate as an indication for laparotomy in cases of acute traumatic peritonitis is being quoted in European journals. Burrell stated that in such cases where there was no special rise of temperature, a pulse-rate of 120 or over per minute, was an indication for an exploratory laparotomy. The value of the pulse-rate as an indication for operation in cases of appendicitis was suggested by J. W. Elliot of this city, several years ago.

MENINGOCELE SPURIA TRAUMATICA.

A case representing this affection at Czerny Klinik has led Bayenthal to investigate this lesion.⁷ His pa-

⁵ Wien. Med. Wochenschr., 1890, iii, 28.

⁶ Lancet, 1890, i, p. 356.

⁷ Beitr. z. Klin. Chir., 1891, vii, 367.

tient was a boy, aged seven. The tumor was noticed two days after birth. Delivery instrumental. Site, left parietal region. Tumor soft, size of a bean when first noticed; growth corresponds to growth of body. Pulsation synchronous with heart. Crying, coughing, etc., causes tumor to increase in size. It is surrounded by a bony ring, the edge of the adjacent bone. Strong compression causes symptoms of cerebral compression, that is, loss of consciousness, dilated pupil, deep and prolonged respiration, convulsions, etc. Bayenthal has found twenty-one cases, including eight autopsies. It is an affection of infancy, not of adult life. Conditions: (1) A thin skull; (2) adherent dura; (3) deficient calcification. Symptoms: First, of concussion; then appearance of tumor contents, at first blood, later (after a few days) cerebro-spinal fluid. Rate of growth and size of tumor varies much. It may be rapid and continuous, or slow, or after attaining a certain size, remain stationary or diminish or disappear. Prognosis: Bad with rapid growth; seen in cases where there is communication with the ventricle. Slow growth good; growth ceases sooner or later since no such communication. Site: In most cases the parietal bone and generally the right. No change, as a rule, in the superadjacent tissues except thinning and rupture of skin in very rapid growths. Contour generally round or elliptical. Pulsation, respiratory disturbance, the surrounding thickened bony edge, fluctuation, possibility of reduction, participation of cerebral tissues, are discussed in detail in the original article. Diagnosis generally easy. To be distinguished from cavernous angioma, bony defects of skull, congenital hernia cerebri, blood cysts of skull connected with the longitudinal sinus, soft sarcoma of the dura which forms a pulsating tumor after perforating the skull. Prognosis: As regards recovery, always unfavorable; as regards life, guarded, uncertain. Treatment, none satisfactory or effective known.

PNEUMATOCELE SYNCIPITALIS.⁸

This rare affection is again brought to notice by C. v. Helly⁹ (Graz), who reports a case and discusses the etiology, condition, frequency and treatment of this disease. He states that it is an air-containing tumor between the skull and periosteum. The source of the aerial contents is from the air-containing cavities of the skull; the contents, atmospheric air. Hence a communication with such an air-cavity through the bone is necessary to the existence of such tumors. These communications are congenital defects or foramina; abnormally thin bone, solution of continuity from trauma, and the effect of inflammatory processes in the cavities above mentioned or of its bony walls. Helly has collected reports of seventeen cases where the tumor was occipital. Those where the frontal sinus is the source, are, on the contrary, seldom seen. He finds record of eight cases and his own makes nine. This was in a patient aged twenty-eight, cause, a kick from a cow. Loss of sight in right eye. Five years after, subsequent to a discharge of sequestra from the nose, the pneumatocele appeared in the left frontal region. Of Helly's nine cases of anterior pneumatocele the youngest was in a patient aged twelve years. He claims that the frontal sinus does not exist before the age of ten. Etiology: Trauma, three; syphilis,

one; empyema of the frontal sinus, four. In some cases the air must pass through congenital foramina in the frontal bone or mastoid, or such openings are enlarged by inflammatory processes. Helly found such congenital openings in the anterior wall of the frontal sinus in four among 474 skulls examined. There were frequently foramina for the transmission of vessels. The diagnosis is usually easy. The tumor is tympanitic. The frontal tumors are never so large as the occipital. Treatment: In three cases puncture was without result; compression can be used where pus is absent. The surest method consists of free division of the wall and healing by granulation.

EXTIRPATION OF LARYNX AND PHARYNX.¹⁰

In October, 1889, K. Poulsen (Copenhagen) performed this operation for carcinoma. The pharynx was also involved in a zone which did not extend below the cricoid cartilage. The growth was throughout the larynx. Preliminary low tracheotomy was done; then a sub-hyoid pharyngotomy, through which the limits of the growth were ascertained by digital exploration. A vertical skin incision was then made from the mid-point of the pharyngotomy wound to half an inch of the tracheotomy incision, then continued downward by two smaller lateral cuts.

The two quadrangular flaps then formed, were dissected back laterally to the sternocleidomastoid muscles. The muscles of the larynx were separated with blunt instruments, also the pharynx from the vertebrae. The pharynx was divided one centimetre above the growth, the oesophagus one centimetre below it, the trachea below the cricoid cartilage. No especial bleeding. The skin flaps, including the pre-vertebral connective tissue were united in the median line with silk sutures. The upper and lower edges of the flaps were sutured to the posterior edge of the divided pharynx above, and the oesophagus below; a tube was passed through the nose down into the severed oesophagus. Wound plugged with iodoform gauze. The wounds healed, and a new posterior pharyngeal wall resulted. The tube was removed after a few days, but passed subsequently three times daily for feeding the patient.

Three weeks later the anterior pharyngeal wall was formed by a flap from each side by aid of one vertical and two horizontal cuts. The flaps were turned in and sutured together in the median line — raw surface exposed. Their upper border was sutured to the anterior edge of the pharynx. Their lower to the anterior edge of the oesophagus. The patient could at once swallow liquids. After three or four days a small opening formed from gangrene of a small area next the oesophagus. This, when tamponed, did not interfere with feeding. The patient died from septic pneumonia (seven weeks after the first operation). Autopsy showed a new-formed pharynx, six centimetres long and nine centimetres in circumference; epidermis intact, and beginning to assume the appearance of mucous membrane.

SHOCK ACCOMPANYING EXTIRPATION OF THE LARYNX.

Alpiger¹¹ (Vienna) reports an interesting and valuable investigation made by him to explain a sudden heart paralysis and death in a healthy man, aged fifty-

⁸ See Surgical Report, Boston Medical and Surgical Journal, 1890, vol. xxii, 247.

⁹ Arch. f. Klin. Chir., 1891, xli, 685.

¹⁰ Centbl. f. Chir., 1891, No. 1.

¹¹ Arch. f. Klin. Chir., 1890, xi, 4, p. 761.

six, from whom Billroth had extirpated the left half of the larynx for carcinoma. The case apparently was explained by the discovery of an anastomosis between the external branch of the superior laryngeal and the superior cardiac branch of the sympathetic. He assumes that this anastomotic branch may contain cardiac depressant fibres, possibly from its connection with the superior laryngeal nerve. However, the practical point for the surgeon is that the danger exists; and since the nerve is more frequent on the left than the right side, left-sided operations are to be considered more dangerous. For a detailed anatomical description the reader is referred to the original article¹² or a good *résumé*.

THE RESULTS OF REMOVAL OF THE BREAST.

Terrillon,¹³ has arrived at the following conclusions as a result of partial or total removal of the breast in one hundred patients, in the treatment of tumors of various kinds:

The gravity of the operation is insignificant; recurrence seems to be the rule when the axillary glands are involved in the disease; when mammary tumors are malignant, or of a mixed character, the entire gland and involved lymphatic glands should be removed if recurrence takes place. The operation may be repeated once or several times, especially if primary union of the skin can be secured; by this means the condition of the patient is ameliorated, the drain attending ulceration is obviated, and the unfavorable course of the disease seems to be retarded.

TREATMENT OF TRAUMATIC PNEUMOTHORAX.

Witzel¹⁴ successfully relieved a case of this nature, which forms such a dangerous complication in wounds of the thorax by impeding respiration and pressure on heart and large blood-vessels, by placing a catheter in the upper angle of the wound, then suturing the opening till air-tight; then filling the pleural cavity with warm boric acid solution, which gradually displaced the air, which escaped through the catheter. The liquid then was removed by siphoning it out through the catheter. After this procedure respiration became quiet and regular, and percussion and auscultation showed normal conditions.

REMOVAL OF THE APEX OF THE LUNG FOR TUBERCULOSIS.

Dr. Tuffler,¹⁵ in a case of early tuberculous disease of the apex of the right lung, resorted to an operation. A simple incision was made through the second intercostal space anteriorly; the parietal pleura was divided, which induced a kind of sub-pleural pneumothorax; the apex of the lung became reduced in bulk sufficiently to be easily drawn through the wound; it was then cut away by the excise, and the stump sutured to the intercostal incision to prevent retraction of the lung. The case progressed very favorably after the operation.

(To be continued.)

THE KING of the Belgians has consented to be Patron of the International Congress of Gynecology and Obstetrics, which will meet this year at Brussels.

New Instruments.

AN IMPROVED APPARATUS FOR ESTIMATING UREA.

BY H. F. ADAMS, M.D., PHOENIX, ARIZONA.

THE convenient hypobromite process has called out numerous devices to make the quantitative analysis of urine for urea at once handy and rapid.

Those of Marshall,¹ Green, Doremus² and Squibb³ are perhaps the best.

The modification figured below, possesses, I believe, the following advantages:

(1) It is inexpensive. It is easily made from ordinary glass tubing with a common alcohol lamp.

(2) It reduces the cost of analysis, requiring only about one quarter of the amount of caustic soda and bromine needed by others.

(3) It is neater to use and easier to clean. Neater to use, because it can be filled and operated without soiling the fingers, and because of the small amount of caustic solution to overflow; and easier to clean, because the apparatus is of uniform calibre, and rinses easily.

(4) It is of superior accuracy: first, because of the small calibres of the urine-pipette and of the nitrogen-receiver, thus giving very close readings; second, because of the adjustment of the urine-pipette, and of the absence of any waste or error in adding the urine, as often happens with the usual pipettes; third, because of the long column of hypobromite solution, favoring a rapid and complete decomposition of the urea as the urine rises.

The ureometer is made from glass tubing having a little more than a quarter-inch bore. It is fifteen inches long, closed at one end, and curved at the other for about three inches, with a radius of one inch. It holds, filled, about seventeen cubic centimetres, and is graduated from the closed end in cubic centimetres. It is best filled with the sodium hypobromite solution by means of a long pipette, with a small delivery, which easily takes the solution from a bottle and prevents any spilling.

The urine is added by a pipette made of very small glass tubing curved to the same radius as the large tube. This curved pipette is long enough to contain

¹ Tyson's Pract. Exam. Urine, 7th Edition, p. 156.

² The Medical News, May 30, 1885.

³ Ephemeris, January, 1891.

something more than one-half cubic centimetre, and is graduated to that amount. It is attached by a short piece of rubber tubing to an ordinary medicine dropper. This attachment allows the analyst to take up a little more than one-half cubic centimetre of urine, and then to adjust exactly to that quantity without touching the bulb.

The pipette thus loaded is introduced into the tube full of hypobromite solution, exactly as a male catheter is passed. The pipette should have a very small delivery, allowing a very slow discharge of the urine. The overflow of the caustic solution is caught in a beaker. The tube may be sunk in a vessel of water to the level of the remaining liquid, in order to correct the pressure, before reading the amount of nitrogen.

The solutions used, and the calculation of the result, are according to the usual standards. Each cubic centimetre of nitrogen is nearly the product of 0.00282 grammes of urea; or, each 1% of urea, in the 0.5 c.c. of urine used, gives 1.77 c.c. of nitrogen. From these figures it is easy to graduate the tube so as to read the percentage of urea without calculation.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. G. SEARS, M.D., SECRETARY.

REGULAR Meeting, Monday, February 8, 1892, the President DR. FREDERICK I. KNIGHT in the chair.

DR. J. C. WARREN read a paper on

THE OPERATIVE TREATMENT OF GOITRE.¹

Dr. Warren: Cretinism is etiologically and pathologically a different disease. Superficially the two diseases resemble one another very much. There is in both a disturbed look about the face, feeble mental condition, imperfect action of the organs of sense, etc. Here the resemblance ceases. In the case of myxedema the distortion is due to the condition of the tissues. In cretinism the distortion is due to the shape of the bones. The widening of the face, of the eyes, peculiar distortion of the head, are characteristic of cretinism, and due probably to the condition of the skeleton rather than of the soft tissues. The connective-tissue is the one chiefly affected in the myxedema cases. The condition of mind in the myxedema cases is not necessarily as bad as one might suppose. They are slow of thought, but they appear to have more or less intellect and do not seem to lose their intelligence. Their movements are slow.

DR. RICHARDSON: This paper has been very interesting to me. I am sorry to say that I have no experience in the entire removal of thyroid tumors. Case I, was under my observation some weeks in the summer, and I did not operate because I did not think that the tumor was large enough to cause any inconvenience except from its unsightly appearance. I was very sorry afterwards that I did not operate when I learned the nature of it. It always seemed to me a very formidable operation. I dare say it is not so difficult as it seems. The position of the inferior thyroids and their relation with the recurrent nerve makes it very important to avoid that nerve. Dr. Dwight had

a large number of observations made to show that relation in the dissecting-room, and I think he found that the nerve generally went behind the artery, although that is not constant. It seems to me to avoid the recurrent nerve you need to keep well away from the trachea and osophagus, because unless the tumor is very low down indeed the nerve is there between the two. I have had quite gratifying results in the treatment of cystic tumors by drainage, and one case in which it was necessary to insert a tube into the trachea through a very large malignant growth, perhaps one of the most difficult operations. In the cystic variety, Dr. Warren may remember the old man who came a year ago with an enormous thyroid tumor. This I succeeded in curing by drainage. I think, if we can find that it is possible to remove thyroid tumors with safety and without the serious after-effects, that we shall have opened a very great and interesting field in surgery, which thus far has been very little explored in this vicinity.

DR. MIXTER: I was fortunate enough to see a very considerable number of these cases in Billroth's ward in Vienna; and a very large number were operated on, some being what were supposed to be total extirpations, but others partial, and there were also a large number treated by the injection of iodine and other substances, so that I had a very considerable number of cases to watch in all the different stages, and also had the privilege of making sections of all the growths removed, and I have now specimens from all the thyroid tumors I believe that were removed for a considerable number of years in Billroth's clinic. There are a number of points that come up in the paper, and the first is the position of the thyroid tumor in its relation to the trachea and the osophagus. Generally the compression Dr. Warren says is from the side, but I have seen, in at least two cases that Billroth removed, where the trachea seemed to be encircled by the enlarged thyroid, in other words, where, instead of passing across, the tumor extended directly round the trachea and the osophagus, completely encircling it, and of course in that position the operation was very much more difficult, the trachea and the osophagus being completely separated. In those cases I think the recurrent laryngeal nerve was generally exposed and sought for and found before the operation was carried to its completion. The injection of iodine I saw in a good many cases and with very varying results. In some cases the tumor was rapidly diminished, and in other cases, as a rule, a swelling following the injection, and then a diminution in size which carried it down to a considerable point below where it stood at the time of the injection. In other cases, after this inflammatory process had apparently subsided, the tumor would grow much more rapidly, and in these cases it was invariably removed; and in a large number of these cases I believe the growth was found to be sarcomatous. In the ordinary cystic tumor it was very generally quite successful, but I have one tumor that was removed, in which this injection had been made a large number of times and at different points. You can see the cicatrices and shrinking following, and there is one point showing the inflammatory process following the injection.

The paralysis of the recurrent laryngeal has been spoken of, and that is a very important thing to avoid. In some of these cases it was rather startling to find that there was this paralysis, but in all these cases it was temporary. In some of the malignant cases these

¹ See page 433 of the Journal.

nerves being pulled upon, I suppose, were temporarily paralyzed; but in all cases the patient recovered inside of a week. It would be noticed immediately after the patient came out of the chloroform, so that in case you find you have the symptom it is not necessary to suppose you have cut the recurrent laryngeal.

There is the danger of sudden suffocation in these cases, and it is well in all cases to have every possible instrument at hand for catheterizing or intubating the larynx or performing tracheotomy. I have seen a tracheotomy tube put through three or four inches of malignant growth where breathing had suddenly stopped.

These cases that Dr. Warren reports are of practically one type, the cystic type, with larger or smaller cysts, the bronchocoele. In Vienna I saw a large number of sarcomas of the thyroid, and several carcinomas. The sarcomas are very rapid in growth, and in all that I saw the recurrence was very rapid, and death took place in each case.

I saw none of these cases of myxedema at that time. I remember it was denied that it was so, and evidently, in those cases where myxedema did not follow, it was because the whole gland had not been removed.

DR. WHITNEY: An attempt has been made to divide the goitres into different classes, such as the hyperplastic, colloid and cystic form. But in all the process is essentially the same, the variation in the relative amount of these *cystic materials* giving the name; as all can usually be found in the same specimen.

For transplantation a modification of the Mixter punch might be used, in which the end opposite to the punch is sharpened to a needle-point. A piece cut out with the punch from one patient, the instrument turned round and the needle-point introduced at the desired place in the second.

DR. J. P. CLARK: In reviewing the recent literature on the thyroid gland, for a certain publication, I have seen several reports of cases of myxedema in which the thyroid gland of a sheep has been transplanted either into the abdominal cavity or beneath the breast. The immediate effect on the myxedema has been excellent, but unfortunately in, I believe, all the cases so far reported, the gland becomes absorbed after a longer or shorter period, and the symptoms return. George R. Murray has reported recently, in the *British Medical Journal*, a case of myxedema which showed marked improvement from the occasional subcutaneous injection of a perfectly sterile extract of a sheep's thyroid.

DR. WARREN: There is one case Dr. Otis kindly sent to me, of a tumor of the thyroid in a girl sixteen years of age. It had been growing rapidly for a few weeks, presented all the outlines of goitre, and was motionless on deglutition, went down apparently into the mediastinum. Its rapid growth and the somewhat cachectic appearance of the patient caused him to advise against thyroidectomy. It is a case I would like to study a little more before making a diagnosis. It seemed to me like a malignant type of the disease of which we have occasional examples here. I have seen a number that were distinctly malignant.²

DR. A. COOLIDGE, JR., reported

THREE CASES OF TUBERCULOSIS OF THE PHARYNX.*

DR. S. W. LANGMAID: I remember many of these cases distinctly and the various ways in which they

* I have since learned that the patient is in a very feeble condition and at times delirious.

² See page 437 of the Journal.

were treated. When the disease is primarily manifested in the skin it is very easy to make the diagnosis, but when it first appears in the nose it is very difficult. It is almost impossible to discriminate between that and syphilis. When it exists in the mouth and palate I do not think it could ever be mistaken for syphilis by one who had had much experience in syphilitic lesions of the mouth. I have never seen but one case in which there was not a manifestation sooner or later on the skin, and I believe that was the only case in which the manifestation did not precede the manifestation in the nose. In that case a very excellent cure was effected which has lasted about two years.

With regard to treatment, I myself have had so little experience that I should hesitate to recommend any particular form of treatment, but I do think that the application of escharotics preceded possibly by curetting will in a certain number of cases yield good results. In the case to which I have referred as being cured, the application of an acid solution of nitrate of mercury seemed to be the most efficacious. I applied it to the nose, mouth, tongue and even to the larynx. It was in no case followed by extensive inflammation or swelling. I was at first very cautious in my applications to the larynx, but I soon became bolder, and it was very interesting to see how ulcerations healed under its application. I think I have a distinct recollection that the application was made in one or more of those cases Dr. Coolidge has reported as unsuccessful.

The fact that the disease has a tendency to spontaneous cure is an interesting one and may be some guide in prognosis. To be sure if the disease exists in the larynx it may result in a stenosis of the larynx, but the progress of the disease is very slow, and generally has cured itself as it were. I do not know enough about lupus on the skin to know whether that is generally the case in lupus of the skin. Dr. White can inform us with regard to that.

It is very singular that up to within a few years so few cases were reported. Very many cases have been reported of scrofulous ulcers of the mouth and pharynx. What those cases are I myself do not know. I have never seen one. All I have ever seen have been tuberculous, syphilitic, lupus or one case of pemphigus. It seems to me likely that the so-called scrofulous ulcers of the mouth and pharynx reported by the French must have been either those of lupus or of tuberculosis.

It has been said that in the large proportion of cases of tuberculosis of the skin if the lesion was sought for in the mucous membrane it would be found there, and I think it is. Braun, of Vienna, who gives an account of such a study being made, and that in a certain per cent., the mucous membrane was found to be the seat of lupus. The reason it is not discovered is because the disease is so painless in its progress and because it causes so little inconvenience. If it goes into the larynx there may be some hoarseness.

It did not seem to me that these cases which Dr. Coolidge has reported were all of the same type. The appearances varied a good deal. While we had the superficial ulceration, with the ulceration in the region of the teeth with here and there raised masses, lupus nodules, still there was a very great variety in the appearances of these three cases which I believe to have been all of the same kind.

Primary tuberculosis of the pharynx is rare. Lupus is probably common. That assists in the diagnosis.

With regard to treatment again, it seems to me that about all means have been exhausted. This one Dr. Coolidge speaks of, the extraction of the teeth, is entirely new so far as my reading goes and my experience, and is worthy of consideration. I do not see why it should cure the disease, but it seems in all of these cases to have been of great benefit and the removal of a portion of the upper jaw seems to have resulted in almost cure, that is, there has been no return of the disease after nine months.

DR. J. C. WHITE: I have little to say about tuberculosis of the mucous membranes for I have no experience with the appearances or treatment of that affection. I would like to make one or two comments on what has been said. The writer speaks of some of these affections of the mucous membrane in the cavity of the mouth and throat as being lupus and of others as being tuberculosis, as though they were distinct clinical forms, but I think that the course of these cases and the diverse lesions as he described them are only examples of the great multiformity of one process and that they confirm one in the opinion that we must abandon these terms: lupus, tuberculous and scrofulous disease as representing distinct anatomical processes, and that they must be all called forms of tuberculous, or tuberculides, as the French would like to call them.

The writer spoke of certain scrapings having been examined for the presence of bacilli and of the failure to find them; negative evidence of that kind is of little value. Leloir, who has extensively studied the different forms in the skin, expects to make eighty sections on an average to find one containing bacilli, so sparse is the growth of the bacillus in the ordinary forms of clinical lupus. Of course there are other forms of cutaneous tuberculosis in which you find it much more abundant.

I think we should abandon these various terms and speak of all forms as tuberculous. In the few cases I have seen in the throat-room I should not be able to state why one of them should receive the name lupus and another tuberculosis by any distinguishing appearance I could recognize.

DR. T. A. DEBLOIS: I had the privilege of seeing Dr. Coolidge's second case. I suppose I may have had cases of lupus myself, but always called them tuberculosis. If lupus is slow-acting tuberculosis, I have one now which has not progressed for five months. There is a lesion of the tongue and larynx. It is easy to watch the progress of the spot on the tongue. I have used escharotics, lactic acid regularly.

I have had cases of dissecting tubercular disease of the mouth and hard palate, but they were very rapid in their progress, and I have always spoken of them as tubercular ulceration of the mouth. I never had a case in which the nose was involved, except secondarily from propagation through the hard palate.

DR. GEO. B. SHATTUCK: My only connection with the case was in treating her with tuberculin, and the results of that were extremely unsatisfactory. She was the least satisfactory patient I had in that treatment. She was unsatisfactory generally and unsatisfactory locally. She reacted locally, as Dr. Coolidge has said, but she did not improve and she did not gain generally as most of the other patients did. She had the usual treatment I gave, namely, from one-half up

to fifteen or sixteen milligrams at intervals of two or three times a week. I think she was under treatment five to six weeks and went away because there was no improvement.

DR. KNIGHT: Dr. Coolidge has referred to a case of mine which I published some years ago, at a time when I attempted with others, to draw a distinction between lupus and tuberculosis, and in thinking over that case and others since the discovery of the bacillus it has seemed to me that the most probable explanation of the different appearances in those cases, as we tried to make it, might be fairly due to the fact that in the cases we classed as lupus the progress of the disease was slow, particularly on account of the non-complication of pulmonary disease, that in those cases which we had been in the habit of pronouncing as decided tubercular, there was the disease of the lung which gave us the confirmation, and that disease of the lung debilitated the patient and necessarily hastened the progress of the disease. In those cases in which it happened to be found only in the throat, the disease was slow as it is in the skin and in that way we got that proliferation of tissue and extensive thickenings which we failed to get in the cases having also tubercular disease of the lungs, which are of short duration.

It always seemed to me that a good many of those cases of so-called scrofulous disease abroad, which are very hastily diagnosed, were probably cases of congenital syphilis.

DR. COOLIDGE: I am glad to hear Dr. White say that on the skin lupus and tuberculosis are merely different forms of the same thing, because it seems to me that in the throat and on the hard palate it is distinctly so. In these cases almost exactly the same appearance has been noticed as in cases which were distinctly lupus, and in cases in which there was nothing which suggested lupus. A similar lesion on the hard palate by extension on the nose and face has produced entirely different lesions, — one typical lupus and one that cannot be called lupus. The same is true in the throat. Entirely different looking lesions in the pharynx have been associated with the same lesion around the teeth.

DR. M. H. RICHARDSON described a case of

PANCREATIC CYST APPARENTLY CURED BY EXCISION
AND DRAINAGE; RECURRENCE, PERFORATION OF
THE STOMACH, DEATH, AUTOPSY.⁴

DR. WHITNEY: Cysts of the pancreas are almost all regarded as dilatations of the duct. Usually the sacculated form is the most common. Here we have dilatation of the middle part of duct with destruction of tissue, leaving the head and tail of pancreas intact.

As regards the formation of fistula, it has been noted that pancreatic fistulae are extremely rare. As a rule, when a communication has been established with the cyst, it readily closes. Perforations into the stomach and into the root of the mesentery are also mentioned.

DR. RICHARDSON: In Senn's article on this subject he reports a few cases, all he was able to collect two or three years ago; and I noticed that the most of them were of short duration, so that they may have recurred. From what experience I have had I believe that no cyst would close up. I do not believe any such cyst as this would ever heal. I do not see how it is possible for it ever to heal from the bottom.

DR. STEBBINS: I have here the ovaries taken from a Jewess, aged twenty-two. She came to the out-pa-

⁴ See page 411 of the Journal.

tient department complaining of pain in the pelvic region for a year or more. She was found to have a small tumor, about the size of an orange, on the right side. On removal, there was found to be a dermoid about the size of a small orange. The tumor was cut open this morning, showing a good deal of hair and some bits of bone and cartilage embedded in it. There is in the Fallopian tube another small cyst. The left ovary was found to contain a cyst smaller than the other, and on section fluid came out. At the fimbriated end of the Fallopian tube were several small cysts.

DR. COOLIDGE showed a piece of sponge removed from the nasal cavity of a patient, who gave the following history: Two years ago he had been etherized, and a polypus had been removed from his nostril. After the operation he found that the impediment to breathing was worse than it had been before; he therefore decided to change his physician. He has done so several times during the past two years. The sponge had evidently been put in to stop hemorrhage, and its presence was not suspected by the patient. The purulent discharge had existed for two years, during which time he had lost much flesh and became very anemic. After the removal of the sponge, the foul odor of the discharge disappeared within a week, and the patient already began to feel very much better. A foul discharge from one nostril only should always suggest a possibility of a foreign body, especially in children.

DR. KNIGHT: A few years ago a gentleman came to me from Newport, who had had a pretty severe hemorrhage from the nose. A physician had plugged posteriorly, but had forgotten to put on the string to the tail end of the plug, but pulled an enormous sponge as far as he could into the nose. The patient went about for three weeks from one to another, and no one got it out. I finally succeeded in breaking up the thing and getting it out anteriorly.

DR. MIXTER showed a stone he had crushed, weighing 900 grains. It was very hard. There was difficulty in grasping it even with the largest Bigelow lithotrite. It was three inches in length, and could not be grasped by its long diameter. The symptoms had lasted two years. The patient left the hospital at the end of a week, without a symptom of pain or discomfort.

Recent Literature.

Sleep, Insomnia and Hypnotics. By E. P. HURD, M.D. Detroit: George S. Davis. 1891.

This little volume is one of the Physician's Leisure Library Series. It contains about one hundred pages, and the title-page indicates the contents, each one of the three subjects of the title being the heading of one of the three chapters into which the book is divided. A concise statement of the physiology of sleep and the causes of insomnia prepares the reader for an intelligent, conservative and sensible consideration of the delicate question of hypnotics and their use. The author does not regard drugs as the most important therapeutic agents; though recognizing their uses, he thinks physicians should be very chary in prescribing the medicinal hypnotics, as many of them by constant or frequent use become positively baneful, and he closes the book with an exhortation to first try fully, when possible, all available hygienic resources before resorting to them.

THE BOSTON Medical and Surgical Journal.

THURSDAY, MAY 5, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

PRESENTATION OF PORTRAITS OF DR. OLIVER WENDELL HOLMES AND DR. ALFRED STILLÉ TO THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

A NOTABLE occasion in recent medical annals was the presentation of a portrait of Dr. Alfred Stillé, ex-President of the Philadelphia College of Physicians, and one of Dr. Oliver Wendell Holmes, an Associate Fellow, to that body. The former, the gift of the physicians of Philadelphia, was presented through Dr. H. C. Wood, and accepted on behalf of the Fellows by the President; the latter, the personal gift of the President, Dr. S. Weir Mitchell, was accepted by the Vice-President, Dr. J. M. DaCosta. The occasion was a dinner of the College of Physicians of Philadelphia, on the evening of the 30th ult., at which were present, besides the Fellows, a number of Associates and invited guests, including Drs. William H. Welch, of Baltimore, Hermann Knapp, of New York, and Wm. Osler, of Baltimore, and Talcott Williams, Esq., the entire number of those who sat down to dinner being nearly two hundred.

Both paintings were of life-size, in oil, half-length, and both excellent portraits. The portrait of Dr. Holmes represented the poet-physician in the black robe of the Faculty; it is the work of Mrs. Sarah Whitman, and is said to be the finest portrait of the genial autocrat that has ever been painted. There are many personal allusions in Dr. Holmes's poem referring to incidents during his attendance upon the second annual meeting of the American Medical Association, which took place in Philadelphia, and regarding which the President made a few explanatory remarks before reading his own contribution.

We venture to think our readers will condone the substitution of unpublished poems by the Doctor-Poet of Philadelphia and the Poet-Doctor of Boston for the customary editorials.

VERSES BY DR. MITCHELL ON PRESENTING THE PORTRAIT OF DR. OLIVER WENDELL HOLMES.

We call them great who have the magic art
To summon tears and stir the human heart,
With festive grief to bring the soul annoy,
And leave a dew drop in the rose of joy.
A nobler purpose had the Masters wise
Who from your walls look down with kindly eyes.
Theirs the firm hand and theirs the ready brain
Strong for the battle with disease and pain.
Large were their lives; these scholars, gentle, brave,
Knew all of man from cradle unto grave.
What note of torment had they failed to hear?
All grief's stern gamut knew each pitying ear.
Nor theirs the useless sympathy that stands
Besides the suffering with defenceless hands;
Divinely wise, their pity and the art
To teach the brain the ardor of the heart.
These left a meander for a nobler George;
These trod the red snows by the Valley Forge,
Saw the wild birth-throes of a Nation's life,
The long-drawn misery and the doubtful strife:
Yea, and on darker fields they left their dead
Where grass-grown streets heard but the bearer's tread,
While the sad death-roll of those fatal days
Left small reward beyond the poor man's praise.
Lo! shadowy greetings from each canvas come,
Lips seem to move now for a century dumb:
From tongues long hushed the sound of welcome falls,
"Place, place for Holmes upon these honored walls."
The lights are out, the festal flowers fade,
Our guests are gone, the great hall wrapped in shade.
Lone in the midst the silent picture stands,
Ringed with the learning of a score of lands.
From dusty tones in many a tongue I hear
A gentle Babel.—"Welcome, Brother dear.
Yea, though Apollo won thy larger hours,
And stole our fruit, and only left us flowers,
The poet's rank thy title here completes—
Doctor and Poet,—so were Goldsmith, —Keats.
The voices failing murmur to an end
With "Welcome Doctor, Scholar, Poet, Friend."

In elder days of quiet wiser folks,
When the great Hub had not so many spokes,
Two wandering gods, upon the Common, found
A weary school-boy sleeping on the ground.
Swift to his brain their eager message went,
Swift to his heart each ardent claim was sent;
"Be mine," Minerva cried. "This tender hand
Skilled in the art of arts shall understand
With magic touch the demon pain to lay.
From skill to skill and on to clearer day,
Far through the years shall fare that ample brain
To read the riddles of disease and pain."
"Nay, mine the boy," Apollo cried aloud,
"His the glad errand, beautiful and proud,
To wing the arrows of delightful mirth,
To slay with jests the sadder things of earth.
At his gay science melancholy dies.
At his clear laugh each morbid fancy dies.
Rich is the quiver I shall give his bow,
The eagle's pinion some bold shafts shall know;
Swift to its mark the angry Arrow-song,
Shall find the centre of a nation's wrong;
Or in a people's heart one tingling shot
Pleads not in vain against the war-ship's lot.
Yea, I will see that for a gentler flight
The dove's soft feathers send his darts aright
When smiles and pathos, kindly wedded, chant
The plaintive lay of that unmurred aunt;
Or sails his Nautilus the sea of time,
Blown by the breezes of immortal rhyme,
Or with a Godspeed from her poet's brain,
Sweet Clémence trips a-down the Rue de Seine.
The humming-bird shall plume the quivering song,
Blithe, gay and restless, never dull or long,

Where gaily passionate his soul is set
To sing the Katydid's supreme regret,
Or creaking jokes, through never-ending days,
Rolls the quaint story of the Deacon's chaise.
Away with tears; when this glad poet sings,
The angel laughter spreads her broadest wings.
By land and sea where'er St. George's cross
And the starred banner in the breezes toss,
The merry music of his wholesome mirth
Sends rippling smiles around our English earth.

"Not mine," Minerva cried, "to spoil thy joy—
Divide the honors, let us share the boy."

LINES BY DR. OLIVER WENDELL HOLMES ON THE PRESENTATION OF HIS PORTRAIT.

"How came I here?" The portrait thus might speak,
The crimson mantling in its canvas cheek,
"Here in this concourse of the grave and wise
Who look upon me with inquiring eyes,
As on some homeless wanderer, caught astray?
An error loci, Boerhaave would say.
Is this great hive of industry my home?
Where is the Common? Where my gilded dome?
Where the Old South? The frog pond? Most of all,
My sacred temple, Freedom's Faneuil Hall?"

No answer comes; no trick of human art
Can force those fixed, unmoving lips apart.
He whom the picture shadows must explain
This lawless inroad on a strange domain.
Were it my votive offering, meant to show
My grateful sense of all the debts I owe
To your fair city, its unlooked-for face
Might find no cavalier to dispute its place.
Yet though the friendly offering is not mine
It bears my benediction to the shrine
Where, if it meets a welcome, longer yet
Will stretch the column which displays my debt.
Friends of my earlier manhood, ever dear,
Whose lives, whose labors all were centred here,
How bright each figure stands before me now
With eyes undimmed and fair un wrinkled brow,
As when, with life before us yet untried,
We walked the "Latin Quarter" side by side
Through halls of death, through palaces of pain
That cast their shadows on the turbid Seine.

When o'er our coffee, at the old "Proeope,"
Smiling, we cast each other's horoscope,
Daring the future's dubious path to scan,
Gerhard, your *Gerhard* was the coming man.
Strong-brained, strong-willed, inquiring, patient, wise,
He looked on truth through achromatic eyes:
Sure to succeed, for Nature, like a maid,
Loves best the lovers who are not afraid.
Lends them her hand to lead them where they please,
And trusts them boldly with her master-keys.
Behold, unfading on the rolls of fame
Typhus and *Typhoid* stamped with Gerhard's name.

Look on the stately form at Gerhard's side.
He, too, shall live to be his city's pride.
Tall, manly, quiet, grave, but not austere,
Not slow of wit, a little dull of ear,
Him we predestined to the place he won,—
Norris, the Quaker City's noble son.
Armed with the skill that science renders sure
His look, his touch, were half his patient's cure;
What need his merits I should further tell?
His record stands; your pages know it well.

Still wandering, lonely, mid the funeral urns
To one loved name my sadening thought returns
Less to the many known, but to the few
A precious memory, — *Stewardson*, to you.

Through many a league we two together fared,
The traveller's comforts and discomforts shared,
When hills and valleys parted distant towns,
Long ere the railway smoothed their ups and downs.
In all the trials wearing days could bring
No fretful utterance ever left its sting :
Pity it was that, chased by pallid fears,
He walked in shadow through his morning years.
Talked of his early doom, and then, and then
Lived on, and on, past threescore years and ten.
Too shy, perhaps too timid, for success
He fought life's battle bravely not the less.
Others left prouder memories, none more dear,
For those a sigh, for Stewardson a tear !

Well, years rolled on, we went our several ways
Not unrewarded with our need of praise ;
Time took the weight and measure of our brains
Set us our tasks and paid us for our pains.
At length (our side-locks fast were turning gray)
He brought our art that-all-important day
When here our Esculapian Congress met
(Its second gathering, you will not forget),
With the crowd your far-famed city sought,
Pleased to behold the schools where Rush had taught,
Where Wistar labored and where Homer led
His thirsting flock to Surgery's fountain-head.

What kindly welcome with the rest I shared ;
A little pleased — perhaps a little scared,
When Chapman hugged me in his huge embrace
With praise that lit a bonfire in my face —
When Francis, guest at Mitchell's generous board,
My humble name across the table roared,
Coupled with one which figures on the roll
Of England's poets — bless his worthy soul !
Garth — good Sir Samuel, whose poetic spark
Scarce seen by day, still glimmers in the dark.
These flitting phantoms of the past survive,
While grateful Memory keeps her fires alive.
Friends of the days that fear and anguish knew,
My heart records a deeper debt to you.

To this kind refuge hallowed evermore,
Her shattered sufferers fond affection bore.
Full many a father tracked his bleeding son
Fresh from the murderous conflict, lost or won,
Strayed through some quiet ward, and looking round,
In pity's sheltering arms the lost was found.

Enough ! Enough ! these eyes will overflow
In sweet remembrance of the debt I owe —
A debt 'twould bankrupt gratitude to pay —
But Heaven, perhaps will hear me when I pray :
Peace to your borders ! Long may Science reign
Supreme, unchallenged o'er her old domain !
While sons as worthy as their sires of old
Her borrowed sceptre still unbroken hold
Till a new RUSH arise who dares to think —
An unborn LEIDY finds the missing link.

MEDICAL NOTES.

YELLOW FEVER IN BRAZIL. — The yellow fever in Brazil is reported to be further spreading from the Brazilian coast to the interior. The principal victims are said to be Germans, English, Swiss, Austrians and Swedes.

SMALL-POX IN ENGLAND. — Cases of small-pox continue to occur with disquieting frequency in various widely separated parts of England. Last week there were two deaths in London, one in Croydon, and one

in Halifax. There were, however, forty-eight cases in the infectious hospitals of the metropolis, and it is thought that the death statistics do not give a true idea of the extent of the present prevalence of the disease. Owing to the enforcement of the vaccination laws in the past, a large proportion of the adult population are more or less protected from small-pox.

A HEART AS A DRUG. — Two Tartars in the neighborhood of Kazan have been sentenced to twelve years' penal servitude for the murder of a little girl of six years of age. They cut out her heart to give it to a sick person to eat, as a human heart had been prescribed by a mullah !

FIRST AID TO THE INJURED IN THE FRENCH ARMY. — The French Minister of War has issued an order that henceforth every officer and every man in the French army shall, when on active service, carry on his person material for a first dressing in case of his being wounded.

NEW YORK.

ST. LUKE'S HOSPITAL. — The trustees of St. Luke's Hospital, at a meeting held April 25th, decided upon the general plans of the buildings to be erected on the new site between 113th and 114th Streets, and Amsterdam and Morningside Avenues. They also decided upon the names of five architects or firms of architects who are to be invited to compete in making the designs for the future hospital. They are to receive the sum of \$400 each for their plans; but the competition is not to be confined to these five, as any other architect is at liberty to submit plans if he so desire. Those who do so voluntarily, however, will receive no money. The buildings are to be fireproof throughout, with basements of stone, and the upper stories of brick, with stone trimmings. It is at present contemplated to provide accommodations for about 600 persons, including 100 nurses, and about one-tenth of the hospital space will be reserved for private patients. In each ward of the hospital there are to be twenty beds, with 1,500 cubic feet of air for each patient, and every ward will have its own dining-room, "quiet-room," private room for nurses, etc. There will be a large administration building, on the front of which is to be placed a statue of St. Luke in a niche, and beneath this tablet with an inscription referring to the former site of the hospital and to its founder, the Rev. Dr. Muhlenberg. The chapel is to seat an audience of 300, and to be easily accessible from the various wards, and the nurses' home will be a detached structure, fronting on 114th Street.

THE WEEK'S MORTALITY IN NEW YORK. — The week ending April 23d there were 901 deaths reported, which is 55 below the average of the corresponding week for the past five years, and represents an annual death-rate of 27.30 per 1,000 of the estimated population. There were three deaths from small-pox and two from influenza. In the week preceding there were nine deaths from the latter disease. On the 26th of April a man suffering from typhus fever escaped from

the Reception Hospital at the foot of East 16th Street, and notwithstanding the vigilant efforts of the health authorities he was not found again until three days had elapsed.

THE CHURCH HOSPITAL AND DISPENSARY. — A new charitable medical institution, under the auspices of the Protestant Episcopal Church, has just been opened on West 41st Street. It represents the union of several parish dispensaries for the more efficient carrying on of the work in their charge, and is to be known as the Church Hospital and Dispensary. The building occupies two city lots, and provision has been made for a large outdoor and distinct visiting service.

AT THE PASTEUR INSTITUTE. — A patient has been admitted to the Pasteur Institute who was recently bitten at Middleton, Mass., by a horse suffering from rabies contracted from the bite of a dog on April 4th, at Danvers. The horse subsequently died of the disease. This is the first case of the kind that Dr. Gibier had since he opened the Institute.

DEATH FROM APPENDICITIS AND ITS SEQUELAE. — In the case of Dr. Charles F. Clark, who recently died in Brooklyn, it was found at the autopsy that there was chronic appendicitis, with acute appendicitis super-induced and multiple metastatic abscesses in the liver, lung and kidney. The caput coli, which is usually held in position on the right side of the abdomen by the peritoneum and connective-tissue, was free, and had swung over to the left side.

Miscellany.

A PHYSICIANS' BUREAU OF SERVICE AND INFORMATION, AT THE WORLD'S FAIR.

A BUREAU of Service and Information, for the exclusive use and benefit of visiting physicians and surgeons and their families, with ample room for the successful operation of each department, and additional space for the use of the secretaries and other officers of medical societies and conventions will be established at the Columbian Exposition by Chas. Truax, Greene & Co. of Chicago.

A list of leading hotels and boarding-houses will be kept, with location, description and rates. A miniature post-office will be established, so that mail matter may be addressed to the bureau and also telegrams.

Telegraph, Telephone, Stenographic, District Messenger, Livery, Cab, Express, Baggage and Freight Service arranged for in the building and legitimate rates secured. Parcels and small packages will be received and checks issued for the same. A reading and reception room, with writing facilities and stationery, will be provided, where physicians may meet their friends, attend to correspondence, etc. Theatre, exposition, sleeping car and railway tickets will be secured, and assistance rendered in purchasing goods in all lines of trade. German, French, Spanish and other interpreters will be permanently located in the building.

These privileges will be granted to physicians and surgeons (and their families) only — college and date of graduation required on registration.

THE BACILLUS OF MEASLES.

CANON and Pieckle¹ have succeeded in isolating a bacillus which they consider the specific organism of measles. This bacillus was found in the blood in fourteen cases of measles. Organisms similar to those found in the blood were detected in the sputum and in the nasal and conjunctival secretions. They succeeded in making first cultures of the bacillus in bouillon, but the organism would not grow on the other media usually employed, nor could further cultivations be obtained from the bouillon. This bacillus is essentially different from the organisms previously suspected as being the cause of the disease. Its size is very variable, sometimes they are as long as half the diameter of a red blood-corpuscle, sometimes they are quite small, and have the appearance of diplococci; between these two extremes they show several gradations in size. Occasionally they are of extraordinary length, almost equal to the diameter of a red corpuscle. They are found in very variable numbers, one specimen of blood sometimes showing only a few bacilli, while in others the field was packed close with them. They frequently occur singly, but in the majority of cases they were arranged in larger or smaller clusters. They were found during the whole course of the disease, and in one case even three days after defervescence. As a rule, they were found most abundantly at the time of defervescence. The authors also examined the blood of seven children who had had measles just before, and in some of whom the rash had not entirely faded away, but the results were negative. Bacilli of the same shape as those found in the blood were seen in the expectoration, and in the nasal and conjunctival mucus of patients suffering from measles. The bacilli stain readily, but are not easily cultivated by any methods so far tried by the authors.

"BICHLORIDE OF GOLD CURE" DENOUNCED BY THE HAMPDEN DISTRICT MEDICAL SOCIETY.

At the annual meeting of the Hampden District Medical Society, held in Springfield, Mass., April 20th, the following resolution was almost unanimously adopted:

Whereas, according to common and newspaper report and upon information and belief it is known that a member of this Society and Fellow of the Massachusetts Medical Society in regular standing, has, by associating himself with one of the most notorious impostors of this century in the application and use of a remedy for the cure of inebriety called "bichloride of gold," and whose exact composition it is pretended is known only by, and is the sole property of, a certain individual; and

Whereas, no such stable chemical combination is possible, and the substance actually used with so much secrecy and profit to the proprietor is and has been employed in suitable cases for years by regular physicians, who well know its limitations and dangers; and

Whereas, by associating himself with a regular physician this pretender hopes to gain prestige and the quasi

¹ Berliner Klin. Woch., April 18th.

indorsement of the regular profession, thus enabling him longer to delude the public; and

Whereas, the association of a regular physician in such a capacity is calculated to injure the public and is degrading to those who are in fellowship with such physician, and, recognizing that "naught but evil can finally result from trifling with moral physical facts, and that it is better to cure rightly and really than wrongly and delusively," and that by the "humbuggery of secrecy, delusion and hypnotic suggestion," a far less number will, in the end, receive benefit; and

Whereas, it is the opinion of the members of this Society that the use of the drugs, in the manner employed, for the cure of inebriety by the aforesaid impostor, produces a cerebral stimulation with intellectual disorders which are sometimes quite serious, together with other grave nervous troubles, themselves constituting a form of inebriety frequently leading to insanity and suicide, and a lowering of vitality rendering the patient less able to resist and recover from ordinary diseases; and

Whereas, in those cases of inebriety claimed to have been cured by means of this pretended secret method of treatment, it is our opinion that such cures resulted, not because of said treatment, but in spite of it; and there seems little doubt that hypnotic suggestion played an important part in effecting said cures; and it is our opinion that in all of the so-called "cures" the result attained could have been better secured by improving the moral condition of the patient, by the use of tonics or hydro-therapeutics, regulating nervous action, and by attention to the digestive tract, without subjecting the patient to the dangers of another form of inebriety, and without the element of secrecy. It is, therefore,

RESOLVED, That this Society hereby directs its president to refer this subject to a proper committee, who shall, before the next regular meeting, ascertain if any member of this Society has identified himself with the manufacture, sale, distribution or use of any secret remedy contrary to the code of ethics under which this Society is organized, and, if so, that such member or members be recommended for expulsion from membership in this Society at said next regular meeting.

THERAPEUTIC NOTES.

SODIO-SALICYLATE OF THEOBROMINE OR DIURETIN.—The last number of the JOURNAL contained an extract from a paper by Dr. H. A. Hare (*Therapeutic Gazette*, March 15th), giving the writer's experience with these drugs. The statement there made in regard to the price of these articles we are now informed by the agents for Diuretin Knoll is incorrect. According to their statement the price of diuretin is \$1.75 and the price of sodio-salicylate of theobromine is the same.

SALOPHENE.—Salophene occurs in small white flakes almost insoluble in water, very soluble in alkaline solutions, in alcohol and ether. It is quite tasteless and odorless. Alkalies break it up into salicylic acid and acetylaminodiphenol. The same change takes place in the body when it comes into contact with the pancreatic or intestinal fluid. It passes unchanged through the stomach. According to Siebel, there is no advantage to be gained by giving more than 5 or 6 grammes during the day. The salophene not decomposed is eliminated by the bowel. The acetylaminodiphenol is partly excreted by the kidneys, and the salicylic acid can be found in the urine fifty hours after the administration of the drug. Siebel comes to the conclusion that salophene is superior to salol, both on account of its want of taste and smell, as well as from its less poisonous properties.

Correspondence.

SECOND MEETING OF THE ASSOCIATION OF MILITARY SURGEONS OF THE NATIONAL GUARD, ST. LOUIS.

MR. EDITOR:—I wonder if the readers of the JOURNAL appreciate the interest which medical men are taking in the National Guard of our States. At St. Louis, on April 19th, 20th and 21st, the second meeting of the Association of Military Surgeons of the National Guard of the United States was held. It is only a few years since the term "militia" was used in hardly a complimentary sense; but if one can judge from the meeting, which occurred in St. Louis, of medical men from all portions of the country, the opprobrium of belonging to the militia will soon be abolished.

A more earnest, zealous, patriotic group of men it has not been my fortune to meet. The East was not enough represented. The men came principally from the middle and western sections of the country; the majority were between forty and fifty years of age, all anxious to advance the efficiency of the National Guard. And by the by, there are few of us who recognize that this National Guard is our "Landwehr." We are, as a country, absolutely defenseless against any of the great powers, and to our National Guard we must turn in time of need. This condition is now appreciated by the regular army, and the presence of Colonels Greenleaf and Alden, from Washington, showed the interest of the United States Army, and I feel sure that the representatives of the regular army were greatly pleased with the personnel of the Association.

It was an American convention in the fullest sense of the term,—bright, active, common-sense men gathered from all parts of the country, who had laid aside their work to devote themselves to the interest of the National Guard and to have a good time. This last element was carried out in full by the hospitable citizens of St. Louis, who entertained the Association in a very liberal manner. Receptions, dinners and a civic ball were tendered the Association, and were appreciated.

This diversion did not prevent the Association from doing good work. A number of very interesting papers were read, and a large number of interesting discussions ensued. The spirit of the Association was towards placing the National Guard of the respective States in touch with the regular army. As was aptly said during some after-dinner remarks, "the regular army surgeons were but the elder brothers of the National Guard surgeons," and certainly a fraternal spirit was manifested by the elder brothers, who, in every way in their power, encouraged and directed the well-meant efforts of the Association.

Possibly some of the titles of the papers will be of interest to you. Lieutenant-Colonel Charles R. Greenleaf, U. S. A., read a paper on "The Practical Duties of an Army Surgeon in the Field during Time of War"; "Some Needs of the National Guard," by Major Lawrence C. Carr, Surgeon Ohio National Guard; and "The Primary Dressing of Fractures," by General Scott Helm, Surgeon General National Guard, Arizona, were of great interest. Fifteen or twenty papers in all were read, some of them by title, and they will form a volume of transactions, which will doubtless come to your hand.

One of the most interesting features on April 20th was an exhibition of the field appliances and work of the Medical Department of the United States Army, and Major John Van R. Hoff, Surgeon U. S. A., commanding a detachment of the United States Hospital Corps from Fort Riley, Kan., gave an exhibition illustrating the following subjects:

- (1) Inspection of the Hospital Corps Detachment.
- (2) Inspection of the Field Hospital. During this inspection, and each day of the convention, an explanation was given of the various field appliances used by the Medical Department, United States Army; of the methods of keeping records; managing field hospital, etc.
- (3) Bearer Drill with Field Litter: extemporized litters

(blanket, coat, rifle, etc.); lifting, lowering and carrying patients by one, two, three or four bearers; passing obstacles with ambulance.

(4) First Aid Drill: the application of temporary dressings; utilizing materials ordinarily at hand on the battlefield for splints, etc.

(5) Assembly of Squads: formation and dismissal of detachment.

Subjects: (1) Fracture of right clavicle; (2) dislocation of left shoulder; (3) fracture of right arm, middle third (compound); (4) fracture of left forearm, near elbow; (5) haemorrhage from right femoral artery; (6) flesh wound of scalp; (7) perforating gun-shot wound, left chest; (8) gaping knife-wound, right abdomen; (9) fracture of left femur, lower third (compound); (10) fracture of right tibia, middle third; (11) sunstroke; (12) resuscitation of apparently drowned.

It is, of course, of interest to us in Massachusetts to remember that the JOURNAL had the honor of suggesting the formation of ambulance corps, in an editorial in the issue of September 25, 1884.

Following the regular army demonstration, a lantern-slide exhibition was made of the work and drill of the Ambulance Corps of the First Brigade, M. V. M. This attracted considerable attention, especially from the regular army officers, who, I fancy, were much pleased with the efficiency of the corps.

The address of the President, General N. Senn, Surgeon-General, of Wisconsin, was filled with interesting suggestions to increase the efficiency of the National Guard. Many of these suggestions were acted upon, and made the sentiment of the Association, and will doubtless be of value to the medical department of the National Guard. Many regrets were felt at the absence of Surgeon-General Bryant, of New York, who has so actively interested himself in the National Guard.

On Wednesday morning a clinic was held at the City Hospital by General Senn. The amphitheatre was crowded with spectators, and an incision of the knee-joint, and an amputation of the leg were performed. The lady who were present were especially impressed by General Senn's ability to talk and operate at the same time, and one of the local newspapers stated, that "he grew as enthusiastic over proving the accuracy of his diagnosis as a good Republican platform-orator does over the benefits of the McKinley bill, and like the latter, he produces something of his own enthusiasm in his audience."

Words of praise were accorded to Colonel E. Chancellor, the Chairman of the Committee of Arrangements, whose duties were so efficiently performed. Much of the success of the meeting was due to his efforts.

The next meeting of the Association will be held in Washington, in May, 1893.

B.

METEOROLOGICAL RECORD.

For the week ending April 23, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 3,462; under five years of age 1,284; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 163; acute lung diseases 598; consumption 423; diphtheria and croup 178; scarlet fever 55; diarrhoeal diseases 46; typhoid fever 39; measles 36; cerebro-spinal meningitis 23; whooping-cough 19; erysipelas 19; malarial fever 19; small-pox 19;

From typhoid fever Chicago 13, Philadelphia 6, Lawrence 3, New York, Brooklyn and Cincinnati 2 each, St. Louis, Cleveland, Pittsburgh, Milwaukee, Washington, Cambridge and Salem 1 each. From measles New York 23, Chicago, Brooklyn and Pittsburgh 3 each, Philadelphia, St. Louis, Milwaukee and Lowell 1 each. From cerebro-spinal meningitis New York, Chicago and Brooklyn 5 each, Worcester 3, Boston, Washington, Lowell, Lawrence and Gloucester 1 each. From whooping-cough New York 7, Chicago 4, Cincinnati 2, Philadelphia, Brooklyn, Boston, Cleveland, Washington and Cambridge 1 each. From erysipelas New York 7, Chicago and St. Louis 3 each, Philadelphia 2, Brooklyn, Cambridge, Springfield and New Bedford 1 each. From malarial fever New York, Philadelphia and Brooklyn 2 each, Nashville 1. From small-pox New York 3, Pittsburg 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,183,736, for the week ending April 9th, the death-rate was 23.3. Deaths reported 4,443: whooping-cough 172, measles 163, diphtheria 57, scirr. fever 45, diarrhoea 31, fever 25.

The death-rates ranged from 12.3 in Croydon to 33.5 in Salford; Birmingham 26.0, Bradford 24.5, Hull 22.4, Leeds 24.6, Leicester 21.4, Liverpool 26.9, London 22.2, Manchester 31.0, Newcastle-on-Tyne 23.6, Nottingham 20.3, Portsmouth 16.2, Sheffield 24.0, Wolverhampton 26.8.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 16, 1892, TO APRIL 29, 1892.

Leave of absence for fourteen days on surgeon's certificate of disability is granted to Captain AUGUSTUS A. DE SOFFE, assistant surgeon, U. S. A., with authority to enter Army and Navy General Hospital, Hot Springs, Ark., for treatment.

MAJOR JOHN H. JANEXWAY, surgeon, U. S. A., is relieved from the further operation of so much of special orders, as directs

him, in addition to his other duties, to perform the duties of post surgeon at Frankford Arsenal, Tenn.

Leave of absence for one month to take effect on or about May 1, 1892, is granted FIRST-LIEUT. OGDE RAFFERTY, assistant surgeon, U. S. A.

By direction of the Secretary of War, Par. 13, S. O. 74, March 29, 1892, A. G. O., removing the suspension of the orders changing the stations of CAPTAIN AARON H. APPEL and FIRST-LIEUT. JULIAN M. CABELL, assistant surgeons, U. S. A., is revoked.

FIRST-LIEUT. GEORGE M. WELLS, assistant surgeon, U. S. A., is relieved from duty at San Carlos, Ariz., and ordered to report in person to the commanding officer, Fort Grant, Ariz., for duty at that station.

Leave of absence for one month to take effect on the final adjournment of the board of officers convened by Par. 1, S. O. 32, c. s. Hdqrs. Dept. Mo., is granted CAPTAIN JOHN L. PHILLIPS, assistant surgeon, U. S. A.

CAPTAIN BENJ. MUNDAY, assistant surgeon, U. S. A., is granted an extension of one month to leave of absence granted in S. O. 40, Dept. Dak., March 19, 1892, S. O. 98, A. G. O. April 26, 1892.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 30, 1892.

L. G. HENNERBERGER, surgeon, detached from U. S. S. "Iroquois" and granted three months' leave of absence.

J. E. PAGE, assistant surgeon, detached from U. S. S. "Iroquois" and ordered to the receiving-ship "Independence" at Navy Yard, Mare Island, Cal.

J. R. WAGENER, surgeon, detached from U. S. S. "Kearsarge" and Naval Hospital, New York, and placed on waiting orders.

ASSOCIATION OF AMERICAN PHYSICIANS.

PROGRAMME OF THE SEVENTH ANNUAL MEETING.

The Association of American Physicians will hold its seventh annual meeting in the Army Medical Museum, Washington, D. C., May 24, 25 and 26, 1892.

TUESDAY, MAY 24th.

Morning Session (10 a. m.) — 1. President's Address, Henry M. Lyman, Chicago, Ill. 2. General Business. 3. "The Cold Water Treatment of Typhoid Fever," G. Wilkins, Montreal. 4. "The Treatment of Follicular Tonsillitis," G. M. Garland, Boston. 5. "A Collective Investigation in Regard to the Value of Quinine in Malarial Haematuria," or Malarial Hemoglobinuria, H. A. Hale, Philadelphia. 6. "Alcoholism," T. S. Latimer, Baltimore.

Afternoon Session (2:30 p. m.) — 7. "Practical Results of Bacteriological Researches," G. M. Sternberg, U. S. N. S. 8. "The Treatment of Experimental Tuberculosis by Koch's Tuberculin, Hunter's Modification, and other products of the Tubercle Bacilli," E. L. Trudeau, Saranac Lake. 9. "Report of a Case of Glanders, with Results of Bacteriological Study," William Pepper, Philadelphia. 10. "The Bacteriological Study of Drinking-Water," V. C. Vaughan, Ann Arbor. 11. "The Morbid Anatomy of Leprus," Heneage Gibbes, Ann Arbor, Mich.

WEDNESDAY, MAY 25th.

Morning Session (10 a. m.) — 12. Discussion on Dysentery; Etiology and Pathology, Referee W. T. Councilman, Baltimore. Symptomatology, Complications and Treatment, Co-Referee, A. B. Ball, New York. 13. "Treatment of Acute Dysentery by Antiseptic Color and Rectal Irrigation," W. W. Johnston, Washington, D. C. 14. Contribution to the Study of Malaria in Africa," M. C. Dahlgren, Virginia. 15. "Pulsating Pleural Effusions," James C. Wilson, Philadelphia.

Afternoon Session (2:30 p. m.) — 16. "A Case Presenting the Symptoms of Landry's Paralysis, with Recovery," F. T. Miles, Baltimore. 17. "A Case Showing Symptoms of Landry's Paralysis; Recovery," A. McPhedran, Toronto, Canada. 18. "The Areas of Anesthesia in Spinal Cord Lesions as a Guide to Localization," M. A. Starr, New York. 19. "A Study of the Seasonal Relations of Chorea and Rheumatism for a Period of Fifteen Years," Morris J. Lewis, Philadelphia. 20. "The Significance of Intermission in Functional Nervous Diseases," W. H. Thompson, New York.

THURSDAY, MAY 26th.

Morning Session (10 a. m.) — 21. "Misconception and Misnomers Revealed by Modern Gastric Research," Charles C. Stockton, Buffalo. 22. "The Production of Tubercular Breathing in Consolidation and other Conditions of the Lungs," Charles Cary, Buffalo. 23. "The Different Forms of Cardiac Pain," Samuel G. Chew, Baltimore. 24. "The Late Systolic Murmur," J. P. Nichols, Galesburg, Illinois. 25. "Tube Casts and their Diagnostic Value," L. N. Banforth, Chicago. 26. "Studies in Hypnotism," E. F. Westbrook, Brooklyn. 27. "Influenza, and some of its Present Aspects," Morris Longstreth, Philadelphia. 28. Concluding business.

The annual dinner of the Association will be held on the evening of Wednesday, May 25th, at eight o'clock, in the Arlington Hotel.

SUFFOLK DISTRICT MEDICAL SOCIETY.

ELECTION OF OFFICERS.

At the annual meeting, April 30, 1892, the following officers were elected for the ensuing year:

President, Edward N. Whittier; Vice-President, A. L. Mason; Secretary, James J. Minot; Treasurer, Edward M. Buckingham; Member of the Nominating Committee of the Massachusetts Medical Society, W. L. Richardson; Censors, H. L. Burrell, G. M. Garland, F. H. Davenport, H. F. Vickery, F. B. Harrington.

JAMES J. MINOT, M.D., *Secretary.*

SOCIETY NOTICES.

THE ASSOCIATION OF AMERICAN MEDICAL COLLEGES. — The third annual session of the Association of American Colleges will convene at the building of the Detroit College of Medicine, at 3 o'clock p. m., Wednesday, June 8, 1892. Dr. N. S. Davis, President of the Association, will read a paper upon the following subject: "To what Extent should Clinical Instruction be afforded the Student of Medicine in a Regular Course?" Another paper will be read by Prof. V. C. Vaughan, of the University of Michigan, as follows: "To what Extent should Laboratory Instruction be afforded the Student of Medicine in Regular Course?" Discussion on the papers will follow.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT, SECTION FOR OBSTETRICS AND GYNECOLOGY. — There will be a meeting of this Section at 19 Boylston Place, on Wednesday evening, May 11, 1892, at 8 o'clock.

Dr. E. W. Cushing will read "On the Methods and Complications of Vaginal Hysterectomy."

Dr. G. H. Washburn, "Tubal Pregnancy: A Case with Rupture, Operation and Recovery."

GEORGE HAVEN, M.D., *Secretary,*
92A Pinckney Street.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held on Monday, May 9th, 1892, at the Medical Library, 19 Boylston Place, at 8 o'clock p. m.

"A Peculiar Form of Nystagmus, with Remarks on its Causation and its Relation to Cheyne-Stokes Respiration," a paper prepared by Dr. W. N. Bullard, assisted by Dr. Wentworth.

"A Case of Congenital Cardiac Disease with Atalectasis; Recovery; Subsequent Sudden and Complete Premature Closure of Cranial Sutures, with Resulting Idiocy," a paper by Dr. H. W. Broughton.

G. G. SEARS, M.D., *Secretary.*

NORFOLK DISTRICT MEDICAL SOCIETY. — The annual meeting will be held at the Norfolk House, Eliot Square, Roxbury, Tuesday, May 10th, at 12.30 p. m.

The Board of Censors will meet at the same place at 12.45 p. m.

The examination of candidates will take place one week later, on Tuesday, May 17th, at 7 p. m., at the office of the secretary. The written examination will begin at 7 p. m., the oral at 8 p. m.

Dinner at 1.15 p. m.

Annual Address by Robert T. Edes, M.D.

Remarks by members.

JAMES C. D. PIGEON, M.D., *Secretary.*
130 Warren Street, Roxbury.

PRESBYTERIAN HOSPITAL APPOINTMENTS — APRIL 12, 1892.

Visiting Physicians. — Francis P. Kinnicutt, William P. Northup, Walter B. James.
Hospital Staff. — F. H. McMaster, second medical assistant; David Boraard, Jr., third medical assistant; Ernest Schultz, second surgical assistant; Ed. H. Bersing, third surgical assistant.

ERRATUM IN COLORED PLATE OF DR. KEEN'S RESECTION OF LIVER.

By error, in the colored plate illustrating Dr. W. W. Keen's case of resection of the liver in the *JOURNAL* of April 30th, the drawing is marked "natural size." It should have been "two-thirds of the natural size."

RECENT DEATH.

ISAAC G. PORTER, M.D., of New London, Conn., died April 30th, aged eighty-six years. He was a graduate of Yale College in the class of 1826, and received the degree of M.D. from the University of Pennsylvania in 1833. During the war he was post surgeon at Fort Trumbull.

Address.**REMARKS ON SPECIALISM.¹**

BY WM. OSLER, M.D., PRESIDENT,
Professor of Medicine in the Johns Hopkins University, Baltimore.

GENTLEMEN: First, let me express my gratitude for your kindness in conferring upon me the honor of your Presidency — an honor enhanced by the standing and character of the men who have previously occupied this chair. To have selected as your presiding officer one whose work has lain in the wide field of general medicine, is an indication that you duly appreciate the relation of the special subject in which we are now interested, and to which this Society is devoted. The diseases incident to infancy and childhood are so varied, covering every department of internal medicine, as well as of surgery, that the broad distinctions emphasized by the names physician and surgeon suffice to characterize us, and happily we have not as yet been stamped with a distinctive appellation, under which so many of our colleagues in other lines labor. In the extraordinary development of modern medicine limitation in work is inevitable, and although as practitioners and teachers we are all necessarily interested, to some degree, in the diseases of children, there are among us those who find in them their chief occupation, and our Society is but an organized expression of a very natural desire to unite for the purposes of study.

On an occasion of this kind it seems best to me not to discuss any particular subject, but to deal with some problem of general interest, with bearings, however, upon our organization. In comparison with the older countries of Europe specialism may truly be said to be the most distinctive feature in the medical profession of America. And it may not be inappropriate to consider here a few of its advantages and disadvantages.

"That which has been is that which shall be." Medicine may be said to have begun with specialists. The Ebers Papyrus is largely taken up with the consideration of local diseases, and centuries later we find in Greece certain individuals treating special ailments; and Aristophanes satirizes a "rectum specialist" in a way not unlike our comic journals would "poke fun" at an oculist or an aurist. The tail of our emblematic snake has returned into its mouth; at no age has specialism been so rife. To follow its gradual development during the present century would take more time than is at my disposal, and would not be a profitable task. The rapid increase of knowledge has made concentration in work a necessity; specialism is here, and here to stay.

The advantages to the profession which followed this differentiation have nowhere been more striking than in this country, and the earnest workers in ophthalmology, gynecology, dermatology, and other branches have contributed largely to inculcate the idea of thoroughness, the necessity for which is apt to be lost sight of in the hurry and bustle incident to the growth of a nation. Better work is done all along the line: a shallow diffuseness has given place to the clearness and definiteness which comes from accurate study in a limited field. The day has gone by for Admirable Crichtons, and although we have a few

notable illustrations in our ranks of men who have become distinguished authorities in eye and skin diseases, and upon syphilis without sacrificing their interests in general surgery, such are necessarily rare, and, unfortunately, from the very circumstances of the case likely to become more uncommon. Then how comforting to the general practitioner is the wise counsel of the specialist. We take him a case that has puzzled and annoyed us, the diagnosis of which is uncertain, and we consult in vain the unwritten records of our experience and the printed records of our books. He labels it in a few minutes as a coleopterist would a beetle, and we feel grateful for the accuracy of his information and happy in the possession of the label. And if sometimes (standing like Aaron between life and death) he illuminates too brightly the darkness of our ignorance, are we not as often beholden to him for gentle dealing?

It is almost unnecessary to remark that the public, in which we live and move, has not been slow to recognize the advantage of a division of labor in the field of medicine. The desire for expert knowledge is, however, now so general that there is a grave danger lest the family doctor should become, in some places, a relic of the past. It must indeed be a comfort to thousands to feel that in the serious emergencies of life, expert skill, is now so freely available. Perhaps, as specialists, no class in our profession has been more roundly abused for meddlesome work than the gynecologists, and yet what shall not be forgiven to the men, who, as a direct outcome of the very operative details which have received the bitterest criticism, have learned to recognize tubal gestation, and are to-day saving lives which otherwise would inevitably have been lost? I have known Forman to show in one year at the Philadelphia Pathological Society, ten or twelve examples of ruptured tubal pregnancy obtained in medico-legal work (sudden deaths) in that city. The benefits which the public reap from specialism may be gathered from the fact that in a not much longer period of time I have seen seven specimens of tubal gestation, not removed by the pathologist, but by the gynecologist, with the saving of five lives. The conservatism, which branded ovariotomists as butchers and belly-rippers, is not yet dead among us, and I say it frankly, to our shame, that it has not always been professional encouragement which has supported the daring advances on special lines. Humanity owes a great debt of gratitude to the devoted men who have striven during the past half-century for exactness in knowledge and for its practical application in all departments, a debt too great to pay, too great, one sometimes feels, even to acknowledge.

Specialism is not, however, without many disadvantages. A radical error at the outset is the failure to recognize that the results of specialized observation are at best only partial truths, which require to be correlated with facts obtained by wider study. The various organs, the diseases of which are subdivided for treatment, are not isolated, but complex parts of a complex whole, and every day's experience brings home the truth of the saying, "when one member suffers all the members suffer with it." Plato must have discussed this very question with his bright friends in the profession, — Eryximachus, perhaps, — or he never could have put the following words in the mouth of Socrates: "I dare say that you may have heard eminent physicians say to a patient who comes to them with

¹ Made at the opening of the Fourth Annual Meeting of the Pediatric Society, Boston, May 2, 1892.

bad eyes, that they cannot cure the eyes by themselves, but that if his eyes are to be cured, his head must be treated; and then again they say that to think of curing the head alone and not the rest of the body also, is the height of folly. And arguing in this way they apply their methods to the whole body, and try to treat and heal the whole and the part together. Did you ever observe that this is what they say?² A sentence which embodies the law and the gospel for specialists.

A serious danger is the attempt to manufacture rapidly a highly complex structure from ill-seasoned material. The speedy success which often comes from the cultivation of a specialty is a strong incentive to young men to adopt early a particular line of work. How frequently are we consulted by sucklings in our ranks as to the most likely branch in which to succeed, or a student, with the brazen assurance which only ignorance can give, announces that he intends to be a gynecologist or an oculist. No more dangerous members of our profession exist than those born into it, so to speak, as specialists. Without any broad foundation in physiology or pathology, and ignorant of the great processes of disease no amount of technical skill can hide from the keen eyes of colleagues defects which too often require the arts of the charlatan to screen from the public.

In the cultivation of a specialty as an *art* there is a tendency to develop a narrow and pedantic spirit; and the man who, year in and year out, examines eyes, palpates ovaries, or tunnels urethra, without regard to the wider influences upon which his art rests, is apt, insensibly perhaps, but none the less surely, to acquire the attitude of mind of the old Scotch shoemaker, who, in response to the Dominie's suggestions about the weightier matters of life, asked, "D'ye ken leather?" There is not a single department, the study of which does not carry with it the correction of this most lamentable tendency. Problems in physiology and pathology touch at every point the commonest afflictions, and exercised in these, if only in the early years of professional life, the man is chastened, so to speak, and can never, even in the daily round of the most exacting practice, degenerate into a money-making machine. And let the younger of my hearers lay this to heart: scan the lives of say twenty of the men most prominent in special lines of medicine and surgery to-day in this country, and you will find, with scarcely an exception, the early years devoted to anatomical, physiological, or pathological studies. They rose high because the foundations were deep. The most distinguished oculists have been men trained in physiology and pathology; and some, like Sir Wm. Bowman, have had reputations so pre-eminent in several departments that the identity of the physiologist has been lost in the ophthalmologist.

In the larger cities the work of the specialist encroaches more and more upon that of the general practitioner, and this condition, though in many ways to be regretted, is not likely to be changed. I have known the head of a household pay, in the course of a year, for the professional services of six physicians—a gynecologist, an oculist, a laryngologist, a dermatologist and a surgeon. What remained after this partition of the general practitioner came in sixth and looked after the health of the children. It is interesting to note that to this one pertains the functions to a large extent

of the old family doctor, and further advice is usually sought through him or at his suggestion. In the evolution of the specialist, the children's doctor is the last to appear, not because of any extreme differentiation, but rather he is a vestigial remnant of what was formerly in cities the general practitioner. May I not say that there are members of our Society whose interest in their work is largely due to this new feature in domestic life? In the division of the household among our brethren, the children alone remain, and fortunately their ailments are too diversified to allow much specialization.

After all, though specialism is rife, and has so carved the "body of physic" that Hippocrates would scarcely recognize it, and though its sounds go out loudly and echo through the journals and society reports, nevertheless, I would boldly make claim for a wider diffusion of its benefits. Of dwellers in cities arrogance is a peculiar trait, and we discuss problems in a "surely-we-are-the-people" style, forgetting that outside lie the greater millions equally precious to *Asclepius*, and under the care of men who cannot specialize, who must be able to set fractures, perform version, treat iritis as well as fever, earache as well as the itch. What of the benefits of specialism to this larger class from whose ranks the cities are replenished and whose health is so essential to the nation? The out-door department of our hospitals and the consulting-rooms of city physicians tell of the necessity of special knowledge to these people, particularly in emergencies and in the graver and more unusual forms of disease; but those who thus avail themselves form but a fraction of the numbers who require technical skill for the purposes of diagnosis or treatment. Very little additional knowledge enables the general practitioner to grapple with a large proportion of the cases which in cities come under the care of the specialist. The question resolves itself into one of education. It is impossible in three sessions to bring men beyond the superficial routine, but in a more prolonged course—as I know from experience—the student can be taught practically, in the wards and dispensaries enough of the technique of the specialist to give, at least, a foundation upon which to work. He should leave the schools knowing the practical application of the microscope, the ophthalmoscope and the laryngoscope, and in these and other lines he should have proceeded to the stage in which he recognizes the limitations of his knowledge. Such a man, in general practice, should know a "choked-disk"; the examination for tube-casts should be a familiar, every-day task; and he should be able to tell whether a vocal chord was paralyzed. A serious obstacle to this happy consummation—which can be reached in a well-ordered system of education—is the absence, in the early years of practice, of material upon which to freshen the memory and to "keep the hand in"; but the man who, as a student, has reached a certain point always retains some measure of the old facility. The post-graduate schools have done much to enable men to revive, and to acquire, technical skill, and have been of great service in generalizing special knowledge. In the practice of a good, all-round man, the number of cases demanding the help of a specialist is, after all, not great. The ordinary run of nervous disorders should be recognized, adenoid vegetations he would treat with the skill of a laryngologist; he would know enough not to tinker with a case of glaucoma; and though he might not diagnose a pus-tube from

² Charmides: Jowett's translation.

tubal gestation, he would (in this as in other details) have learned to know his limits and be ready to seek further advice.

With the revival and extension of education the benefit of specialism will become more widespread, and to this end the efforts of colleges and hospitals should be directed.

The organization of societies for the study of particular diseases has been of late a very notable feature in the professional life of this country. Since the foundation of the Ophthalmological Society, more than a dozen associations have been formed, and their union in a triennial congress has proved a remarkable success. These societies stimulate work, promote good-fellowship, and aid materially in maintaining the standard of professional scholarship. They are nearly all exclusive bodies, limited in membership, and demanding for admission evidence of special fitness. This point is sometimes urged against them; but the members exercise no arbitrary privilege in asking of candidates familiarity with the subject, and evidence of ability to contribute to the general store of knowledge. In some of the specialties these societies have been particularly useful in disciplining men who have traduced, not the code, but the unwritten traditions of our craft, acting as if they were vendors of wares to be hawked in the market-place.

Our own Society may be regarded as the outcome of a notable revival, during the past few years, of interest in the study of the diseases of children. The existence of a special journal devoted to pediatrics, and the successful issue of a large cyclopedia of the diseases of children testify to the appreciation on the part of the profession of the necessity for the more accurate study of this branch. This body offers to men who are working and teaching in pediatrics are opportunity of knowing each other, of discussing subjects of common interest, and through the medium of their publications making general the more special details of value in practice. The programme before you indicates clearly that we are all workers in general medicine; and may the character of the papers and the discussions be the best justification of the existence of an organization devoted to the study of a particular section in that field.

RENAL ALBUMINURIA NOT DUE TO ORGANIC DISEASE OF THE KIDNEYS.¹

BY EDWARD S. WOOD, M.D.,
Professor of Chemistry in Harvard Medical School.

It has been my experience during the last twenty years to examine the urine in numerous cases of transient albuminuria of renal origin, as shown by the presence in the sediment of renal casts. In most of these it has naturally been impossible to follow out the cases to the complete disappearance of the albumin and casts, since most patients do not have an examination of the urine made after they feel that recovery has taken place. In very many of them, however, I have been able to make repeated examinations, and have known the albumin and casts to disappear, even in some cases which had been pronounced to be those of chronic Bright's disease.

Transient albuminuria is exceedingly common, and frequently occurs in persons who are apparently in perfect health, so that it often happens that it is only detected when an application is made for a policy in some life insurance company. In many cases the diagnosis of Bright's disease is made intentionally or accidentally; and it is to the recovery of such cases after taking some of the so-called "kidney cures," that these nostrums have obtained their popularity.

I do not propose to consider all of the causes of albuminuria included in the above title, since most of them are so universally recognized, and have been so well treated of in other places, that they are always borne in mind, and there is no danger of their being overlooked in cases in which traces of albumin are found in the urine. I refer, for instance, to the familiar classes of cases, in which transient albuminuria accompanies ordinary acute febrile diseases with high temperature (one exceptional class of cases will be mentioned), or cases of permanent albuminuria due to organic diseases which produce obstruction to the venous circulation, such as organic heart and liver diseases, or abdominal tumors which exert pressure on the abdominal vessels. Nor, as the title of my paper implies, shall I refer to renal albuminuria due to organic disease of the kidneys, nor to non-renal albuminuria, such as is due to hemorrhage or suppuration caused by diseases of the urinary mucous membranes below the kidneys, or of the genito-urinary membranes.

The cases which I do wish to consider are those due to causes which, although generally recognized, are not so apt to be borne in mind, and those in which, when the quantity of albumin reaches a decided trace, an erroneous diagnosis is liable to be made.

I think we may consider that, clinically, all cases of renal albuminuria, not due to organic disease of the kidneys, may be arranged in one of the three following classes:

I. Those due to some general disease or disturbance (not renal) which causes some change in the renal circulation.

II. Those due to irritation of the kidneys, which irritation may be general, as in the case of the chemical (or dissolved) irritants, or circumscribed, as in the case of some mechanical irritants, such as concretions in the substance of the kidneys.

III. Those due to some change in the composition of the blood.

The duration of the albuminuria naturally varies with the cause. It may be permanent, as when due to organic disease of some other organ, in which case the kidneys themselves may, after a long time, become affected with some form of organic disease, or it may be temporary, lasting for a longer or shorter time according to the cause.

I. In the first class, due to some interference with the renal circulation, we may include:

(1) The febrile albuminuria which is invariably seen in acute diseases attended with high temperature. In these cases the quantity of albumin is usually only the very slightest trace, which with the accompanying casts, entirely disappears as soon as, or very shortly after, convalescence begins. In rare cases in ordinary acute diseases the quantity of albumin may become quite large and the renal casts very numerous, so that from a single examination, it may be impossible to say whether acute nephritis has been superadded to

¹ Read at the Boston Society for Medical Observation, February 1, 1892.

the other febrile affection or not, as the following case will illustrate:

CASE I. A young adult male, suffering with typhoid fever.

December 29th. Urine had a specific gravity 1017. Quantity of albumin, large trace (nearly one-fourth per cent.). Sediment: free blood and renal epithelium; numerous hyaline, granular, blood and epithelial casts; an occasional fibrinous cast; and an occasional cast with a few oil-globules adherent.

December 30th. Quantity of urine, fifty-six fluid ounces, specific gravity, 1014. Albumin, slight trace. Character of the sediment the same as yesterday, except the number of casts decidedly smaller.

January 8th. Specific gravity, 1008. Albumin, very slight trace. Sediment: little free blood and renal epithelium; few hyaline and granular casts, some with blood and renal cells adherent; many of the casts of large diameter.

January 18th. Specific gravity, 1019. Albumin, slightest possible trace. Sediment, less in quantity but of the same character as on the 8th.

January 29th. Specific gravity, 1014. Albumin, slightest possible trace. Sediment: very few hyaline and finely granular casts; few blood globules; slight excess of renal cells.

March 5th. Specific gravity 1025. Albumin, absent. Sediment, amorphous urates and uric acid.

In this case the diagnosis of Bright's disease was actually made by one or more medical friends of the patient in another city, to whom my first analysis was shown.

I have met with a few of these exceptional cases of severe albuminuria occurring during the progress of ordinary febrile diseases, and it is interesting to note the rapidity with which the albumin diminishes to the very slightest trace. The quantity of albumin remains a large trace (from one-eighth to one-fourth per cent.) only for a day or two, then diminishes very rapidly to a very slight trace, but does not disappear entirely usually for several weeks, until the renal epithelium has been restored.

(2) Disturbances of the renal circulation due to nervous diseases, such as delirium tremens, acute mania, and the like. Albuminuria is so common in these cases that no illustrations are necessary.

(3) Passive hyperaemia of the kidneys, due to certain organic diseases of the heart and liver, to the pressure of abdominal tumors, etc.

(4) Almost any serious disease, wherever located, tends to produce secondary effects upon the kidneys, which result in albuminuria and the presence of casts in the sediment. These effects may be due to a simple disturbance of the circulation from pressure, as in the case of some tumors, or through the action of the nervous system, or they may be due to the diminished or modified metabolism resulting in an increased formation of calcic oxalate or uric acid, which will locally irritate the kidneys when separated from the urine within the renal tubules. In all of these cases of renal albuminuria secondary to serious disease elsewhere, the quantitative analysis of the urine will show the diminution of the metabolism, which, other things being equal, will be in proportion to the gravity of the principal affection. In these cases the urine as a whole (the mixed twenty-four-hour urine) does not resemble that of any of the organic diseases of the kidney, although it is in some cases very difficult and

sometimes impossible to diagnosticate them from an organic renal disease, if we only have a single specimen to examine.

(5) Albuminuria of adolescence. In this class is also usually arranged the albuminuria of adolescence, on the theory that there is at about the age of puberty, or a little earlier, a slight physiological hypertrophy of the heart. In my opinion, however, in many cases another element must be considered, namely, that of local renal irritation by a very concentrated condition of the urine, or by the separation of crystalline substances (particularly uric acid and calcic oxalate) from the urine within the renal tubules.

The following cases would usually be classed among cases of albuminuria of adolescence:

CASE II. Female child, aged thirteen.

March 21st. Specific gravity 1023. Albumin, very slight trace. Sediment: an occasional hyaline, granular and epithelial cast; excess of renal cells; an occasional blood-globule, free and adherent to casts.

April 4th. Specific gravity 1027. Albumin, very slight trace. Sediment: excess of renal cells; few blood-globules; an occasional small hyaline cast mostly with renal cells and blood-globules adherent; uric acid and calcic oxalate crystals.

April 11th. Specific gravity 1015. Albumin, very slight trace. Sediment: few blood-globules; an occasional hyaline cast.

May 1st. Specific gravity 1008. Albumin, slightest possible trace. Sediment: an occasional blood-globule; vaginal epithelium; no casts detected.

May 6th. Specific gravity 1010 $\frac{1}{2}$. Albumin, slightest possible trace. Sediment: an occasional blood-globule and renal cell; no casts detected.

June 7th. Specific gravity 1018. Albumin, very slight trace. Sediment: little calcic oxalate and an occasional hyaline cast, and blood-globule.

January 29th. Specific gravity 1021. Albumin, absent. Sediment: nothing abnormal.

CASE III. Boy, aged thirteen.

February 20, 1885. Specific gravity 1017 $\frac{1}{2}$. Albumin, very slight trace. Sediment: little blood; excess of renal cells; an occasional granular cast.

February 27th. Specific gravity 1022. Albumin, very slight trace. Sediment: little blood; excess of renal cells; hyaline and finely granular casts, mostly with blood and renal cells adherent.

April 16th. Specific gravity 1013. Albumin, very slight trace. Sediment: hyaline and granular casts, of medium diameter, some with granular renal cells adherent.

April 25th. Specific gravity 1017 $\frac{1}{2}$. Albumin, slight trace. Sediment: numerous hyaline casts, with renal cells adherent; uric acid. The casts mostly of medium diameter.

July 21st. (Fever turn.) Specific gravity 1025. Albumin trace. Sediment: uric acid; calcic oxalate; few hyaline casts; an occasional epithelial and blood cast. The casts of medium and large diameter.

November 12th. Specific gravity 1025. Albumin, trace. Sediment: calcic oxalate; hyaline casts, mostly large, and some with renal cells adherent; free granular renal epithelium.

August 10, 1886. Specific gravity 1024. Albumin, very slight trace. Sediment: little blood; calcic oxalate; an occasional large hyaline cast with renal cells and blood adherent.

October 8th. Specific gravity 1030. Albumin,

absent. Sediment: amorphous urates; little calcic oxalate.

February 2, 1887. Specific gravity 1020. Albumin, very slight trace. Sediment: calcic oxalate; little blood and excess of renal epithelium; an occasional hyaline and finely granular cast with blood and renal cells adherent; an occasional calcic oxalate cast.

July 16th. Specific gravity 1022. Albumin, absent. Sediment, nothing abnormal.

January 7, 1888. Specific gravity 1025 $\frac{1}{2}$. Albumin, absent. Sediment, uric acid.

July 29, 1890. Specific gravity 1025. Albumin, slightest possible trace. Sediment: calcic oxalate; an excess of renal cells; an occasional blood-globule; an occasional hyaline cast with few blood-globules and renal cells adherent.

August 5th. Specific gravity 1020. Albumin, slightest possible trace. Sediment, same as July 29th.

August 25th. Specific gravity 1020. Albumin, absent. Sediment, nothing abnormal.

February 13, 1891. Specific gravity 1028. Albumin, absent. Sediment, nothing abnormal.

(6) Normal albuminuria, so-called, or the albuminuria which appears in perfectly healthy individuals at certain times, such as after strenuous exertion, as in the case of soldiers after a fatiguing march, is also naturally arranged in this class. In these cases, the albuminuria lasts for an hour or two only, and, so far as I know, is never accompanied with casts in the sediment.

II. Renal irritation.

This class includes, I think, by far the largest number of cases, since it may be produced by so many different causes, and is so frequently seen in persons apparently in perfect health. It is in these cases most frequently that the albuminuria is first discovered by the life insurance examiner, since the patient, as a rule, has no other reason for consulting a physician, or having his urine examined.

Renal irritation may, according to the cause which produces it, be very mild, and last for a very long time before it is detected and its cause removed, or it may be very severe, producing a catarrhal nephritis, which may become a regular acute nephritis.

The most common causes of renal irritation are: (1) a very concentrated condition of the urine. (2) The action of chemical (or dissolved) irritants, which include some of the abnormal constituents of the urine, (a) sugar, (b) bile, (c) the irritating products of scurbita, diphtheria, and the like, and (d) numerous irritating drugs and poisons, such as cantharides, arsenic, salicylic acid, salol, and many others. (3) Mechanical irritants, such as crystals and concretions of uric acid, urates, calcic oxalate, cystin, etc. We often see two or more of these causes acting at the same time. Especially are we apt to have a very concentrated condition of the urine associated with one or more of the other irritants.

(1) Concentrated urine may be caused by errors in diet, both of omission and commission, and if a person habitually possesses a very concentrated urine, he is apt to have albuminuria accompanied by renal casts in the sediment. I see this form of renal albuminuria in apparently healthy persons more commonly than any other. Very frequently my students consult me about themselves, they having detected albumin while testing their own urine in the laboratory, and I usually find that the students having albuminuria are habitually

passing only about 800 or 900 cubic centimetres of urine of a specific gravity of 1028 to 1032. In those cases where I have made an examination of the sediment I have found a few casts, an excess of renal cells, and a few blood-globules both free and on the casts. This condition may be brought about by drinking too little — a habit which is easily acquired — or by over-eating and, at the same time, not taking enough water to properly dissolve the products formed, thereby overworking and irritating the kidneys.

The following cases will illustrate this form of albuminuria:

CASE IV. May 7, 1889. Specific gravity 1034. Albumin, slightest possible trace. Sediment: large excess of mucus; an occasional blood-globule; excess of renal cells, some of which are slightly fatty; an occasional hyaline and granular cast, most of which have an occasional renal cell, blood and oil globule adherent.

CASE V. Adult male. "Frequent micturition."

December 2d. Specific gravity 1029. Albumin, very slight trace. Sediment: excess of renal cells; few blood-globules; an occasional small hyaline cast with blood globules and renal cells adherent.

CASE VI. Rejected by life insurance examiner.

April 3d. Specific gravity 1030. Albumin, slightest possible trace. Sediment: excess of renal cells; few blood-globules; few casts, mostly of small diameter and with blood and renal cells adherent.

CASE VII. Male adult.

May 26, 1888. Specific gravity 1026. Albumin, very slight trace. Sediment: slight excess of renal cells; few blood-globules; an occasional hyaline and granular cast, some with blood and renal cells adherent.

November 8, 1889. Specific gravity 1027. Albumin, slightest possible trace. Sediment: excess of renal cells; an occasional small hyaline cast with renal cells adherent.

May 30, 1891. Specific gravity 1027. No albumin or casts.

As is well known, such a concentrated condition of the urine favors the deposition of crystalline sediments, which, if the separation occurs within the tubules, aids mechanical irritation to that of the concentrated urine, as the following case shows:

CASE VIII. Male adult.

March 12th. Specific gravity 1022. Albumin, slight trace. Sediment: calcic oxalate; acid sodium urate; an occasional finely granular cast; spermatozoa.

March 25th. Specific gravity 1016. Albumin, slight trace. Sediment: an occasional blood-globule, only one cast with blood, and renal cells detected after prolonged search.

June 28th. Specific gravity 1025. Albumin, slightest possible trace. Sediment: spermatozoa, prostatic shreds; few blood-globules. No casts.

October 5th. Specific gravity 1027. Albumin, slightest possible trace. Sediment: prostatic shreds; an occasional blood-globule; spermatozoa. No casts.

October 25th. Specific gravity 1015. Albumin, absent. Sediment, only a few secondary calcic oxalate crystals.

In all cases in which the renal irritation is chiefly due to concentrated urine, it soon subsides on diluting the urine to the normal quantity and specific gravity, and the albumin and casts gradually disappear.

(2) Chemical irritants.

(a) A urine containing a large percentage of sugar

probably acts in the same way as a concentrated urine in producing renal irritation. The following case illustrates this:

CASE IX. Adult, male.

November 5, 1888. Specific gravity, 1033. Sugar, 6½ per cent. Albumin, very slight trace. Sediment: excess of renal cells; an occasional blood-globule; few hyaline casts, some with blood and renal cells adherent.

May 24, 1889. Specific gravity, 1043. Sugar 11.4 per cent. Albumin, very slight trace. Sediment: same as above, and also few uric acid and calcic oxalate crystals.

May 25th. Specific gravity, 1037. Sugar, 7.7 per cent. Albumin and sediment, same as last examination.

June 17th. Specific gravity, 1028. Sugar, trace. Albumin, absent. Sediment, uric acid and spores.

June 20th. Specific gravity, 1023. Sugar, trace. No albumin or abnormal sediment.

October 1st. Specific gravity, 1023½. No sugar, albumin or abnormal sediment.

The following year, owing to neglect in diet, both the sugar and renal irritation reappeared.

(b) Jaundiced urine of more than a few days duration always produces more or less irritation of the kidneys. I have never examined a jaundiced urine, even in cases of simple catarrhal duodenitis, which had lasted for more than a few days without being able to detect a slight trace of albumin, and in the sediment, renal cells stained with bile-pigment, a few blood-globules, and casts with renal cells and blood adherent. If the jaundice be prolonged for a long time, it may produce marked pathological changes in the kidneys, as in one case in which the jaundice was due to a malignant growth of the pancreas, which gradually encroached upon the bile-duct. The urine was perfectly free from albumin and casts before the jaundice; these appeared in the urine, however, a few days after the patient became jaundiced, and continued until death, which occurred some weeks later. On examination of the kidneys after death, Dr. W. W. Gannett found a glomerulo-nephritis.

(c) The albuminuria of scarlatina, and the like, need only to be mentioned.

(d) The following cases illustrate renal irritation due to some of the more common drugs and poisons:

CASE X. Male adult, three weeks after a poisonous dose of arsenic.

March 2, 1891. Specific gravity, 1013. Albumin, slight trace. Sediment: excess of renal cells; few blood-globules; few hyaline and granular casts with blood and renal cells adherent.

CASE XI. Adult, female, three weeks after a poisonous dose of arsenic.

March 2, 1891. Specific gravity, 1014. Albumin, slight trace. Sediment: amorphous urates; uric acid; excess of renal cells some of which are fatty; hyaline, granular and epithelial casts, some with blood and oil globules adherent.

CASE XII. Adult, male, ten days after a poisonous dose of Paris green.

November 12, 1891. Specific gravity, 1029. Albumin, slightest possible trace. Sediment: excess of renal cells; an occasional blood-globule; an occasional hyaline cast with renal cells and blood adherent.

CASE XIII. Adult, female, after therapeutic use of bromide of arsenic.

March 27, 1890. Specific gravity, 1014. Albumin, slightest possible trace. Sediment: excess of renal cells; an occasional blood-globule; an occasional small cast with few blood-globules and renal cells adherent. (Drug omitted.)

April 11th. Specific gravity, 1017. Albumin, slightest possible trace. Sediment: uric acid; an occasional blood-globule; an occasional hyaline and epithelial cast.

April 24th. Specific gravity, 1027. No albumin. No abnormal sediment.

May 8th. Specific gravity, 1016. No albumin. No abnormal sediment.

I have seen similar results after taking Fowler's solution.

CASE XIV. Adult, female, chronic arsenic poisoning.

March 17, 1890. Specific gravity, 1021. Albumin, slightest possible trace. Sediment: excess of renal cells; an occasional blood-globule; an occasional cast with blood and renal cells adherent.

March 6, 1891. Specific gravity, 1012. No albumin. No abnormal sediment.

I have seen numerous cases of renal irritation due to chronic arsenic poisoning.

CASE XV. After therapeutic use of salicylic acid.

February 10th. Specific gravity, 1019. Albumin, trace. Sediment: numerous hyaline, granular and epithelial casts; most of the casts have few adherent blood-globules; free renal cells and blood-globules.

CASE XVI. After therapeutic use of salol.

May 26th. Specific gravity, 1022. Color, black. Albumin, slight trace. Sediment: chiefly blood-globules; excess of renal cells; few brown, granular casts, some with blood and renal cells adherent.

(3) Mechanical irritants, of which the principal ones are uric acid and urates, calcic oxalate and cystin, act by being separated from the urine in crystalline form within the renal tubules, the lining membrane of which they may irritate by their sharp angles and points. Aggregations of these crystals with mucus and blood may become lodged in the tubules, increase in size by the deposition of other crystals upon their surface mixed with blood, mucus and débris of cells, and thus form a renal concretion, which may cause a permanent circumscribed irritation or inflammation, and consequently permanent albuminuria. This form of albuminuria requires no illustrative cases.

III. Blood diseases. The albuminuria due to changes in the composition of the blood is also accompanied by the presence of renal casts in the sediment. These are almost always pure hyaline in their character, unless the blood-pigment is also separated by the kidneys, in which case we find in the sediment brown-granular casts and brown amorphous matter, as in cases of hemoglobinuria.

I have by no means attempted to exhaust the list of the causes of renal albuminuria, but merely to call attention to some of the very common ones, most of which are readily amenable to treatment, and which so frequently fall into the hands of charlatans who pronounce the case one of Bright's disease.

THE Great Charité Hospital, where most of the university clinics and special institutes for teaching and research in Berlin are housed, is about to be rebuilt on a new site.

**THE WOUNDED OF THE WOUNDED KNEE
BATTLEFIELD, WITH REMARKS ON WOUNDS
PRODUCED BY LARGE AND SMALL CALIBRE
BULLETS.¹**

BY CHARLES B. EWING,
Captain and Assistant Surgeon, U. S. A.

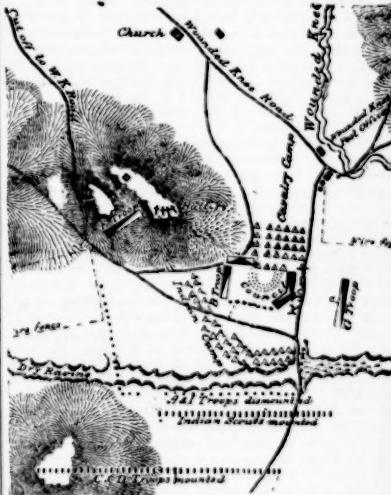

THE Great Sioux Indian War of 1890 has been fought so often that I feel an apology is necessary for inflicting it upon you on this occasion, but, while much has been said of the combatants, little has been written of the casualties of which this paper will treat.

The causes which led to this sanguinary hostility are, in brief, "the failure of the government to fulfil its obligations," and the Messiah delusion, together with a determination of the hostile Sioux not to surrender their arms to the government; this latter more particularly led to the Wounded Knee affair.

The theatre of war was located in South Dakota, and especially that part known as the Pine Ridge Indian (Ogallala Sioux) Reservation, situated in the southern part of the State mentioned. I cannot do better than to quote from the annual report of that very gallant and able soldier, Major-General Nelson A. Miles, regarding his disposition of troops. He says: "Seven companies of the Seventh Infantry, under Colonel Merriam, were placed along the Cheyenne River to restrain the Indians of that reservation, and intercept those from Standing Rock. In the meantime, a force had been gathered at the Rosebud and Pine Ridge agencies. Those at the Rosebud, under the command of Lieutenant-Colonel Poland, were composed of two troops of the Ninth Cavalry and battalions of the Eighth and Twenty-First Infantry; Colonel Shafter, with seven companies of the First Infantry controlled the country to the south and west of the Rosebud agency, with station at Fort Niobrara; those at Pine Ridge agency, under the immediate command of General Brooke, were eight troops of the Seventh Cavalry, under Forsyth; a battalion of the Ninth Cavalry, under Major Henry; a battery of the First Artillery, under Captain Capron; a company of the Eighth Infantry and eight companies of the Second Infantry under Colonel Wheaton. West from Pine Ridge agency was stationed a garrison of two companies under Colonel Tilford of the Ninth Cavalry; north of that, with headquarters at Oelrichs, was stationed Lieutenant-Colonel Sanford of the Ninth Cavalry, with three troops, one of each from the First, Second, and Ninth Cavalry; north of that, on the line of the railroad at Buffalo Gap, Captain Wells, with two troops of the Eighth and one troop of the Fifth Cavalry, was stationed; north of that, on the same railroad at Rapid City, Colonel Carr of the Sixth Cavalry, with six troops, was in command; along the south fork of the Cheyenne River, Lieutenant-Colonel Offley, and seven companies of the Seventeenth Infantry; and to the east of the latter command, Lieutenant-Colonel Sumner, with three troops of the Eighth Cavalry, two companies of the Third Infantry, and Lieutenant Robinson's company of scouts. Small garrisons were also stationed at Forts Meade, Bennett, and Sully. Most of the force was placed in position between the large hostile camp in the Bad Lands, which had gathered under Short Bull and Kicking Bear, and the scattered settlers endangered by their presence. As the line under Colonel Carr was considered the most liable to be

brought in contact with the hostile force, the division commander established his temporary headquarters at Rapid City, S. D., where this force was in close communication, and from which their movements could be directed with the least delay."

Everything indicated a peaceful settlement of affairs, when the well-laid plans of Major-General Miles looking to an early and amicable adjustment of trouble were suddenly "frustrated" by the lamentable occurrence at Wounded Knee Creek on the morning of December 29th. The opposing forces were the following: the United States troops were eight troops, Seventh Cavalry; Light Battery E, First Artillery, and Company A, Indian Scouts, making a total of 470 fighting men, under the command of Colonel Forsyth, Seventh United States Cavalry. The Indian war party consisted of 106 warriors and 294 women and children, all of the Minnecousjous Sioux, under Chief Big Foot.

This map is drawn on a scale of 300 yards to the inch. The figure at the lower left-hand corner of the Cavalry Camp shows the location of one-half of A and I troops.

So many descriptions of this unfortunate affair have been published that I shall limit myself simply to so much of an account as is to be found in the very brief and concise language of my report, made upon request, to the department commander, and in so doing, I ask pardon for using the personal pronoun to the extent that I do, but, inasmuch as a report of my personal services was desired, I was obliged to frame it in the following terms:

OFFICE OF ATTENDING SURGEON,
ST. LOUIS, Mo., June 23, 1891.

To the Adjutant-General, Division of Missouri, Chicago, Ill.
Sir:—Understanding that a report of my services at the battle of Wounded Knee is desired, I have the honor to submit the following:

The battle began at 9:30 A. M., December 29, 1890, and the troops withdrew from the field about 2 P. M., and

¹ Read before the Association of Military Surgeons of the National Guard, U. S., at St. Louis, April 19, 1892.

marched to Pine Ridge agency, reaching that point sometime between 9.30 and 10 o'clock that evening.

Lieutenant Kinzie, Second United States Infantry, Mr. James Asay, Indian trader at Pine Ridge agency, and myself, were seated in an open wagon within ten to fifteen feet of one end of the parallelogram of soldiers that surrounded the Minneconjous Sioux band under Big Foot.

Colonel Forsyth, Seventh United States Cavalry, was writing a communication which one of our party was to carry to General Brooke, commanding Department of the Platte, then at Pine Ridge agency, and while waiting for communication, the firing commenced. A volley came in our direction, the bullets whistling unpleasantly about us; our horses took fright, and, becoming uncontrollable, ran right across the line of fire, but were turned, and finally stopped near Louis Moosonee's store, about three hundred yards distant from the field of battle; we alighted, and I was then informed by Lieutenant Kinzie that he had been shot in the foot; after examination of the same, I immediately returned to the camp and bussed myself in the care of the wounded.

I did not think it a time for ceremony, hence dispensed with the formality of reporting for duty, and at once went to work. The work consisted principally of what is known as first aid to the wounded. The only exception being an operation of a plastic nature, when I replaced and stitched the severed nose of Mr. Wells, the interpreter, belonging to Lieutenant Taylor's command of Indian scouts. This was the only operation, if my memory serves me, that was performed on the field.

This first aid consisted in stopping hemorrhage; applying dressings to wounds; putting up fractures; giving stimulants; and allaying pain. Later it became necessary to redress many of the wounds, as is often the case, the first dressing being only temporary.

I accompanied Captain Edgerly's troop to a point about three miles to the west, where Captain Jackson was reported to be surrounded by hostile Brûlés. Truth forbids that I place this in the light of a medical service, and I freely confess that it was only after arriving at our destination that I was aware that I lacked everything in the way of dressings to render aid to the wounded in case of trouble; of course, much could be done in that regard by using the clothing and equipment of the men. My only excuse is that I went very suddenly, so quickly in fact that there was no time for obtaining dressings. It was in this way: I was standing on the brow of the hill watching the firing of the Hotchkiss guns and the barreling of the ridge, when Captain Edgerly's troop galloped past, and seeing a horse in the troop without a rider, I ran out and jumped in the saddle. I had provided myself with carbine and ammunition, hence was in good shape. It did not take us more than fifteen minutes to ride the three miles, and we were just in time to see the Indians disappear in the direction of Pine Ridge agency. After remaining about fifteen or twenty minutes, I suddenly remembered that I had absolutely nothing in the way of dressings, hence returned to camp with Lieutenant Brewer for the purpose of obtaining some, but learning that the command was to return immediately, I found my services would not be needed, hence did not obtain dressings as I intended doing.

Now, to sum up: I was on the field from 9.30 A. M. to about 4 P. M., at which hour we began our march back to the agency. Of that six and one-half hours, I am quite sure I spent two and one-half to three hours at the dressing station, and the same length of time superintending the removal of a part of the wounded and at least three-fourths of the dead, to which must be added about three-quarters of an hour taken up in accompanying Captain Edgerly's command and returning as stated above.

We consumed about five and one-half hours on the march to the agency, which was of necessity slow. I rode a horse (kindly furnished me by a troop commander), as did also Assistant Surgeons Hoff and Glennan. I did not render any medical service on the march, and think it quite unlikely that such could have been rendered efficiently, as darkness came on quickly and lights were not permitted

in the command. I was not called upon to render any aid by the surgeon officially in charge, and I fail to see, under the conditions, how the wounded could have been benefited further till arrival at division hospital. I would be failing in a proper appreciation of the work of my brother surgeons in this connection were I not to mention the very efficient and untiring services of Captain Van R. Hoff and Lieutenant Glennan, of the Medical Department, who labored unceasingly in ministering to the wounded. Upon arriving at Pine Ridge agency, the wounded were placed in that part of the divisional field hospital of which I was in charge. It was my duty to attend and redress some twenty of the wounded, which occupied my time till two o'clock the following morning.

Very respectfully, your obedient servant,

CHARLES B. EWING,
Captain and Assistant Surgeon, U. S. A.

Now, to the consideration of the casualties, which I shall separate into the killed and wounded; of the former we had one officer and twenty-nine men, a total of thirty.

The great majority were killed outright, the very few surviving a variable time from a few minutes to a few hours after the reception of their injuries. Captain Wallace, besides the fatal gunshot wound of the lower abdomen, received two cuts with a tomahawk or hatchet; one across the forehead just above the superciliary ridges, and the other conforming to the anterior two-thirds of the sagittal suture. In neither case did these cuts fracture the skull.

This officer's death, coming as it did in the heyday of his career, was indeed a "tragedy." No words of mine can portray the love and admiration in which he was held by his family, friends and brothers-in-arms.

"His life was gentle; and the elements

So mixed in him, that Nature might stand up

And say to all the world, 'This was a man.'"

The greater portion of the dead I saw had received two or more wounds. In order that you may clearly appreciate the treatment of the cases to be presented, I shall premise by stating that my knowledge of them dates from the battlefield, on the morning of December 29, 1890, and ended, so far as three-fourths of them are concerned, upon their transfer to Fort Riley, Kan., January 4, 1891; remaining in charge of those whose condition could not permit of transfer at that time, till a day or two later, on which date I was placed in command of a company of the Hospital Corps.

The wounded consisted of two officers, twenty-nine enlisted men, and one civilian interpreter, attached to the scouts. I shall classify the above, broadly speaking, according to the part of the body injured, leaving out of detailed consideration twelve cases of gunshot wounds, mostly of minor import, which did not come under my care.

In brief, then, we have gunshot wounds of the head, body, upper and lower extremities.

We will now consider the wounds as classified, taking up those of the Head, three in number:

CASE I. Private H. D., Troop A, Seventh Cavalry. Pistol-ball entered right side of face half an inch anterior to lower part of right meatus auditorius externus, passing transversely through bones of face and obtaining exit two and one-half inches anterior to lower part of lobule of left ear. Calibre of pistol not known, but from size of wound of entrance, think it about a .38. Discharge of blood from both ears, and persistent flow of saliva, the latter giving evidence of the wounding of Steno's duct. A violent cellulitis supervened, which

finally subsided under treatment, and he was in excellent shape when transferred.

CASE II. Gunshot wound of inferior maxilla. Quartermaster-Sergeant C. C., Seventh Cavalry. Ball entered left inferior angle of chin, passing transversely through body of inferior maxilla, with inclination downward, gaining exit at right inferior angle of chin, crushing and comminuting bone in its passage. Treatment consisted of removing broken particles of bone, with corresponding teeth; stitching the lacerated integument of chin; applying antiseptic dressings; felt splints and bandages to support chin. This man was doing as well as he could under the circumstances when transferred. I understand that he has since had false teeth and plate made.

CASE III. Incised wound of nose. Mr. W., Indian interpreter attached to Company E, Indian Scouts, had all that part of nose anterior to nasal bones slashed off with a knife in the hands of an infuriated Indian of Big Foot's band. The severed part was hanging by a mere shred and bleeding profusely. Fifteen minutes after reception of wound, I replaced nose, and held same in place with numerous silk stitches. This man immediately after the operation, took his Winchester and went at once to the skirmish line, and afterwards on our return to Pine Ridge agency, took his place in the advance with Lieutenant Taylor's Indian Scouts. I did not see Mr. W. for some days after operation, when I found good union, and removed stitches. This, if it can be so dignified, was the only operation performed on the field.

I now come to Gunshot Wounds of the Body. Under this heading we have five cases:

CASE I. Penetrating gunshot wound of chest. Private J. C., trumpeter Troop K, Seventh Cavalry. Ball entered two and one-half inches below and one inch from left nipple toward median line, passed transversely in straight line, gaining exit two and one-half inches below right nipple. No rise of temperature, and patient in good condition when transferred.

CASE II. Sergeant H. H., Troop A, Seventh Cavalry. Ball entered posterior surface of left chest, passed forward, coming out just internal to the left nipple. Besides the above, Sergeant H. suffered two additional gunshot wounds, one above and the other below left elbow. Pneumonitis supervened.

CASE III. Sergeant L., Troop I, Seventh Cavalry. Ball entered to right of sternum just below clavicle, passed backwards and outwards, obtaining exit at axillary line in the fifth intercostal space, where incision was made, and the ball removed, with pieces of blouse and fragments of undershirt. Pneumonitis followed.

In considering the treatment of the cases coming under this particular heading of Penetrating Gunshot Wounds of the Chest, I should like to mention the cases of one officer and two enlisted men, who suffered gunshot wounds of like character in an affair with Chiricahua Apaches at Chevelon's Forks, Ariz., July 17, 1882.

The treatment of all these cases was alike, with recoveries in all of them. It was as follows: thorough cleansing of wounds; application of corrosive sublimate solutions; iodoform powder dusted upon parts; antiseptic dressings just sufficient to cover each particular wound; then the application of collodion, sealing part "hermetically" or by what is known as primary occlusion; finally restraining the muscles of respiration by circular bandages of chest, and fixing arm of

side affected. I do not wish to place myself on record as treating all penetrating gunshot wounds in this way, but simply present my experience to your consideration for what it is worth. I am quite of the opinion that I should modify my treatment by substituting the plaster-of-Paris bandage, with the flannel roller, for the circular cotton bandages, to restrain the muscles of respiration.

This treatment by primary occlusion may seem very radical indeed, when such an authority as Ashurst says, "The vast majority of penetrating wounds of the chest are gunshot injuries, the exceptions incised or punctured wounds. Applying the ordinary principles of surgery, even to the exceptional group, nothing but absolute necessity would justify the complete closure of the wound." And again, "Surely the conditions of a wounded lung and thorax are unfitted for the experiment of closure." And further, "Nothing appears more repugnant to the principles of surgery than the attempt to close a bullet-track which, however it be placed, under its ordinary conditions must afford ample material to be discharged externally." I quote the above to present the other side of the question as well as my own. I think this kind of dressing for chest wounds would become very necessary, particularly where traumatic pneumonitis has been set up, which would preclude the constant change of dressings and the consequent exposure of the chest at those times. The consensus of opinion among military writers is that the least fatal injuries are those in which the projectile has passed entirely through the chest, being less injurious than those in which the bullet has lodged. While my cases are few, the results are certainly very satisfactory, when we consider that during the last two years of the war, the death from penetrating wounds of the chest reached almost 33 $\frac{1}{2}$ per cent.

CASE IV. Gunshot wounds of vertebrae, upper and lower extremity. Private —, Troop B, Seventh Cavalry, suffered four distinct gunshot wounds: one passing transversely through lumbar vertebrae from left to right, crushing and comminuting vertebrae and severely injuring the cord and its membranes, and finally lodging in the muscles of the right lumbar region; penetrating gunshot wounds of right and left arms below elbow-joints; and the fourth passing through left leg just above ankle joint. It would not be economizing fact very much to say that this man was literally shot to pieces. The bullet which I now exhibit, weighing 385 grs., was removed from the right lumbar region by simple incision, without anesthetic, immediately after his arrival in the divisional field hospital at Pine Ridge, and, as Nature had not moulded him to resist three ounces of lead in this form and method of distribution, he died shortly afterwards. The injuries of this soldier were so severe that it was hardly expected that he would survive the journey from the battlefield to the field hospital, sixteen miles distant.

CASE V. Gunshot wound in neighborhood of right inguinal region. Lieutenant H. H., Light Battery, Second Artillery, received gunshot wound (Winchester) of right side, ball entering just external to anterior superior spine of right ilium and passed downwards and inwards. This officer was in charge of a Hotchkiss gun some six hundred yards distant from a party of hostiles that had gained the shelter of a ravine, and who were beset upon two sides by the fire of carbines and upon the third by Hotchkiss guns.

The gun in charge of this officer was moved from its original position upon an eminence to lower ground, so that better range could be obtained, rendering the fire more effective. This was so successful that the Indians sought to silence this particular piece, resulting in the shooting of Lieutenant H. The ball was deflected from its original course, seemingly a fatal one, by a watch worn at the time and which was completely destroyed. I saw Lieutenant H. when shot on the field; he fell under my care that evening at the field hospital; and the same night or the following morning I examined and dressed his wounds, at which time the course of the ball had been fully determined. Having a great deal of work on my hands, I was glad when relieved of this case by another medical officer. I understand Lieutenant H. has so far recovered from his injury as to be able to perform duty.

Let us now consider Gunshot Wounds of the Upper Extremity.

Sergeant H. H., Troop I, Seventh Cavalry, was admitted to the field hospital, Pine Ridge agency, December 29th, from the field where I first saw him. Ball entered just external to coracoid process of scapula, passed through deltoid muscle, finally entering the head of humerus. Severe. This man was treated upon the expectant principle till his transfer to Fort Riley on January 6th, for the following reasons: no appreciable rise of temperature; complained very little of pain; was able to sit up and walk about to a certain extent. Treatment consisted of securing thorough drainage of wound; absolute rest by appropriate position and posterior splints of felt or plaster-of-Paris (I have forgotten which); antiphlogistic regimen; hypodermic administration of morphia when necessary.

I find myself well supported in the above treatment by Billroth, who declares against operative procedures, under like conditions, as follows: "As in cases of resections, you can have no control as regards the protective functions of the arm, especially when a large portion of bone is to be excised, it is always better for the patient to escape with an ankylosed joint, without resection, than to have a dangling joint after resection."

Von Langenbeck says: "If it be true that ankylosis of the shoulder-joint enhances the usefulness of the rest of the extremity, and especially of the hand, we would be obliged, in shot-injuries of the shoulder-joint, to constantly strive for the accomplishment of ankylosis. The presumption that ankylosis would bring about greater usefulness of the arm than could be had with a shoulder-joint even with limited motion, rests upon a fallacy, occasioned by neglect to take into consideration the various degrees of severity of shot-wounds of the shoulder-joint." The same author cites nine successful cases of shot-wounds of the shoulder-joint treated on the expectant plan, the patient in every case recovering, "completely with conservation of good motion of the arm." He further says: "It is certain that the results of the cases of conservative treatment of shot-wounds of the shoulder-joint above cited challenge greater attention to the side of conservative surgery."

Two of the cases under this heading were gunshot injuries in the neighborhood of the shoulder-joint, one of them made by a Winchester 38, and the other by a gun of larger calibre. Both cases were given complete rest by means of splints and position; drainage

of wounds; antiphlogistic regimen, and opium in cases of pain, which complaint was rare.

No symptoms up to the time of transfer to warrant operative interference. I am quite of the opinion, however, that if the temperature, pain, etc., had so indicated, I should at once have made an exploratory incision, and an exsection or amputation, according to the conditions in each particular case; but up to the time of transfer to Fort Riley, there occurred nothing to warrant such procedure.

Gunshot Wound of Upper Extremity.

Lieutenant G., Troop G, Seventh Cavalry, received a shot which entered olecranon process of right ulna, comminuting that part, passing forwards through shaft, and gained exit at the posterior surface of arm, at junction of inferior with middle third. Treatment consisted of removing portions of bone; applying antiseptic dressings, and supporting arm. This case was turned over to another surgeon the day following his arrival at the field hospital. I have since learned that this officer has rejoined his regiment.

Gunshot Wound of the Right Hand.

Private F. L., Troop B, Seventh Cavalry. Ball entered internal border of wrist, and passing through comminuted bones of same, coming out on palmar surface at base of thumb. Wounds cleansed, dressed antiseptically, and given rest by application of splints. This man was transferred in good condition.

Gunshot Wounds of Lower Extremity, consisting of two of thigh, one of knee and two of leg.

CASE I. Private Wm. H. G., Troop C, Seventh Cavalry, while mounted, received a gunshot wound which entered middle of posterior surface of left thigh, at junction of middle with upper third, ranging slightly downward (missed femur), passed forward and inward, obtaining exit at about middle of internal surface. Wounds were cleansed, dressed antiseptically, and when transferred patient was about well.

CASE II. Private E. S., Troop C, Seventh Cavalry. Gunshot wounds of right and left thighs. Ball entered inferior surface of left thigh, ranged upward in front of femur, passing out at internal border of anterior surface at junction of middle with upper third; this ball continuing its course entered internal border of posterior surface of right thigh, and ranging transversely behind femur, passed out at middle of upper third of external border of posterior surface. Treatment consisted of thoroughly cleansing wounds, using bichloride of mercury solutions and dressing antiseptically. This man had about recovered when transferred.

CASE IV. Private G. E., Troop K, Seventh Cavalry. Gunshot wound of right leg, middle third. This was a very severe compound comminuted fracture of both tibia and fibula, with much destruction of the soft parts, including a division of both anterior tibial and peroneal arteries. Am of the opinion that this was a case of primary infection. Thirty-six hours after entrance into field hospital it was decided to amputate limb. I performed the operation, assisted by Surgeons Hartsoff and Spencer, United States Army, under rather unfavorable auspices. A Sibley tent with the earth for a floor served as an operating-room, which is very unsatisfactory, inasmuch as your light passes to you through a mere "chink" of a door, and the tripod which supports the central upright pole of the tent permits very little room for the operating table, assistants and tables for antiseptic

fluids. Then again, you may sprinkle your floor assiduously with water, yet those moving about run great risk of stirring up clouds of dust. Patient was placed under chloroform and a lateral flap amputation was performed, four inches below knee-joint, under antiseptic conditions so far as they could be obtained. Leg was found as described above; flaps were brought together, permitting of the best drainage. Treatment then consisted in supporting patient, and using persistent antiseptic irrigation of the stump, but despite all our efforts, the products of the staphylococcus pyogenes were formed abundantly, and the patient succumbed to pyæmia resulting from a primary infection upon the battlefield.

Now, to sum up, we have reviewed: Gunshot wounds of the head, three cases; of the body, eight, including the three cases quoted; of the upper extremities, six; and of the lower, four; making a total of twenty-one cases.

The difficulties of the situation, as they appeared to the medical director of the department, Colonel Baché, can be learned by a reference to his own language when he says: "Had that regiment (the Seventh) been operating at a distance from support or organized assistance instead of having a receiving hospital within easy reach, it is not hard to cast the sum of its suffering." In comparison with the difficulties met with in this instance, in which there were three (although the medical director says two) medical officers, and four hundred and ten men to care for, thirty-one wounded, I would like to place for a moment those met with and successfully overcome, in an affair in which I played a part some years since upon another field.

My memory recalls the battle of Chevelon's Forks, (Ariz.), the 17th of July, 1882, where the fighting strength of the Chiricahua Apaches was about the same as that of the actual Indian combatants in this affair under consideration; the opposing forces being two troops of the Third and one of the Sixth Cavalry, under Major Evans and that brilliant cavalryman, Captain Chaffee, respectively. These Indians were the most warlike in the entire Southern country, and among them were the renegade scouts that had turned against General Carr's command at Cibecue Creek, Ariz., the year before. The engagement was a sanguinary one, the Indian foe holding a very inaccessible point in the mountains some five or six hundred feet high, with precipitous sides except upon the south, which, while permitting the approach of our forces, was so strongly fortified and the Indians so well armed and such good marksmen, that this line of approach was exceedingly dangerous. The casualties were two officers and twelve men wounded and two men killed. The Indians lost fifteen killed, (left upon the field), and a number of wounded carried off under cover of darkness. The Indian camp was captured, and with it two Indian squaws and two children; one of these squaws suffered a very severe gunshot wound of the right leg, which made amputation necessary. I performed this operation at once, upon the field, using as an operating-table a box placed upon the ground, which was at that time covered with three to four inches of hail, having plenty of spectators in the shape of soldiers. This case with seven others, we carried by hand on rude litters fashioned from the branches of the pine tree, for a distance of fifteen miles, such was the roughness of the country. Upon gaining the table-land of the Mogollon Mountains, where a comparatively smooth country was

found, mule litters were made, upon which the more serious cases were placed, and carried ninety miles to Whipple Barracks. The lamented Crawford was detailed with two troops of cavalry to help me out of the mountains with the wounded, and his men acted as litter-bearers, relays being necessary every two or three hundred yards. This task, from the roughness of the country and the rudeness of the litters, was found not a very agreeable one. Our base of supply in this instance was fifty miles distant, whereas in the affair under consideration it was only sixteen. The difficulties were really not great, and I can only recall one case in which I thought the operation of amputation of the limb should have taken place on the battlefield rather than at the field hospital twenty-four to forty-eight hours later.

This unfortunate battle provoked another hostility upon the following day, in the shape of the White Clay Creek affair. Such, however, was the masterly manner in which that gallant soldier, General Miles, controlled the situation, both by his comprehensive knowledge of the art of war as indicated by the disposition of troops and his clear insight into the Indian character, that he prevented what at one time threatened to become a serious Indian war. Peace as well as safety was again assured the settlers of that sparsely populated country, a month after the arrest of Sitting Bull, by the surrendering of nearly 4,000 Sioux Indians at Pine Ridge agency, February 15, 1891. The entire sentiment of the country is well voiced by no less a personage than the President of the United States, in his last annual message, when, in speaking of General Miles, he says, "*He is entitled to the credit of having given thorough protection to the settlers and of bringing the hostiles into subjection with the least possible loss of life.*"

It is not surprising that the casualties of the foe, as well as ourselves were great, when we remember that the fire-arms used were those of largest calibre at close range. The Sioux were armed with three different kinds of guns, namely, Winchester of pattern 1866 and calibre 45; Winchester, calibre 38; and the Springfield carbine, calibre 45. The principal weapon was the Winchester, calibre 38, together with very few of the other patterns mentioned.

The United States troops were armed with Springfield carbines, calibre 45; weight of bullet 400 grs., composed of lead and projected by 55 grs. of powder. The wounds resulting from the above were sinuous and irregular, with lacerated edges; and the apertures of exit were frequently much larger than those of entrance. Fragments of clothing, splinters and pieces of lead were at times left in the wounds by the bullets, which, when permitted to remain, frequently led to long and obstinate suppurations (as instanced in the Indian wounded), often rendering secondary operations necessary. These bullets, by reason of the malleability of the metal (lead) of which they are made, are expansive; they easily lose their regular form and "mushroom," readily bursting into fragments upon contact with a hard body. By reason of the above, wounds of blood-vessels are more frequent, and attended with laceration, and the gravest of all dangers to the wounded on the battlefield hemorrhage. These wounds are further complicated by the splintering and not infrequently the complete shattering of bones.

I am of the opinion that three-fourths of the casualties of the opposing forces were received in what may

be termed the "explosive zone" of the projectiles' trajectories.

If, then, for the sake of illustration, we divide the trajectory of a small-arms projectile into three zones of action, indicative of the effects of its penetrating power on the human body, we should designate them as: (1) a "zone of explosion"; (2) a "zone of penetration"; (3) a "zone of contusion."

With record of the remaining velocity of the projectile, at successive stages of its trajectory, which it is perfectly possible to have with fair accuracy; and with an assumed value of the work of penetrating the average human body, which assumption could be made within reasonable limits of error; and with an assumed value of the remaining velocity after penetration, the projectile reappearing to leave a wound of the explosive type, which would be a very vague assumption,—accurate calculations of the zones could be made, but the result could be no better than the assumed data of the problem. Looking to experience, for the zones of the Springfield rifle, the wounds at the Wounded Knee fight, mostly within 100 yards range, were distinctly of the explosive type. The wound of Lieutenant Hawthorne, delivered at 300 to 400 yards, just failed of this type. I have seen, at target practice at known range, the body of a man perforated by the Springfield bullet at 1,000 yards, and my memory retains no note of the wound of exit being of remarkable character; from which I infer that this range is well within the zone of penetration. I shall therefore estimate these zones, for effective range of 2,400 yards, to be as follows: explosion, up to 250 yards; penetration, thence to 1,200 yards; contusion, thereafter.

The discussion of the zones of "explosion," of "penetration," and of "contusion," is a mixed one, involving both mechanics and physiology. Its mechanical features are essentially as follows: a very rapidly moving projectile practically shatters and destroys the material opposed to it, and makes a clean hole, as a pistol-bullet through a pane of glass, or as the entering bullet in the familiar type of gunshot wounds. A projectile of less velocity tears or breaks the material opposed to it, as a bullet thrown from the hand against a pane of glass, or as the issuing bullet in the ordinary gunshot wound.

The "zone of explosion" for any given piece is that part of its range in which the projectile has so great velocity that its loss of speed by penetrating the body of a man still leaves such velocity as to make the wound of exit similar in character to that of entrance; the loss of velocity by the work of penetration is so great that this zone is very narrow except for pieces of great power.

The "zone of penetration" for any piece is that part of its range in which the velocity of its projectile is such that it perforates the human body, but the loss of velocity in doing so leaves the projectile unable to make the wound of exit similar to that of entrance. This zone makes up the important effective range of most fire-arms.

The "zone of contusion" covers the whole range from the last to the harmless "spent ball." Much of it is still effective range.

The penetrating power of the projectile varies directly with its weight, directly with the square of its velocity. The resistance of the human body may probably be taken to be proportionate to the area struck, that is, to the square of the calibre.

In comparing the more modern arms with the Springfield rifle, the higher velocity and the less area of resistance more than counterbalances the less weight of projectile, and the "zone of explosion" confined to a very short range in our arm, is with them a considerable part of their effective range. We are neither keeping pace with the humanity of nations nor increasing the effectiveness of our army, by still holding on to the antique, single-loading Springfield rifle, calibre 45.

This old-fashioned gun cannot be compared to that of France, the weapon of Germany or that of Austria; and while our arm possesses a larger calibre than that, I think, of any other civilized nation at this time, it cannot be classified with such old calibres as those of 68 and 72 (the latter known as the Minnie carbine), carrying projectiles that weighed as much as 740 grs. We find, however, a gradual change for the better, as in the last Franco-Prussian war the Germans were using an arm with projectile weighing 478 grs.; twenty-two grains less than our own. The French, upon the other hand, were armed with the Chassepot, calibre .43, carrying a bullet weighing 385 grs. The Gras, which superseded the Chassepot in 1874, did not reduce the calibre or weight of bullet. The real advance was made, however, in the direction of increased velocity and reduced calibre, when the Lebel was adopted. Germany kept pace with France in substituting the Mauser model (1888) for that of 1871-84; and Austria followed suit by arming her troops with the Mannlicher.

Now, to sum up, from the standpoint of ballistics, the modern arms mentioned are superior to ours by reason of possessing (1) greater initial velocity, (2) flatter trajectory, (3) greater accuracy, (4) greater penetration, (5) greater range.

Added to these qualities, we find the quantity of powder lessened, the weight of projectile decreased, and from a financial view less cost of the arm as a whole. The most interesting phase is presented, however, when we consider this matter from a surgical aspect. Chavasse and Delorme are of the opinion that all wounds received in the space between three hundred and nine hundred yards, are equally dangerous, but this is not concurred in by Chauvel, who contends that the explosive effects are as frequent in arms of small calibre. Dr. Noel, in the *Medical Bulletin* of February and March, 1891, says, "The disorganization of the soft parts is so extensive and the loss of tissue so considerable, that in general all reparation is impossible and a considerable sacrifice, is rendered unavoidable." "The zone of penetration," however, presents a more marked difference; here the bullet, as a rule, maintains its shape; the wounds of entrance and exit are more equal; the fluids of the body are not thrown violently toward the periphery, as in the case of balls of large calibre, and the edges of the wounds are not bruised or lacerated, but look as if the integument had been "punched out." As we have stated, the bullet does not change its form, except in very rare cases, so that fragments of clothing and foreign bodies are not usually left in the track of the wound; hence consequent suppuration is not to be feared. It is said that union is, as a rule, to be expected by first intention; the period of recovery will be shortened; paralysis or extensive shock rare; gangrene less grave and infrequent. Bones will not suffer fracture to the extent heretofore known, as they will

be pierced in their entirety, and the fissuring and splintering will not be so extensive. Blood-vessels and nerves will run less risk of being struck proportionate to the reduced diameter of the projectile, consequently hemorrhage will not be so frequent, and the wounded in better position to await for first aid. In the "zone of contusion" we will find either simple contusions or contused wounds, their gravity diminishing as the bullet reaches the end of its trajectory, thereby losing its force. Periostitis, abscesses and exfoliations will ensue at times where bones have been struck, but these form the most serious cases, for generally we will find mere extravasations of blood into the connective tissue. The optimistic picture just drawn portrays what is thought by some of the French and German writers upon the subject of their respective arms; but this is not shared in by Billroth, who recently spoke to a question relating to the reorganization of the army medical corps of the Austrian army. He is of the opinion that the modern small arm will aggravate suffering and slaughter in the battle of the future, and informs us that as eighty per cent. of all wounds result from rifle-balls, fifteen per cent. from heavy guns, and five per cent. from cavalry weapons, surgical attention must be devoted principally to the infantry projectile. Accurate statistics of the war of 1870-71 show that comparatively few were killed by artillery.

Speaking of the maneuvering at a distance which the long range of the modern arm will lead to, he says: "A collision must come sometime, and then what will the effects of the new rifle be? Bullets that formerly stopped at the bone will pierce it, and perhaps two or three other bones; the number of the severely wounded will be rapidly increased, and the armies will dwindle rapidly."

"In consequence of the greater length of range, the wounded must be treated at a longer distance from the enemy, say four hundred paces further than heretofore. Moreover, with the quicker movements of the troops comes the necessity for the quicker moving of the field hospitals. The number of porters of the wounded, already too small in the Austrian army, will have to be largely increased; in fact, many wagons must be drawn up immediately behind the line of battle to carry off the injured."

After dwelling upon the increase of the mortality to result from the use of smokeless powder, Professor Billroth continued to speak very disparagingly of the stretcher service in these words: "At Gravelotte St. Privat there were 5,000 dead and 15,000 wounded. Two-thirds of the latter were only slightly wounded, and were carried off by railway. For the severely wounded, when we calculate that two porters with one stretcher made the trip of 500, 600 and 700 paces ten times during the eight hours of battle, we find that for the Germans alone 500 stretchers and 1,000 porters were necessary. We have left out of all consideration the French, for whose severely wounded the Germans, as victors, had to care. This at least doubled the requirements, so that 2,000 porters and 1,000 stretchers were needed. This shows how entirely impossible the whole stretcher service is."

Doctor.—H'm! You are run down, sir. You need an ocean voyage. What is your business?

Patient.—Second mate of the *Anna Marie*, just in from Hongkong.—*Brooklyn Life.*

IS IT EXPEDIENT TO HAVE A PHYSICAL EXAMINATION OF MEN BEFORE ENLISTING THEM IN STATE TROOPS?

BY HERBERT L. BURRELL,

Lieutenant-Colonel and Medical Director, First-Brigade, M. V. M.

In the title of this paper I have used the word expedient, believing that all persons interested in State troops recognize the propriety of a physical examination. The difficulties which present themselves in carrying such a measure into effect in the States with which I am familiar are the following:

(1) The expense involved in conducting such an examination.

(2) The annoyance to the citizen of being rejected, and the influence that a rejected recruit may have in deterring other enlistments; hence, added difficulty to the company-commander in keeping up his enlistments to the required quota.

In the State encampments which I have visited, I have been impressed with the necessity for a judicious discrimination being exercised by some medical officer in making enlistments. In my own Commonwealth the militia of the State includes (Sect. 1, Chap. 411, Acts of 1887, Mass. Militia Laws) "every able-bodied male citizen resident within this State of the age of eighteen years or under the age of forty-five." This constitutes the persons subject to military duty. "The active militia (Sect. 21, *ibid*) shall be composed of volunteers, and shall be designated the Massachusetts Volunteer Militia, and shall first be ordered into service to resist invasion, to quell insurrections, to aid in the suppression of riots, and to aid civil officers in the execution of the laws of the Commonwealth, or in time of public danger."

This gives us two distinct services for which the militiamen can be called upon to act; first, to resist invasion; and second, as an aid to the civil authority in enforcing the laws. It would seem that all men would recognize that a force to be used for either of the above purposes should be free from any serious imperfection. Is that the case in the National Guard in my own Commonwealth? I regret to say that it is not. The personnel of the militia in Massachusetts has steadily improved during the last twelve years. Not only have active, more able-bodied men been enlisted, but more influential men have officered the State troops. Drill and discipline has steadily improved; but there has been no movement in the medical department towards an examination of enlistments. In the report of the Adjutant-General of Massachusetts, which will soon be published, there is recommended a recruiting standard, as follows:

"A recruiting standard should be established, to prevent the enlistment of men unfit for military service. No youth of immaturity should be accepted, nor should a man be enlisted because of his giant proportions."

This recommendation assumed the importance of a general order (No. 1), which was issued January 13, 1892, an abstract of which is, "Enlisting and muster ing officers will be assured of the good physical condition of recruits before enlistment and muster into the service, and no man of abnormal proportions will be accepted."

The State of New Jersey has taken a step farther.

¹ Read before the Association of Military Surgeons of the National Guard at St. Louis, April 21, 1892.

On March 29, 1892, in General Order No. 2, "The following resolution, adopted by the State Military Board and approved by the governor and commander-in-chief, is published for the information and guidance of the National Guard:

"Regimental and battalion commanders are authorized, whenever they deem it expedient, to send any recruit before the surgeon or assistant surgeon of their commands for physical examination, and upon report being rendered that he is unfit for service, his application for membership shall be rejected."

Owing largely to the efforts of Major Marion in my own State, there has been introduced in several of our regiments an athletic association; competitions have been held, and the time has come for a physical examination of recruits.

The brigade in which I have the honor to serve as medical director was mobilized one cool October day at Worcester, which is in the centre of our State. Nearly twenty-five hundred men were brought into the city of Worcester; carried out the work of the day; which consisted of drills and regimental movements, a street riot drill, and a four-mile march. During this march there were twenty-eight men from the brigade who were assisted by the ambulance corps, some of whom were obliged to ride in the ambulance. Many of these men were disabled by temporary illness; but a number were physically incapacitated for serving as guardsmen. They were the following: Five men had serious flat-foot, which they confessed incapacitated them from walking long distances; three men had varicose veins, two of them having large varicose ulcers on their legs; and four men had serious cardiac disease, two having loud aortic murmurs. These twenty-five hundred men were mobilized in a large city. The discipline could be termed almost perfect, for not an arrest was made for disorderly conduct.

In a company of cavalry in one of the New England States some ten years ago, on a warm June day the troops were mounted and rode about twenty miles. The battalion started with seventy-two men. When they arrived at their destination, there were sixteen men rode into the camp-ground; the rest for various reasons, among which a fair proportion of bad horsemanship should be considered, had stopped by the wayside, shipped their horses forward, and came on by train. The next day it was estimated by a medical man that only eighty-five per cent. of this force would have been able to stand three days' campaigning.

Numerous instances of confirmed epileptics have been brought to the brigade hospital during our annual encampment in Massachusetts.

At one of the smaller State encampments in the East, there was discovered a man, who had been enlisted a fortnight before camp, who had a hard chancre of the lip. This was, of course, a constant menace and source of infection to every man in the company mess. The man was promptly discharged when the disease was recognized.

It is a perfectly fair question whether a physical examination of recruits is not a matter of ordinary safety to the individual and to the State itself. Numerous cases have been brought before the Military Committee of our State legislature for compensation received for injuries. In one instance in the past year a man has claimed that his eyesight was destroyed on duty, and has received an annuity of two

hundred dollars a year for five years. In 1887 a man with epilepsy enlisted and had a sunstroke, from which his friends claim that he became insane. The State is now paying his wife an annuity of two hundred dollars a year for five years.

A physical examination would be a great protection against fraudulent claims against the State. How easy it would be for a man with a hernia to enlist in the artillery, and after riding on the hard caissons to claim that he was ruptured from this service, and bring a bill for compensation against the State. My own belief is that such an examination would not alone be of benefit, but is almost an absolute necessity. The State of New York has recognized the importance of this subject by issuing a general order, directing a physical examination of all recruits before enlistment.

The question of expediency is one of tact. It is not necessary to adopt so strict a physical examination for State troops as in the United States Army. The guardsman is a volunteer; but any serious defect in his physical condition which would prevent him from doing full duty to the State, or injuring himself by performing the duties of a guardsman, should cause his rejection.

I think that all recruits before enlistment should be examined by a medical officer, and that after consultation with the company-commander he should reject those found unfit.

The reason for this introduction of the company-commander into what at first seems a purely medical question, is one of expediency. Recruits as they are enlisted into companies often come in batches. John Smith and Tom Brown will go into the company if Frank Jones, who is the best fellow in their crowd, goes in. This may seem a departure from a standard of medical requirements; but to the line officers and company-commanders it is a condition requiring consideration. If Frank Jones is rejected because he has a varicose which does not interfere with his occupation, the State may lose the services of John Smith and Tom Brown. This is looking at it from the company-commander's standpoint.

The advantages of a medical examination of troops can, I think, be made quite evident. If the State pays for the services of able-bodied men it is our duty as officers to see that she receives an equivalent. A man who is incapable of sustaining the fatigues of a four-mile march would be an incubus upon the rapid movement of troops, and in all future uses of State troops rapidity of movement will be an important consideration. Every officer who has campaigned knows that the sick are the greatest impediment to the movement of troops. A body made up of integral parts has the strength of the weakest, not of the strongest. Efficiency of recruits, not numbers, should be the guide. At present the State pays annuities for (alleged) permanent injuries. The amount of money expended for this purpose would nearly pay for a systematic examination of massed recruits.

The advantages of this system are the following:

- (1) The securing for the State of able-bodied men, and its protection against fraudulent claims.
- (2) The eventual improvement of the *esprit de corps* of organizations, by establishing the principle that only sound men can be members of the National Guard.
- (3) The knowledge of the civil authorities, that,

when they call upon the reserve strength of their State for the enforcement of laws, they will not be leaning upon the staff of a bruised reed.

TREATMENT OF TONSILLAR HYPERTROPHY.¹

BY JONATHAN WRIGHT, M.D., OF BROOKLYN, N. Y.

An apology for bringing up again the question of the treatment of tonsillar hypertrophy can best be made by an explanation. While there are many well-known and almost universally conceded facts in the question, these very points, in many discussions, have been dwelt on to the almost entire exclusion of certain matters of detail which possess a more lively interest for those who annually see a large number of throat cases. The hope of giving more prominence to these points forms my apology for the resumption of a discussion already exhausting and in many directions exhausted.

On a reference to *Sajous' Annual* for 1891 (Vol. IV), it will be found that statistics, as far as they go, show that hemorrhage of a serious character occurs after tonsillotomy, about once in 3,000 cases (or exactly as stated there, 7 to 20,000.) This ratio is made up from a consideration of all cases, without distinction; and this may, and undoubtedly has, given rise to great misapprehension. A year or two ago I had the records in the surgeon-general's office searched for certain facts concerning tonsillar hemorrhage. In twenty-five years it was found that 31 cases of serious hemorrhage had been reported. In nine of these cases the age was not given. Two cases were in children, of which one was a haemophile and one was a case of abnormal course of the internal carotid artery. The other 20 cases were all eighteen years of age or over; therefore, although Moure has lately published a case of hemorrhage in a child from abscission during acute tonsillar inflammation, we can practically rule children out.

I have no way of accurately knowing how many more children have their tonsils cut than adults. For the sake of argument, let us say we do one tonsillotomy in an adult to twenty in children. Exactitude in figures is neither possible nor desirable here; and you will all admit, I think, that this assumption is not far enough out of the way to invalidate the argument. To obtain the ratio of adult hemorrhage after tonsillotomy, therefore, we must divide 20,000 by 20; this then would give us a proportion of 7 to 1,000, or about one case of hemorrhage to 150 adult tonsillotomies. I leave it to your individual opinions to say whether this is a ratio to be regarded in deciding the question.

Personally, I have very little respect for statistics in medicine; every case is to be considered on its own merits. I have only brought forward this statistical argument, so often urged, to show its fallacy. If every case were reported, I believe the figures would be still less favorable to the cutting of adult tonsils. Of course, opinions must necessarily differ as to what is serious hemorrhage. It is always difficult to estimate the amount of blood lost, mixed as it is with saliva and mucus, and much of it swallowed. What is a trifling loss of blood to one patient may be very serious

to another. The personal factor both of patient and operator is to be considered.

Before leaving this part of the subject, I would like again to draw attention to the fact that two cases of death from tonsillotomy are on record in the thesis of Ricordeau, as occurring in the practice of the French surgeon Broca. He also mentions two other cases as occurring in the practice of Cheselden. It is folly to deny that death may occur from tonsillotomy; it is folly also to dwell on these few cases as any argument in themselves against tonsillotomy, any more than against the use of ether or the dentist's forceps because occasionally some one dies during ether anesthesia or from hemorrhage after a tooth-pulling.

Dr. Delavan, at the last meeting of this Section, said that the advocates of the galvano-cautery treatment of tonsils should state more clearly the cases which they select for it, and intimated that more people would then agree with them. If any one will read the papers of our Chairman, Dr. Charles H. Knight, on the subject, or my own more feeble presentations, even with moderate attention, they cannot fail to see that we have never, from the first, advocated its use in children where the cutting operation could be used. On reviewing these statements, I cannot see how, without brass bands and flaming transparencies, they can be made more emphatic or how the English language can make their meaning clearer.

I will not repeat the rules which our Chairman has laid down for the use of the galvano-cautery, with which I am in thorough accord, but I think it wise to go a little further and exclude the cutting operation in all patients past eighteen years of age. This conviction arises, not so much from the evidence of the somewhat battered statistics just mentioned, as from the common experience of others and from our knowledge of tonsillar pathology. (I myself have never seen a case of excessive tonsillar hemorrhage.)

It is impossible to tell by feeling or by inspection in an adult case what the vascular condition of a tonsil is at the place through which the incision is to pass. Parenchymatous oozing is more frequently the form of hemorrhage than the spouting of blood from an arterial twig. The fibrous tissue of an old tonsil is more often found in the deep layers than near the surface. Deep down, also, is where the arterial twigs are found. The surface is, therefore, not a safe criterion of the deeper tissue.

Galvano-cauterization is the most commonly employed alternative to the cutting operation. The use of the cautery point should be reserved for those tonsils around which the loop of the cautery snare or of the galvano-cautery tonsillotome cannot be adjusted; but I do not understand the statement made by many, that it takes from thirty to fifty sittings to reduce large tonsils by ignipuncture. Seven to ten is the usual number in my experience, while the largest and most refractory tonsils I have ever seen were reduced in fifteen sittings. The production of pain at the time of the operation, as well as subsequently, can nearly always be entirely avoided by the use of cocaine, and by being careful to confine the cauterization entirely to the lymphoid tissue. The same care and precaution will, I believe, largely prevent the formation of annoying cicatrices. The spiral-wound porcelain buttons for sale in the shops, it seems to me, should never be used, either in the throat or nose; they are clumsy articles, and from their size are sure to produce not

¹ A paper read to reopen discussion of the subject before the Laryngological Section of the New York Academy of Medicine, March 23, 1892.

only pain but must leave behind bad cicatrices. The slender cautery point should alone be used for this work, I believe. It is unnecessary to speak further of the technique of cauterization of the tonsils, although there are, of course, many other points than those here mentioned to keep in mind. One who has not devoted special attention to throat work, we know, has no business to poke around in a patient's pharynx with a hot platinum point.

Abscesses and diphtheria as mentioned by some speakers, I have never seen, though I am willing to admit their occasional occurrence after the cauterization of tonsils, as well as after tonsillotomy. Astringent or antisepic gargles should always be prescribed after each cauterization or tonsillotomy, not so much for astringency or antisepsis as for pharyngeal gymnastic exercise.

The cold snare, electrolysis, caustics, incisions, and other substitutes for the cutting operation other than the cautery, I leave to the consideration of those who have had more experience with them than I.

In a child of eight or ten years of age, two symmetrically-rounded tonsils, free of the faecal pillars jutting into the oral pharynx, presents to the young laryngologist a temptation only second to that of a rosy-cheeked, juicy apple in a neighbor's orchard to the enterprising small boy. Those tonsils are usually sliced off in a way that delights the heart of the operator and fills the child's mother with wonder and admiration. The after-effects are as brilliant and satisfactory as the operation itself.

Quite a different affair are those flat, ragged tonsils which project but little or none at all beyond the somewhat bulging anterior pillars. Their area is extensive. Their edges slope off gradually and join with the general lymphoid infiltration of the surrounding mucous membrane, angry, red, and covered with slimy mucus. This condition is certainly seen almost daily by most of us, both in children and adults, and I am sure that there are many beside myself who want to know how this condition of affairs is to be remedied by any cutting operation. I hope, more for the sake of information than of argument, that this question will be answered by those who never use the galvano-cautery in the throat. In children ignipuncture is almost attended with the greatest difficulty in these cases. A great amount of improvement can often be attained by removing the lymphoid hypertrophies from the post-nasal space where they are present. These cases are the ones, *par excellence*, in which we have to thank Dr. Bosworth for the introduction of his very useful and suggestive term "Lymphatism," where syrup of the iodide of iron in large doses is of great value.

Another question occurs to me. We are told by many that, when the tonsil is fast to the faecal pillars, we are to separate it by means of the blunt hook before tonsillotomy. In a certain very moderate proportion of cases, this can be done, where the adhesions are recent and easily broken up. In a much larger proportion of cases there is cohesion, not adhesion, to the faecal pillars. The lymphoid tissue making up the tonsil is continuous with the hypertrophied lymphoid elements in the surrounding mucous membrane. So intimately are they blended that it is impossible, without a microscopic section, to tell where tonsil leaves off and faecal pillar begins.

Again, for information, I would like to ask if there

are any so skilful that they can separate these structures in the living subject, one from another, with a blunt hook? I am perfectly ready to acknowledge that I am not able to do it, and am equally frank in saying I have never seen it done. To cut off the projecting portions and subsequently to trim down to a proper shape the distorted fauces with a galvano-cautery point, is the best I can do.

Dr. C. H. Knight has quoted Dr. Ingalls as very graphically saying that a child suffers about as much in anticipation of a tonsillotomy as an adult in anticipation of a hanging, and urges the use of anesthesia in children. Those who remember, and nearly every one with the right kind of heart does remember, the piteous look of terror on the little patient's face when he looks upon the gleaming steel of the guillotine, will be disposed to agree with him. On the other hand, the picture of the little victim about to be smothered with an ether cone, the terror and the struggles nearly always induced by this procedure, will also appeal to the soft-hearted operator. I am sure, as far as I am personally concerned, that the memory of one picture is just as vivid as the other. It takes just as much force to put the child under ether as it does to hold it for tonsillotomy. The struggle with ether is prolonged. The struggle in a tonsillotomy is short, sharp and decisive. Of course, I am speaking of children who do struggle in each case. There are children who take ether as calmly as they do their milk,—very few. There are children who open their mouths and never make a sound while their tonsils are being cut off,—not a few. I recently operated on a little six-year-old boy, before a class of medical students, who walked to the slaughter and conducted himself on the scaffold with all the *sang froid* of a Stafford or a Vane. A strong, firm assistant is, however, usually necessary. Occasionally a little tar-tar is caught, an infant John L. Sullivan, whose squirmings are entirely beyond control. The gentle-hearted operator will have to strap that youngster down to the table while the ether is being forced by artificial respiration into his lungs.

In other words, the choice between the two struggles usually simply comes down to the point of the most successful issue. In such a case etherization is easier than the tonsillotomy without it. As to the operation itself, certainly every one who has had experience with both methods must admit that with anesthesia the difficulties are greatly increased. The illumination of the pharynx becomes a matter of some difficulty. The tongue has to be controlled. It falls back into the pharynx or up against the roof of the mouth unless the patient is put in the upright position. The greatest difficulty, however, is in engaging the tonsils in the loop of the tonsillotome.

Without anesthesia, the "gagging" of the patient throws the mass toward the middle line and the pillars of the fauces are retracted from the tonsil back to their line of attachment. Not so in the unconscious patient. Even in primary anesthesia the muscles of the fauces and the external muscles of the neck are relaxed, and the tonsil which formerly projected beyond the pillars may and often does sink back between them. Pushing them inward by the hand at the angle of the jaw also pushes inward the pillars and the subjacent structures with them. The difficulty, of course, is very greatly increased where there is firm adhesion of fauces to the tonsil.

Hæmorrhage is always more profuse. In fact the only instance in which I have ever seen anything approaching even to profuse hæmorrhage was in an anesthetized child.

It is often necessary in these cases to also remove the lymphoid tissue from the pharyngeal vault. I think it preferable here to take out the tonsils without ether and wait a few weeks, even months, before proceeding to operate in the naso pharynx. Many a case of moderate post-nasal adenoid will be relieved by the removal of large tonsils,—the lymphoid hypertrophy in the vault will retrograde and give no further trouble. Where the adenoids are well developed, of course a subsequent operation will be necessary. In the double operation the blood from the amputated tonsils will flow into the naso pharynx and considerably embarrass operative procedures there. While it is frequently necessary, from reasons of expediency, to do everything at one operation under ether, I do not believe that this is, in the majority of cases, the procedure of choice.

If I have been a little emphatic in laying down personal views, it is done only in the desire of being contradicted and of thus exciting discussion. I trust others, having experience, will say something of the methods of controlling tonsillar hæmorrhage, and bring out more fully these matters of detail.

Reports of Societies.

AMERICAN PEDIATRIC SOCIETY.

THE Fourth Annual Meeting was held in Boston, May 2, 3 and 4, 1892.

FIRST DAY, MONDAY.—FIRST (AFTERNOON) SESSION,

The President, DR. WILLIAM OSLER, of Baltimore, Md., delivered the annual address, entitled

REMARKS ON SPECIALISM.¹

DR. AUGUSTUS CAILLÉ, of New York, then read a paper on

EXPERIMENTS AS TO THE VALUE OF NASCENT OZONE IN CERTAIN FORMS OF DISEASES OF CHILDREN, WITH DEMONSTRATION OF AN EFFICIENT GENERATOR.

Dr. Caillé had tested nascent ozone in the treatment of three cases of incipient phthisis, three of chlorosis in children and five of pertussis. He also included in his report three cases of pertussis and eight of chlorosis and anæmia treated with nascent ozone by other physicians. These inhalations were given by means of the apparatus of Labbé and Oudin. There were usually three inhalations daily, lasting about fifteen minutes. The conclusions thus far reached were as follows: That inhalations of ozone, by means of Labbé and Oudin's apparatus, had not been followed by noticeable ill effects; that daily inhalations of ozone increased the quantity of oxyhaemoglobin in the blood from one per cent. to four per cent. in a short time, and this increase remained stationary for some time; that in three typical cases of limited apex tuberculosis a local improvement was not obtained by inhalations; that in pertussis ozone inhalations had a very marked curative effect as regards the duration and severity of

the disease; that in chlorosis and anæmia ozone inhalations were exceedingly valuable from a therapeutic standpoint, and gave better and prompter results than any other form of medication known to the writer; that atmospheric disinfection was readily secured by means of the apparatus, making this of value in the treatment of scarlet fever, etc.

DR. CAILLÉ, in reply to questions, stated that in the cases of pertussis the treatment was instituted after the attacks had become frequent, and that the effect on the attacks was marked and immediate. He had not treated a case of pernicious anæmia in this way, but thought it would be of value in such cases. The examinations of the blood in the cases treated had been only with reference to the amount of oxyhaemoglobin.

DR. T. M. ROTCH, of Boston, thought this might prove a great advance in the treatment of cases of advanced anæmia which were so fatal in children. It was possible that some of the cases reported were on the verge of being pernicious anæmia, and had been cured.

DR. CAILLÉ, in answer to a question as to the immediate effect of these inhalations, said he had observed that the heart was slower and that the pulse was strong.

DR. FISHER, of New York, asked whether, in the cases of anæmia, the sputum had been examined for bacilli, and whether some of these might not be tuberculous.

DR. CAILLÉ, in reply, stated that no examination had been made in those cases, since there was no cough, and the diagnosis of anæmia seemed clear. He thought the patients with incipient phthisis who were in good hygienic surroundings and circumstances furnished a fair test of the efficacy of the treatment in such cases, and in these no local improvement resulted.

MANIFESTATIONS OF LA GRIPPE IN CHILDREN, by CHARLES W. EARLE, M.D., Chicago, Ill.

Dr. Earle dwelt especially upon the profound depression and marked effects upon the nervous system produced by la grippe in children in Chicago. The constitutional disturbance was very marked. He had seen more severe cases of diarrhoea and vomiting in the middle of the winter, during the epidemic of influenza, than during the middle of the summer during an epidemic of cholera infantum. He believed that as we had found that it was not the bacillus peculiar to diphtheria, but rather the products of that bacillus which produced the diphtheritic paralysis, so we should find that it was the products of the germ peculiar to influenza which produced the nervous manifestations of that disease.

DR. ROTCH, of Boston, said his experience in a large number of cases of grippe in children had differed from that of Dr. Earle. It seemed that the disease must have appeared in the West in a much severer form than in the East. The cases in children had been much milder than in adults. He had not seen fatal cases of uncomplicated grippe. It was being more and more acknowledged that grippe was a nervous disease affecting the sympathetic rather than the central nervous system.

DR. JACOBI, of New York, could not find that the symptoms of grippe in children were much different from those in the adult. If we distinguished three forms, namely, respiratory, nervous and gastric, the

¹ See page 457 of the Journal.

symptoms were principally respiratory or nervous, the nervous often very severe.

DR. CAILLÉ called attention to a peculiar cough resembling whooping-cough, which he had noted in a number of his cases. This cough lasted for two or three weeks in some instances, and did not get well without local treatment.

DR. L. EMMETT HOLT, of New York, said the cases he had seen had not been of the severe type described by Dr. Earle. In the New York Infant Asylum during the epidemic of two years ago scarcely any of the small children were affected. During the epidemic of last year, however, a large number between the ages of one and two were affected. There had also been a severe epidemic of pneumonia in which about two-thirds of the cases were fatal. In many of the cases there were none of the ordinary symptoms of influenza before the pneumonic attack. Whether this was to be looked upon as an epidemic of influenza with pneumonic complication, he was unable to say. It looked, however, as if the two had some relation to each other.

DR. S. S. Adams, of Washington, thought the epidemic had materially changed in many of its characters in young children in the past three years. He believed climatic conditions and locality influenced the type of the disease. Some of the cases had presented a peculiar rash or general erythema together with high temperature and the symptoms which usually accompany high temperature, so that at first the diagnosis of scarlet fever would be suggested. Many of the cases also were accompanied by so marked pulmonary congestion as frequently, in his judgment, to be mistaken for pneumonia. There might be bronchial breathing, slight dulness, high temperature, with decided initial symptoms, making it in the beginning a difficult matter to differentiate from pneumonia. In many of the cases in the last epidemic there had been decided symptoms of rheumatism, so that for a time the diagnosis was in doubt.

DR. BLACKADER, of Montreal, said that in Montreal there had been more cases of gripe in children in the last epidemic than in the previous one. The epidemic had been of a mild character, there being no deaths so far as he had seen in uncomplicated cases. He had observed the reflex cough to which Dr. Caillé had called attention.

DR. W. D. BOOKER, of Baltimore, had seen one case in which this peculiar reflex cough led to the diagnosis of whooping-cough on the part of the parents. The cough lasted two weeks, and was relieved by irrigations with boracic acid.

DR. T. M. ROTCH, of Boston, stated that he had observed this cough in some of his cases, and at first supposed it to be whooping-cough. He had also noted the rash to which Dr. Adams had referred.

DR. EARLE, in closing the discussion, spoke of the cases in which, at first, one apparently had to deal with a commencing pneumonia, but in which, after a few hours, all the signs of localized inflammation had disappeared and there existed an extensive bronchial catarrh.

DR. C. P. PUTNAM gave an account of an

EPIDEMIC OF ALOPECIA AREATA IN AN ORPHAN ASYLUM FOR GIRLS DURING THE YEAR 1891.

One girl had been attacked in January and another in March; and a little before the first of June sixty-one suddenly broke out with disease. The whole

number of pupils in the school was sixty-nine, the ages ranging from three to fourteen years. Six girls being found free from the disease at the end of June, were sent into the country to board, and they never showed any signs of the affection. The matrons and also four older girls who acted as assistant matrons, also escaped, though they were at times closely associated with the children.

The cases had been seen frequently by Dr. J. T. Bowen. Dr. Bowen and Dr. Putnam had also repeatedly examined the hair without finding any micro-organisms. The hair-roots were found to be atrophied and the hairs more slender than usual.

All the heads were shingled, and corrosive sublimate was applied to each daily. Thirty girls were divided into five classes, and treated with as many different preparations, namely; in addition to the regular washing with corrosive sublimate solution, six had the spots dabbed with corrosive sublimate, two grains to the ounce; six were painted frequently with tincture of cantharides; six had thorough inunctions with sulphur ointment; six with cantharidal ointment; six with turpentine.

About the middle of July a general stand-still, and soon after a general improvement, was noticed, and this has gone on gradually, until at present no signs of the disease can be seen except by careful observation, when it is noticed that there are a few bare spots on the heads, and also that the hair grows sparsely over the affected spots, while some of the bald patches are entirely covered in.

The treatment seemed to have no particular effect. The cases in each class appeared to improve at about the same rate as in all the other classes.

DR. J. T. BOWEN, of Boston, had examined the whole sixty-three children on two occasions, and was positive that ring-worm was not to be considered. It seemed to him impossible clinically to separate these cases from the ordinary alopecia areata. The only point of difference he could detect was that there were more of these very small spots. He had no hesitation in including this epidemic in the class of cases described by the French writers as alopecia areata in schools, camps, etc. So far as he knew, such epidemics had not been described in America.

DR. J. C. WHITE of Boston, had seen several of the cases. So far as surface appearances went, he thought they did not differ from ordinary cases of alopecia areata; but to his mind the spots were more irregular, more angular than ordinarily seen in alopecia areata. The spots were far more numerous than ordinarily, and the development of the disease was far more rapid than he had ever seen in cases of alopecia areata. If we studied the pathology of the disease and the history of these so-called epidemic instances, it seemed to him that we might be dealing with a disease which was not alike in all cases. He did not see how it was possible to explain these cases, and cases like these without the acceptance of the theory that it was a germ disease. He was not prepared to say he considered this a case of typical alopecia areata becoming epidemic or showing itself to be contagious, but we might very well be dealing with one of those rare instances of germ disease characterized by the ordinary surface appearance of alopecia areata, but by a difference in the gross appearances of the disease; and therefore he thought this would show that there was more than one disease characterized by alopecia

in areas, and he considered this as a probable example of that much rarer affection, and different from ordinary alopecia in such respects.

SECOND DAY.—MORNING SESSION.

DR. A. JACOBI, of New York, showed

SPECIMENS FROM A CASE OF HYDORRHACHIS AND HYDROCEPHALUS.

DR. HENRY KOPLIK, New York, read a paper entitled,

FORMS OF DIPHTHERIA WHICH SIMULATE SIMPLE ANGINA.

He said: Since the specificity of the Klebs-Loeffler bacillus has become more an accepted fact by all clinicians, the clinical study of diphtheria has presented many new and hitherto unexpected difficulties. A careful study of the question does not seem to substantiate the supposition at first entertained that the specific nature and virulence of this peculiar micro-organism once established, the clinical aspects of diphtheria would become much simplified. We are now recognizing the condition, diphtheria a membrane, and diphtheria the disease. The presence of a membrane does not by any means complete the diagnosis of a case of throat disease. In a series of studies upon diphtheria of the tonsils, pharynx, and larynx begun in the early part of this year, and conducted in the Carnegie Laboratory, he was impressed by certain facts from a clinical standpoint. Among other things, he directed his attention to an immense number of cases which are of daily occurrence, the so-called doubtful cases. His studies include an analysis of thirty-four such cases. In many of these cases physicians differed in opinion. These cases included, first, those in which a careful inspection of the throat revealed no membrane or even specks of membrane. Again, other cases presented a mere speck of membrane upon one tonsil, which could not be distinguished in appearance from a follicular crypt or lacuna. In other cases there was the typical appearance of follicular tonsillitis in one tonsil. In all of the cases, the membrane, exudate, or secretions were removed from the tonsil, soft palate, or posterior pharyngeal wall by means of a very small, thin, sterilized scoop, such as is used in ear work. This was then passed over the surface of one or more tubes of Loeffler blood-serum and bouillon mixture. Pure culture of the Loeffler bacillus were obtained, first by the dilution methods of Loeffler, and then upon agar plates. The pure culture was studied in the regular way upon various substances, — agar, glycerine-agar, bouillon, gelatine and potato. The first series of cases begin suddenly with symptoms of laryngeal involvement. The patients may have suffered a few days or a week from an amygdallitis which has been diagnosed and treated as benign. Suddenly new symptoms appear in the form of stridulous cough and breathing and temperature, completing a picture of laryngeal disease. In some cases, even when the laryngeal complications appear, a careful daily examination of the throat fails to reveal any membrane, and even in the whole course of the case no visible membrane appears, and the patient recovers. In this absence of membrane and recovery lies the danger of the disease, and its power to harm others by disarming suspicion and rather concealing the true diphtheritic nature of the affection. Again, another series of cases are those which we may treat for days as simple amygdallitis,

daily inspection failing to show any membrane. Suddenly a croupy cough appears, also stridulous breathing, then upon looking into the mouth one or two very small specks of membrane just forming on the tonsils are seen. Death may follow with laryngeal stenosis within twenty-four hours. The most puzzling cases are those afflictions of the tonsils in which, with the ordinary symptoms of swelling of the tonsils, with or without glandular enlargement at the angle of the jaw, we have, as a sole manifestation of diphtheria, a single small speck of varying color on one or the other tonsil. But specks upon the tonsil are deceptive, and the means of diagnosing them with certainty are found only in the bacteriological method. Some pathologists believe that diphtheria can exist without any membrane.

A paper by J. LEWIS SMITH, M.D., New York, was read by title.

F. HUBER, M.D., of New York, read a paper on

TWO TRACHEAL AND BRONCHIAL CASTS,

and showed specimens.

ETIE L., eight years old; diagnosis, pseudo-membranous croup (diphtheria). With the exception of an occasional mild suffocative attack, the prognosis was satisfactory during the first few days. A few days afterwards, following a severe spell of coughing attended with asphyxia, quite a large piece of membrane was coughed up. The voice now became clear and the dyspnoea was relieved for some hours. A return of hoarseness and stridulous breathing showed that the membrane was being deposited anew. The next morning another and larger piece of membrane was expelled. Later in the day the condition became worse. Intubation was practised. Suddenly severe dyspnoea and other symptoms set in, and the following morning tracheotomy was performed. Almost immediately a larger cast was expelled, followed by a little blood and mucus. Symptoms for a few hours cleared up, but within twenty-four hours patient died.

DR. AUGUSTUS CAILLE, New York, recalled a case in an older girl, where tracheotomy was done, followed by the expulsion of a very thick membrane. He thought the casts from Dr. Huber's case very well preserved.

DR. FISHER, New York, while in Berlin last year, saw and made many experiments with the bacillus of diphtheria. He referred to the difficulty of getting at the throats of young children in order to get a piece of the membrane for bacteriological examination, but considered the bacteriological examination itself a comparatively easy task. He does it at the bedside.

DR. A. JACOBI, New York, spoke of the difficulty and impossibility of making positive diagnosis in every case, and valued the interesting information given. The bacteriologists, as well as the clinicians, however, have much yet to learn.

(To be continued.)

THE DUFFERIN FUND.—The National Association for supplying Female Medical Aid to the Women of India is now on a sure footing. During 1891 over 466,000 patients were treated. There are forty-eight hospitals controlled more or less completely by this society.

T. C. ALLBUTT, M.D., F. R. S., has been appointed Regius Professor of Physic in the University of Cambridge (Eng.).

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

J. C. MUNRO, M.D., SECRETARY.

REGULAR Meeting, Monday, February 1, 1892, DR. C. F. FOLSOM, Chairman.

DR. E. S. WOOD read a paper entitled,

RENAL ALBUMINURIA NOT DUE TO ORGANIC DISEASE OF THE KIDNEYS.¹

DR. F. C. SHATTUCK: This is a timely and interesting paper, which illustrates the great advance that has been made in our clinical knowledge of renal disease in the past twenty years. As a student, I was taught that albumen and casts in the urine were of fatal import. The more conscientiously we make routine examinations of the urine of every patient who comes to us, the more are we impressed by the slight significance of albumen and casts in many cases. My own attention has been called, within the past few years, to the frequency with which they are found in the urines of those who are past fifty years of age, and who are presumably in, or approaching, the degenerative period of life. I am now engaged in collecting a large number of these cases for analysis with reference to this point, and am not yet prepared to speak finally with regard to it. But experience has led me to expect to find small traces of albumen and hyaline and granular casts, perhaps pretty abundant, in such urines, whether direct or indirect renal symptoms are absent or not. As probable instances of concentrated urine as productive of albumen and casts, I recall two brothers, prominent business men in one of the larger towns of the State, who were solicited to take out life insurance policies to the amount of \$100,000. The examiner found albumen and casts, and the offer of insurance was promptly withdrawn. I have seen them both a number of times during the past year, and have been unable to detect any other evidence of disease about either of them. They would, indeed, appear to have an enviable expectation of life. We constantly see well-to-do persons, who can and will take reasonable care of themselves, live for years happy and useful lives, although their hearts or arteries or both are clearly not in their pristine integrity. The same thing obtains with the kidneys, and it is of the utmost importance for our patients that we realize this fact.

DR. R. H. FITZ: I think it is desirable for Dr. Wood to bring up this subject, particularly from the practical side, so that we shall not be too ready to consider that our patients have any serious disease of the kidney because they have albuminuria and casts. I have been impressed by the frequency with which the record of the sediment of his cases shows the presence of something more than casts, particularly the association of blood with the casts, pointing, it seems to me, distinctly toward a local pathological process in the kidney. We ought to bear particularly in mind the importance of not calling every pathological condition in the kidney Bright's disease where albuminuria and casts are present. This term has led to a great deal of fear on the part of the community. It seems to me highly probable that many of the cases which Dr. Wood has reported are distinctly associated with lesions of the kidney, lesions which are temporary, but destructive, and which will leave alterations in the kidney not sufficient to produce any permanent disturbance of

function, but to be found afterwards as evidence of a pre-existing pathological process. I am particularly impressed with this from the anatomical side. It is very common to see scars upon the surface of the kidney and thickenings and destruction of the Malpighian bodies on microscopic examination. Dr. Shattuck says after the age of fifty he expects to find albumen and casts. After the age of fifty I expect to find a kidney showing evidence of what may be called focal destructive changes, and I have in mind an illustration. It was that of a gentleman who recovered from an acute and severe attack of pyelo-nephritis, lived several years, and finally died uremic. Numerous renal scars were found, and a considerable amount of kidney had been destroyed. It seems to me, with regard to several of these cases which Dr. Wood has presented, that, in connection with albuminuria and casts, there was very likely, at the time of the occurrence, a local pathological process in the kidney. It was evidently not a Bright's disease. It was perhaps an inflammatory disturbance or a necrosis or a degenerative destructive condition, and the patients recovered. In fact, they could hardly be said to have recovered, for, at the time of the occurrence, there were no symptoms of renal disease other than an abnormal urine; at the same time it is not unlikely that there was actual disease of the kidney, very limited and manifested by such signs as Dr. Wood has described, although there were no symptoms of sufficient gravity to lead either the patient or his friends or physician to consider that he was diseased.

DR. A. T. CABOT: I was very much interested in the paper, since it constantly comes in my way to see cases in which albumen and a few casts, generally hyaline and from the straight tubules, are found, not associated with serious renal disease, and continue to appear intermittently for years, perhaps, without ill consequences. Some years ago I saw, with Dr. Edes, an interesting case of albuminuria in a child. This girl had albumen and casts in the urine, and, owing to some slight frequency and occasional difficulty in urination, Dr. Edes called me to see her in consultation. Under ether we found a narrowing of the urethra at the internal meatus, which yielded readily to large French bougies. The result of dilatation was the entire disappearance of the albumen and casts, and relief to the renal symptoms. I see that same thing constantly in older people; but that was the first case in which I had observed it in a child. The condition of tightness at the neck of the bladder I have seen several times in small boys associated with symptoms that led to examination for stone in the bladder. Apparently the tightness is behind the constrictor muscle at the real neck of the bladder, and the symptoms have in my experience been relieved by the dilatation. I think in those cases probably, judging from this child's case, the urine would show some albumen owing to the obstruction.

DR. WOOD: The case which Dr. Cabot mentions is interesting, and recalls one reported by Dr. Farlow of obstructive suppression of urine due to a morbid growth compressing both ureters. There was a decided trace of albumen in the urine, and casts.

In connection with Dr. Fitz's remarks, I have often wondered how much organic change may be produced in a kidney by a long continued renal irritation. It has always seemed to me that it is very desirable to detect by the examination this renal irritation early, and to

¹ See page 459 of the Journal.

remove the cause when possible so to do, whether it was simply concentrated urine or separation of abnormal sediment within the tubules.

Dr. A. T. CABOT showed a specimen of

PAPILLOMA REMOVED FROM THE BLADDER,

and gave the following history:

S. C. W., a strong man of fifty-five, who had always been well, began to notice the appearance of blood in the urine one year ago. The attacks of haematuria became gradually more and more severe, though with some long intermissions. The final attack began about five weeks before he was seen, and had gradually increased in severity until, at the time when Dr. Cabot saw him, his bladder was partly filled with clots, and the urine contained almost pure blood. There had been examinations of the water made at some considerable time before, but no villi or other evidence of new growth had been discovered. The prostate was not enlarged or tender, and examination with the sound revealed nothing in the way of a calculus in the bladder.

An exploratory incision in the perineum was made, the membranous urethra was opened, and the finger introduced through the prostate into the bladder. It at once encountered a large pedunculated growth springing from the trigonum, about the size of a small hen's-egg. This was so friable that it easily broke off before the finger, and presently was loose in the bladder. It was then removed piecemeal through the perineal opening. The base from which the tumor had been detached was not hard, nor indurated, and was thoroughly curetted with a sharp spoon, and a drainage-tube was then introduced. The hemorrhage was not severe after the operation, and entirely ceased after the second day. The urine came mostly through the perineal opening, and this persisting, on the tenth day a catheter was introduced through the penis for the purpose of diverting the urine, and giving the perineal opening an opportunity to close.

Dr. WHITNEY gives the following report upon what was removed: "The tumor of the bladder consists of several quite friable papillomatous-looking masses, the bulk of all of which would equal that of a small egg. Sections through these showed under the microscope narrow, fibrous, vascular stalks covered with many layers of large, irregularly-shaped epithelial cells. It could not be determined whether the growth had grown into the deeper layers of the bladder, as there was no place that could really be fixed upon as the base."

The diagnosis was papilloma, as far as could be made out. The feeling of the base, as above described, would certainly lead to no suspicion of malignancy, and Dr. Cabot reported the case as one of simple papilloma.

Dr. WOOD: I should like to ask if he had bladder symptoms besides hemorrhage.

Dr. CABOT: He had no symptoms but the haematuria, which did not annoy him much, and that had only been considerable for five weeks when I saw him.

THE new Russian Pharmacopœia has recently been issued. Compared with the preceding, it contains a smaller number of articles, 318 having been discarded, while only 100 new ones have been added. The total number of articles is 808.

Recent Literature.

Handbook of Materia Medica, Pharmacy and Therapeutics. Including the Physiological Action of Drugs, the Special Therapeutics of Disease, Official and Extemporaneous Pharmacy and Minute Directions for Prescription-Writing. By SAMUEL O. L. POTTER, M.A., M.D., Professor of Theory and Practice of Medicine in the Cooper Medical College of San Francisco; author of "Quiz Compend," Late Acting Assistant Surgeon, U. S. A. Philadelphia: P. Blakiston, Son & Co.

Into this book the author has succeeded in putting a surprising amount of information in a very accessible form.

Under *Materia Medica* and *Therapeutics*, which occupies about one-half of the work, the drugs are arranged in alphabetical order. This allows the reader to find readily any desired title; and in this he is facilitated by the use of large type for the headings. Under each remedy there is succinctly given an outline of its sources, its properties, its preparations and a few lines descriptive of other compounds of a similar nature. The physiological action is then considered, and finally the uses. These are all treated without elaboration; but, so far as one may judge from examples taken at random, in a suggestive manner, useful to practitioners and students who have gained a more detailed knowledge from fuller works on therapeutics, and who need to refresh their memories by such an outline as is here given.

Under "Sulphate of Magnesia," the statement that its "purgative action is chiefly due to increase of the intestinal fluids by an outward osmosis from the vessels and not from increase of the secretions of the glandular appendages," is open to question in the light of Matthew Hay's investigation.

The author takes the ground that no really scientific classification of medicinal agents is possible, and he only attempts to group the medicines after each one has been studied singly. Among these groups are a few not usually found in works on therapeutics, which will commend themselves to some practitioners, such as alkalinizers of the urine and acidifiers of the urine.

Part II, on "Pharmacy and Prescription-Writing" is an excellent outline of these subjects, and adapted to the needs of students. The use of triturations, a kind of preparation used a century or more ago, is recommended.

Part III includes special therapeutics, and is an attempt to suggest the treatment in various diseases. The synopsis of treatment is serviceable, though, of course, open to criticism. For example, under cancer, is given the following:

B. Acidi Arseniosi	•	•	•	•	•	3 lb
Muci. Acacia						31

As a paste on a cancerous sore followed after two or three days by bread poultice until slough separates.

No caution about the risk of arsenical poisoning from absorption is given.

The Appendix includes a list of Latin words used in prescriptions, with their contractions and corresponding English equivalents; hypodermic formulae; treatment of poisoning; table of differential diagnosis; the examination of the urine; tables of specific gravity; and other convenient information.

CHLOROFORM VS. ETHER ONCE AGAIN.

WAR wages still between the advocates of chloroform and ether abroad. The *Dublin Journal of Medical Sciences* for April has begun to publish a review of the Hyderabad Chloroform Commission's report — which appeared in the *Lancet* at least two years ago — and Surgeon-Major Lawrie is severely criticised for attempting to formulate the status of the ether-chloroform question in America. Dr. Lawrie says that ether is preferred by the majority of American surgeons on account of the prevailing opinion that it is safer; in return for this he is fairly scorched by the reviewer, who goes so far as to recall our late civil war and waves the bloody shirts of our Southern brothers. And all this, forsooth, to strike terror into the heart of a surgeon of Her Majesty's Army in India who believes in the chloroform as firmly as does the reviewer himself.

The following quotation explains itself :

"Like many others, Dr. Lawrie confounds the New England States with the United States. In so doing, he reminds us of those politicians who in describing Ireland leave out Ulster. The New England States are not the United States, neither is their opinion the American opinion. The men who raised American surgery to its present high standard were Southerners, men of the cotton States; and when the States's-rights War occurred, the Confederate surgeons exhibited a skill and resourcefulness, and produced better results, than (*sic*) up to that time any military surgeons ever recorded; and this was done amidst the greatest difficulties. The men who have this splendid record to their credit without exception are chloroformists. Two of the most distinguished of these Southern surgeons have expressed their views in no uncertain manner on the chloroform questions, as may be seen by reference to Mr. Foy's book, '*Anesthetics, Ancient and Modern.*'"

"That the Eastern States advocate ether in season and out of season, and that they are intolerant of any

difference of opinion, is notorious; but, nevertheless, the United States refuses to be dominated by a noisy, didactic faction, and with the majority of American surgeons chloroform continues to be the favorite anesthetic."

It is just possible that Dr. Lawrie may be right after all about the majority of American surgeons. It is hoped that the reports of careful investigations of all deaths under anesthesia will soon show where the majority is in this country. At all events we are glad that our Southern medical brethren come in for a share of praise. The warriors of the old world have learned many things from us during the late war, and not least among these things was the improved organization of army medical work in the North as well as the South.

It is a pity that so much unnecessary warmth is exhibited whenever the respective merits of the two anaesthetics are discussed in the medical journals. A little cool discrimination and candid impartiality would be more apt to lead to statistics of some real value, both scientifically and to the world at large.

THE VEGETARIAN'S HEART VS. THE MEAT-EATER'S HEART.

In the *Nineteenth Century* for April, 1892, Lady Paget, writing on the subject of vegetarianism and in its defence, gives the following among several arguments: "While the meat-eater's heart has seventy-two beats in the minute, the vegetarian's has only fifty-eight, therefore 20,000 beats less in the twenty-four hours."

Without waiting for proof of the above statement — which may not be easily obtained — or insisting on the well-known fact that there is great variability in the frequency of the pulse even among meat-eaters, some carnivorous men and women having habitually a pulse below fifty-eight, we might provisionally assume the writer to be correct. What then? A pulse of fifty-eight is not necessarily a strong pulse; does not necessarily imply a vigorous heart. A heart that beats seventy-two times or eighty times a minute may be a stronger and sounder heart than one that beats fifty-eight times, and may retain its vigor much longer.

If Lady Page's vegetable-eater will still farther reduce his heart-beats, by taking a recumbent instead of maintaining a sitting or a standing posture, he will find that his pulse will fall still lower — to fifty, or even forty-eight! To be consistent, then, with the principle suggested by this inductive inquiry, *he should keep his bed all the time*, for by so doing he will spare his heart 480 beats an hour, or 11,520 beats in the twenty-four hours! If he gets up to take exercise he at once increases his heart's beatings by imposing more work on that organ. If he eats a hearty meal, even of vegetables and cereals, he again compels his heart to quicken its pulsations by several more beats per minute during eating and during active digestion. He must also avoid all mental excitement, as this accelerates the pulse, and increases the work of the heart.

The question is, of course, not broached in the foregoing article — though necessary to a scientific inquiry — whether the heart of the meat-eater may not be stronger and better fitted for its tasks by virtue of a diet which is largely animalized. A well-nourished heart will be more competent than one that is ill-nourished to perform its really very important part in furthering the conditions of successful living, but this is a truth that is so trite that we need not dwell upon it longer. The data for an intelligent appreciation of the subject are not lacking, and it is quite possible to determine with much scientific exactness by an appeal to physiological truths and to common experience — national and individual, due allowance being always made for exceptions — what kind of diet is best for nations, for climates, and for individual conditions. Unfortunately for the vegetarian, he is too blinded by bias and prejudice to see aught but a partial and fragmentary side of the question.

THE ALMY MURDER TRIAL.

IMPARTIAL MEDICAL EXPERT TESTIMONY.

The proceedings in connection with the reopening of the Almy murder last week, at Plymouth, N. H., on the motion of the prosecution, offered two interesting medico-legal features. The medical evidence on the part of the State show that, in New Hampshire, there is need, in the conduct of medical examinations in cases of death by violence, of some system like that of which we have the benefit in Massachusetts. The other incident illustrated the feasibility of an innovation, long desired by physicians, by which medical experts may appear in court without being discredited, justly or unjustly, as partisans. One of the experts in this case before he answered any questions, asked and received permission to read the following:

STATE v. FRANK C. ALMY.

By agreement of the parties, it is ordered by the court that Dr. Frank W. Draper, Professor of Legal Medicine in the Medical School of Harvard University, be called to testify as an impartial expert. [Signed] G. Dor. C. J.

The questions that followed were asked by the court and by counsel, thus establishing the independent attitude of the witness and relieving him from all temptation to indulge in partisanship at the expense of candor. The precedent is clearly an important one, and has an obvious value for future use in similar cases.

The result of the trial, in the reaffirmation of the proven guilt of the accused, is thoroughly acceptable to all who are familiar with the evidence in this cowardly and lustful homicide.

THE PASTEUR INSTITUTE, PARIS. — Since the 1st of January, 1886, over 11,000 people have been treated for rabies; and of these only 98 or 0.88% have died.

MEDICAL NOTES

CHOLERA is announced to be spreading in the Punjab. Many fresh cases have appeared since the return of the pilgrims from Hurdwar, where they were disbanded owing to a virulent outbreak of the disease.

LADIES' DRESSES AND CONTAGION.—The medical press in different parts of the world appears to have begun a crusade against the recent fashion of long skirts. This stirrer of dust and carrier of infection is supposed to be especially dangerous as a distributor of a tubercle bacillus.

VIRGINIA MEDICAL LAW.—Our note of April 14th, that the Supreme Court of Virginia have decided that the Medical Law of the State was unconstitutional, was founded on an erroneous communication from Richmond. We have since been informed that the decision in the case referred to did not deny the constitutionality of that law.

MORTALITY OF NEW YORK STATE FOR THE FIRST QUARTER OF 1892.—During the first three months of the present year there were 35,193 deaths in the State. According to the estimate of the State Board of Health, the last epidemic of influenza beginning in December has already caused about 10,000 deaths, or one in each six hundred of the population.

MRS. OSBORNE'S RELEASE.—The Home Secretary has pardoned Mrs. Osborne, who is serving a sentence of nine months' imprisonment in England. Much has appeared in English papers concerning her state of health and her responsibility for her crime. Being pregnant, it was urged that her imprisonment was dangerous both for her and her future child, and this view appears to have been finally taken by the Home Secretary.

TUBERCULIN IN LEPROSY.—The *Lancet*, in a leading article, refers to forty-five cases of leprosy treated by tuberculin in different parts of the world and hitherto published. While some patients have shown improvement that has not been proved to be permanent, and in some was certainly only temporary, the benefit is too uncertain, too limited in character and time, and purchased at too great a risk of aggravation of the disease by the dissemination of new foci, for it to be recommended as a treatment for leprosy.

MEDICAL LEGISLATION IN OHIO.—The late Ohio legislature appears to distinguish itself by its bad medical legislation. A very moderate medical practice bill was before it, but the opposition of itinerant doctors and other medical monstrosities was so great that the bill was defeated "amid roars of laughter." On the other hand, it appropriated \$5,000 to test the efficacy of the Keeley cure. Each member is to have the privilege of sending one patient to be cured (or of going himself). As an offset to this they passed a law that any physician may ride on any freight train at his own risk by paying the full passenger fare.

A LAW TO SUPPRESS TUBERCULOSIS, especially in milk cows, has been signed by the governor of New

York. In general, the law authorizes the health inspectors to examine all the cattle in the State, and, when the disease is found, to cause the animal to be killed. The owner will be reimbursed for the actual value of the cow. The plan of carrying on this inspection has not been decided upon. An appropriation of only \$5,000 has been made for the purpose. The diary statistics of the State show that milk production is the largest industry in the State, and that it is greater than that of the milk production of all the other States put together. There are 11,600,000 milch cows in the State. The farmers sell to New York City \$11,500,000 worth of milk, and to the people of the whole State \$40,000,000 worth.

NEW ENGLAND.

PUBLIC INSTITUTIONS OF BOSTON.—The Mayor has sent to the Board of Aldermen requesting an appropriation to the amount of \$287,000.00 for the purpose of enabling the Department of Public Institutions to dispense with the insane hospital at South Boston.

DIPHTHERIA IN DORCHESTER.—A small epidemic of diphtheria has broken out in Dorchester among the pupils of the Atherton School. The first case occurred on April 14th; a little girl spent a whole day in her class while suffering from unsuspected diphtheria. Ten children who sat in the same room with this patient were subsequently affected.

NEW YORK.

MEMORIAL PAVILION TO DR ABRAM DU BOIS.—The family of the late Dr. Abram Du Bois have announced to the Trustees of the New York Eye and Ear Infirmary their intention of presenting the sum of \$80,000 for the erection of a new pavilion as a memorial of Dr. Du Bois, who for nearly fifty years was attending and consulting surgeon to the Institution, and was always one of its most devoted friends and munificent benefactors. The plans for the new buildings of the Infirmary include three pavilions. One of these has already been erected, and in order to remove the old buildings and put up the other two pavilions about \$70,000 in addition to the Du Bois gift is required.

THE COLLEGE OF PHARMACY.—The sixty-second annual commencement of the College of Pharmacy of the city of New York was held in the Carnegie Music Hall on May 3d. There were 103 graduates, who received their degree from President Samuel W. Fairchild.

INFECTIOUS DISEASES.—Cases of typhus fever are still continuing to develop occasionally in the city, and on the 5th of May no less than three were discovered. Two of the patients were inmates of tenement-houses where typhus fever cases had previously existed. Vessels are now constantly arriving from Brazilian ports on board which there have been cases of yellow fever during the voyage, or

before leaving. Five of the crew of the British steamer *Glengoil*, which reached quarantine on May 3d, died of the disease, and another, believed to be fatally ill with it, was left at the hospital in Rio Janeiro. The steamship *Advance*, which arrived May 4th, had also had yellow fever on board, and the ship's surgeon, Dr. Randle, was sent to the hospital at Para, suffering from the disease. Measles is now more prevalent, it is said, than has been the case for a quarter of a century. During the week ending April 23d there were reported 529 cases, with 23 deaths, and during that ending April 30th, 628 cases, with 25 deaths. Since then the cases have been even more numerous.

Miscellany.

INVESTIGATION OF THE OUTBREAK OF TYPHUS FEVER.

On April 30th the sub-committee of the joint Senate and House Committee on Immigration and Naturalization, examined a number of medical witnesses in regard to the recent outbreak of typhus fever.

Dr. Wm. T. Jenkins testified that the surgeon of the steamship *Massilia* was a capable and careful officer. The Russian Hebrew passengers, he said, were in a starving condition, not owing to the negligence of the steamship company, but because they refused all food other than that prepared by their own rabbi. He expressed the opinion that his own legal responsibility ceased after the passengers of any vessels passed examination at quarantine. He described the method of quarantining four patients who were discovered in the city, and stated that the Health Department of New York had been successful in practically stamping out the typhus outbreak.

Dr. Cyrus Edson, Sanitary Superintendent, was next examined, and in reply to a question from the Chairman of the Committee, Mr. Chandler, as to whether a ship at sea was a likely place for the development of typhus fever, described the conditions which were peculiarly favorable for such development.

Mr. Chandler then paid a graceful compliment to the New York Board of Contagious Diseases, saying, "Dr. Edson, all the senators and members of the House are impressed with the manner in which the disease was handled. I speak for them all, or I should not speak at all."

Dr. H. I. Biggs, one of the pathologists to the Health Department, was examined with a view of ascertaining from him as an expert, the possibilities and probabilities of infection and the mode of development and spread of typhus. His opinion in regard to the *Massilia* outbreak was that the disease had developed in the baggage or that otherwise its spread would have been greater. He, too, expressed the opinion that the conditions on board the vessel afforded ample scope for the development of typhus. He had little faith, he said, in the method of fumigating vessels.

The agent of the Fabre Line, to which the *Massilia* belongs, was requested to notify the Committee immediately on the next arrival of that steamer, in order that the captain and surgeon might be summoned before them for examination.

THE REFORM OF GERMAN ANATOMICAL NOMENCLATURE.¹

PROF. WILHELM KRAUSE, who has resigned his professorship at Göttingen, is coming to Berlin to create a uniform anatomical nomenclature. He has undertaken this task at the instance of the Anatomical Society, which has busied itself for five years past with the question, How is the confusion in anatomical nomenclature to be remedied? This question was thoroughly discussed at the third assembly of that Society in 1889. Professor His of Leipsic showed on that occasion how the present multifrom anatomical nomenclature had arisen, and how it could be simplified. It was determined that, in the creation of a new nomenclature, regard must be paid not only to descriptive, but also to general and comparative anatomy and to embryology, and that the reform must be based on a complete list of the technical expressions of anatomy, in which all the changes of meaning which each expression has undergone are stated. It was further decided that all that is good in the present nomenclature should be retained, and that expressions containing proper names should not be dropped. Professor His uttered a warning against going too far in the Germanization of words derived from the Greek and Latin, on the ground that such a change would render mutual understanding between German and foreign anatomists more difficult. A committee was appointed to arrange for and superintend the work, and it was resolved that the work itself should be entrusted to an anatomist of reputation. The members of the committee elected in 1889 are Kölleker, Oskar Hartwig, His, Koilmann, Merkel, Schwalbe, Toldt, Waldeyer, and Karl Bardeleben; and their number was augmented in following year by the election of Cunningham of Dublin, Leboucq of Ghent, and Romiti of Pisa, in order that due regard may be paid to the necessities of foreign anatomists. The work was entrusted to Professor Wilhelm Krause, who will have to devote several years to it. The expenses will be defrayed by the Anatomical Society and the Universities of Berlin, Vienna, Munich and Leipsic.

MYXEDEMA WITH INSANITY TREATED BY INJECTION WITH EXTRACT OF THYROID GLAND.

DR. ERNEST C. CARTER of the Lancashire County Asylum reports (*British Medical Journal*) one case treated in this way apparently with great benefit. The patient had been an inmate of the asylum for four years. Undoubtedly the amelioration of bodily condition was much more distinct than that of the mental; for while one could not well say that there were any obvious morbid physical conditions after the course of treatment, and certainly none characteristic of myxedema, the patient's intellectual powers remained in a degree impaired. She was still partially demented, with a tendency to emotionalism. The injections were stopped on account of failure in the supply of fresh thyroids, or possibly a further improvement might have taken place; but the long establishment of mental symptoms makes it more than probable the irreparable degenerations have taken place in the cells of the brain cortex. Nevertheless the rapid progress of improve-

ment in the bodily and mental condition of this patient is strongly corroborative testimony to the value of this method of treatment.

Regarding the method of preparing and administering the extract, Dr. Carter says: "At the outset I followed strictly the procedure detailed by Dr. Murray, but, subsequently, with the object of getting the strongest possible dose of the active principle in a bulk not inconveniently large for injection, I modified the steps, and the method ultimately arrived at was as follows: The gland having been cleared of fat and fibrous tissue, a portion, as large as a damson, was cut up, put into a mortar with some glass (for example, a broken test tube), about half a drachm of glycerine and a drop or two of five per cent. of carbolic acid solution, and the whole ground together to a fine paste. The latter was allowed to settle in a test tube for twenty-four hours, leaving a clear, dark-red extract at the top, which was decanted off, and filtered through linen to insure freedom from glass particles. The extract was made fresh every week, strict antiseptic precautions being observed with regard to all utensils, etc., used, which were cleansed by means of boiling or washing with carbolic lotion, and a drachm of it was given every week in divided doses.

It seemed useless to pretend to any accurate dosage, and my efforts were directed, as above described, to procuring the strongest extract that could be conveniently used for injection. The site of the latter was on alternate sides, between the shoulder-blades, and an ordinary hypodermic syringe employed.

CREDÉ.

CARL SIEGMUND FRANZ CREDÉ, whose death was recorded in the *JOURNAL* of March 31st, was born at Berlin in 1819, and received his medical education at Berlin and Heidelberg. In 1843 he was made assistant to Busch, who was then at the head of the obstetric clinic at Berlin. He remained in this position until 1848. In 1850 he became a *Privat-docent*. His work, at this time, was put in a permanent form and published in two volumes under the title of *Klinische Vorträge über Geburtshilfe*.

In 1852 Credé was appointed director of the Berlin School for Midwives and the lying-in department of the Charité; with this he combined a gynecology clinic, which he himself started. Gynecology at that time was little more than a name, and a gynecological clinic was a novelty, not only in Berlin, but in Germany. From this time he began to teach the method of managing the third stage of labor, which is, in German obstetric literature, identified with his name. His method was modified by others, and changes introduced which were not improvements, and which were sometimes erroneously associated with Credé's name; but the directions which he gave at the beginning of his career were those which he taught at the end, and which are now recognized as being sound and safe practice.

In 1853 he began to be associated with Busch, Ritgen and Siebold in the editorship of the *Monatsschrift für Geburtkunde und Frauenkrankheiten*. In this occupation he continued until his last illness. The *Monatsschrift* ceased to appear, the *Archiv für Gynäkologie* taking its place, but Credé remained at

¹ Lancet, Berlin Correspondence.

the head of the new as of the old journal, greatly to the advantage of both, for nearly thirty-nine years.

In 1856 he succeeded Jörg in the chair of midwifery at Leipzig. Soon after his settlement in that town he founded the Obstetrical Society there. He established an out-patient department both for obstetrical and gynecological cases, and thus more fully utilized the material which that large city offered for the instruction of students. He held this post till April 1, 1887, when illness obliged him to resign it. His most conspicuous public service was the introduction of his method of preventing ophthalmia neonatorum. This great and solid discovery became known and practised all over Germany, and, indeed, in every civilized country, although in different places changes in detail have been made. Crede had the great satisfaction of knowing, even as soon as ten years after the introduction of this mode of preventing the disease, that in the asylums and other institutions for the blind a distinct diminution in the number of applicants whose blindness dated from their birth was perceived. He strongly advocated the delivery with forceps of the after-coming head.

Crede devoted his best energies to the teaching of midwifery, which he considered his most important duty. He held that those who, as students, had not paid much attention to gynecology, could repair this omission afterwards; but that no one should go forth into practice insufficiently instructed in midwifery. He wrote a text-book on midwifery for midwives, the clear style of which made it very acceptable, and which has gone through five editions. When gynecology took the surgical direction in which it has of late been advancing, Crede began to undertake the major operations; but, as he found himself growing old, he gave them up.¹

THERAPEUTIC NOTES.

GUAIACOL CARBONATE. — Seifert and Hölscher² have used this preparation in the treatment of tuberculosis, and have obtained better results than with either creosote or guaiacol. Beginning with a dose of one-third grain, the amount was increased as high as ninety grains daily, without disturbance of the digestive or nervous system. Carbonate of guaiacol is an odorless, tasteless, micro-crystalline powder, insoluble in water, slightly soluble in cold alcohol, and easily soluble in hot alcohol. It is a solid crystalline, chemically pure substance. It is separated into guaiacol and carbonic acid in the intestine.

A REFRESHING BEVERAGE. — Bamberger³ suggests the following to quench the thirst of pneumonia patients:

R. Acid phosphorhei	3 ij.	M.
Syrup rubi idem	3 ij.	M.
Sig. To be taken in water.		
R. Potassii bitartratis	3 ss. ij.	
Syrup rubi idem	3 ss. x.	
Aqua	3 xiij.	M.
Sig. Use as a refreshing drink.		

EXOPHTHALMIC GOITRE. — Dressman⁴ reports three cases of exophthalmic goitre, which were very much benefited by tying the inferior thyroid arteries. The goitre diminished in size, the exophthalmia almost en-

³ Satellite, May.

⁴ Deutsche med. Woch., February 4th.

tirely disappeared, and the cardiac disturbance was quite, or nearly cured.

THIOPHENIODID. — Spiegler and Hoch⁵ report a new drug which they consider superior in many ways to iodoform in the treatment of wounds. This drug has the formula $C_4H_2I_8S$, forming in tubular crystals, slightly volatile and melting at 40.5°C . In water it is insoluble, but easily dissolved in ether, chloroform and warm alcohol. The odor is an unpleasant aromatic one. To saturate gauze the following is used:

R. Thiophen-di-iodid	50
Alcohol }	55 500
Ether }	
Glycerine	10 M.

Correspondence.

COTTAGE HOMES FOR TRAINING NURSES.

YOKOHAMA, JAPAN, March 25, 1892.

MR. EDITOR: — A recent writer on Japan is reported to have been inspired by the earthquake to express himself in this wise: "It imparted a feeling of pleasure rather than apprehension to realize that the planet itself was also quick and active, full of secret developments and hidden evolutions, shaping itself for fate's destinies with these throes and soft, mysterious upheavals." The earthquake, with its disastrous results, has moved the woman's heart of Madame Sannomiya to do something for the young girls whose homes have been destroyed by these "mysterious upheavals." Some of these children were at the same time bereft of parents and relatives.

The practical outcome has been the preparation, in Tokyo, of a home where the Japanese girls are taught the various duties and industries which experience has shown to be useful and appropriate to their sex. One house, with suitable grounds, has lately been bought, and arranged for fifteen girls, though at present but thirteen are under instruction. The education is to prepare them to act as nurses, in addition to the usual occupations of woman's life; for the natural condition of woman includes marriage, and this is kept in view by those who are thus striving to start a new form of home-economy in the midst of this nascent civilization change. It is not designed to erect large orphan asylums, but rather to establish, in various places, small houses similar to that referred to, which will serve as seed-plants or centres whence the new light and mode of living (single or married) may spread, to be a model for those who are able and willing to be and to do better, physically and in mind and heart.

A great merit of such doings is the purpose that the less informed Japanese may thus learn and be incited to do for themselves, taking a lively and properly selfish interest in progressive improvement.

Other ladies associated as a committee with this enterprise of loving-kindness are Mrs. Caroline Kirkes and Mrs. Mary Shaw.

Very respectfully,

F. B. STEPHENSON.

A SWINDLER.

WATERBURY, CONN., May 5, 1892.

MR. EDITOR: — It may be of use in exposing a swindler and stopping his further operations if you will state in the *Boston Medical and Surgical Journal* that a man giving his name as "Jno. D. Martin," and pretending to be an agent for the "Home Supply Association, 315-321 Wabash Avenue, Chicago, R. S. Peale, General Manager," with a branch office at No. 2 Beacon Street, Boston, has been exploiting towns in Connecticut. He has no credentials.

Yours truly, WALTER H. HOLMES, M.D.

⁵ Medical Press.

METEOROLOGICAL RECORD.

For the week ending April 30, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:

Deaths reported 3,292: under five years of age 1,259; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 450, acute lung diseases 617, consumption 427, diphtheria and croup 179, scarlet fever 64, diarrhoeal diseases 58, measles 37, typhoid fever 33, cerebro-spinal meningitis 27, whooping-cough 26, erysipelas 10, malarial fever 8, small-pox 5.

From New York 25, Brooklyn 4, Chicago 3, Philadelphia and Cincinnati 1 each, Milwaukee 1, Fall River 1, typhoid fever Philadelphia 11, Charlestown 9, New York 6, Brooklyn 1, St. Louis, Boston, Cincinnati, Pittsburgh, Nashville and Lawrence 1 each. From cerebro-spinal meningitis Chicago 9, New York 6, Brooklyn and Washington 4 each, Cleveland 3, Nashville 1. From whooping cough New York 10, Fall River and New Bedford 3 each, Chicago and Washington 2 each, Philadelphia,

Brooklyn, Boston, Cincinnati, Pittsburgh and Milwaukee 1 each. From erysipelas Brooklyn 3, New York, Chicago and Philadelphia 2 each, St. Louis 1. From malarial fever New York 4, Charleston 2, Brooklyn and Cleveland 1 each. From small-pox New York 5.

In the thirty-three greater towns of England and Wales with an estimated population of 10,185,736, for the week ending April 16th, the death-rate was 20.9. Deaths reported 4,080: acute diseases of the respiratory organs (London) 389, measles 177, whooping-cough 175, diphtheria 50, diarrhoea 43, scarlet fever 20, fever 20.

The death-rates ranged from 13.9 in Brighton to 28.3 in Saltford; Birmingham 21.1, Bradford 23.2, Croydon 14.2, Oldham 23.4, Hull 21.3, Leeds 21.5, Liverpool 22.0, Liverpool 28.1, London 19.4, Manchester 27.0, Newcastle-on-Tyne 21.2, Nottingham 19.1, Sheffield 24.7, West Ham 15.1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,188,449, for the week ending April 23d, the death-rate was 21.8. Deaths reported 4,253: acute diseases of the respiratory organs (London) 389, measles 197, whooping-cough 172, diarrhoea 58, diphtheria 46, scarlet fever 44, fever 20.

The death-rates ranged from 13.9 in Brighton to 28.3 in Bolton;

Birmingham 22.8, Gateshead 18.2, Hull 20.6, Leeds 22.4, Leicester 21.4, Liverpool 23.6, London 21.9, Manchester 25.8, New-

castle-on-Tyne 25.5, Sheffield 25.6, Sunderland 23.9.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 1, 1892, TO MAY 6, 1892.

Leave of absence until July 10, 1892, is granted LIEUT.-COL. WILLIAM D. WOLVERTON, assistant medical purveyor, U. S. A.

CAPTAIN AARON H. APPEL, assistant surgeon, is relieved from duty at Fort D. A. Russell, Wyoming, and will report in person for duty to the commanding officer, Fort Buford, N. D., relieving CAPTAIN JULIAN M. CARELL, assistant surgeon, who will then report in person for duty to the commanding officer, Fort D. A. Russell, Wyoming.

CAPTAIN ROBERT R. BALL, assistant surgeon, U. S. A., is relieved from further duty at Fort Spokane, Washington, and will report in person to the commanding officer, Fort Townsend, Washington, for duty at that station.

CAPTAIN LOUIS W. CHAMPTON, assistant surgeon, U. S. A., is relieved from further duty at Fort Townsend, Washington, and will report in person to the commanding officer, Fort Spokane, Washington, for duty at that station.

FIRST-LIEUT. ALFRED E. BARDLEY, assistant surgeon, U. S. A., will, upon the activation of acting assistant surgeon, GEORGE D. DESHON, U. S. A., at Columbus Barracks, Ohio, return to his proper station (Omaha, Nebraska).

The leave of absence granted CAPTAIN GEORGE McCREEVY, assistant surgeon, U. S. A., for seven days, is extended fifteen days.

FIRST-LIEUT. HENRY D. SNYDER, assistant surgeon, U. S. A., granted leave of absence for one month and fifteen days, to take effect, when his services can be spared by his post commander.

AMERICAN SURGICAL ASSOCIATION.

PRELIMINARY PROGRAMME.

The Association will meet in Boston, Mass., Tuesday morning, May 31, June 1 and 2, 1892, in the hall of the Natural History Society on Berkeley Street.

1. "The Treatment of Uncomplicated Fractures of the Lower End of the Humerus and of the Base of the Radius," by JOHN B. ROBERTS, M.D., Philadelphia, Pa. Discussion by DR. JOHN E. OWENS, of Boston, and DR. W. B. DODD, of Philadelphia, C. B. 2. "Fibroid Tumors of the Uterus," by JOHN HOMANS, M.D., Boston, Mass. Discussion by DR. F. E. LANGE, of New York, M. H. RICHARDSON, of Boston, A. M. VANDER VEER, of Albany, J. EWING MEARS, of Philadelphia, and GEORGE R. FOWLER, of Brooklyn.

3. "Surgical Operations in Persons Suffering from Diseases not connected with that necessitating the Operation, such as Chronic Malarial Poisoning, Diabetes, Organic Heart Disease, etc." by W. T. BRIGGS, M.D., Nashville, Tenn. Discussion by DR. T. F. PREWITT, of Cincinnati; HUNTER McGUIRE, of Richmond, and W. W. DAWSON, of Cincinnati.

4. "Surgery of the Tongue," by N. P. DANBRIDGE, M.D., of Cincinnati, Ohio. Discussion by DR. D. W. CHEEVER, of Boston, DR. D. W. YANDELL, of Louisville, and L. MCLEANE TIFFANY, of Baltimore.

5. "Conditions demanding Excision of the Globe of the Eye," by W. H. CARMALT, M.D., New Haven, Conn. Discussion by DR. W. M. THOMPSON, Philadelphia, Pa.

6. "Ancient Contractures of the Hip and Knee Joints," by

T. F. Prentiss, M.D., St. Louis, Missouri. Discussion by Drs. DeForest Willard, of Philadelphia, and Robert Abbe, of New York.

7. "Report of Operations upon Spina Biifida and Encephalocele, with remarks," by A. T. Cabot, M.D., Boston, Mass.

The Association will meet on Wednesday morning, in the Amphitheatre of the Massachusetts General Hospital, and on Thursday morning in the Amphitheatre of the Boston City Hospital.

PHINEAS S. CONNER, President.

J. R. WEIST, Secretary.

ANNUAL MEETING OF THE BOSTON MEDICAL ASSOCIATION.

The annual meeting of the Boston Medical Association will be held at 19 Boylston Place, Friday, May 30th, at 4 o'clock. This Association has adopted and maintained the fee table which is the standard used in the City of Boston. Membership in the Association may be had by the payment to the secretary of a nominal fee of one dollar and the signing of the Constitution of the Association.

The special business before this annual meeting is the election of a member to the executive committee to fill the vacancy made by the death of Dr. Buckminster Brown.

CHARLES L. SCUDDE, M.D., Secretary, 94 Charles Street.

CENSORS' EXAMINATION.

The Censors of the Suffolk District Medical Society, officiating for the Society of Boston, will meet for examination of candidates for admission to the Massachusetts Medical Society, at 19 Boylston Place, on Thursday, June 2, 1892, at 2:30 P.M.

Candidates should make personal application to the Secretary, and present their medical diploma, or its equivalent, at least three days before the examination.

For further particulars, apply from 2 to 3 P.M., to
JAMES J. MINOT, M.D.,
188 Marlborough Street.

MASSACHUSETTS VOLUNTEER MILITIA.—BOARD OF MEDICAL OFFICERS.

There appeared before the Board this day (May 5, 1892) LIEUTENANT JOHN F. HARRY, of Boston, who was examined and qualified as Assistant Surgeon, Battery A, Light Artillery, Second Brigade.

APPOINTMENTS.

W. T. COUNCILMAN, M.D., Associate in Pathology in the Johns Hopkins Hospital, Baltimore, has been appointed Shattock Professor of Pathological Anatomy in the Harvard Medical School.

The Governor has reappointed DR. ELIJAH U. JONES, of Taunton, to be a member of the Massachusetts State Board of Health.

At a meeting of the Trustees of the Free Hospital for Women, held April 13th, DR. JOHN HOMANS was unanimously elected consulting surgeon to fill the vacancy caused by the death of DR. D. Humphreys Storer.

RESIGNATION.

DR. F. L. KNIGHT has resigned the Clinical Professorship of Laryngology in the Harvard Medical School and the position of Physician for Diseases of the Throat in the Massachusetts General Hospital.

RECENT DEATHS.

JOHN B. VAN BIBBER, M.D., died in Baltimore, May 5th, aged forty-two years. He was a member of the American Neurological Association and of the Medical and Chirurgical Faculty of Maryland.

HARVEY G. MCINTIRE, M.D., died in Concord, N.H., May 9th. He graduated from the Harvard Medical School in 1848, and has lived in Concord since 1863.

RUTSON MAURY, M.D., died in New York City, May 5th, aged twenty-seven years. He graduated from the Bellevue Hospital Medical College in 1887.

W. S. HOPKINS, M.D., of Vergennes, Vt., died May 8th, aged sixty-five years. He had been in active practice for more than forty years, and had served as mayor of the city and in the State legislature.

JOHN GEORGE MOORE, M.D., died in New York, April 30th, aged twenty-nine years. He graduated with honor from the

College of Physicians and Surgeons in 1888, and was subsequently house-physician at St. Vincent's Hospital.

CHARLES F. STILLMAN, M.D., formerly of New York, but lately of Chicago, died of tuberculosis in Plainfield, N.J., on April 30th. While still a young man he showed marked ability in his profession, and he early attained unusual success, especially in the department of orthopedic surgery. At the time of his death he was not yet forty.

GEORGE BROWN, M.D., M.M.S.S., of Barre, died in New York, May 6th, aged sixty-eight years. He graduated from the College of Physicians and Surgeons in New York in 1850, since which year he has lived in Barre. In 1851 he became proprietor of the Institution for Feeble-Minded Youth, which he conducted until his death. He was for several years a councilor of the Massachusetts Medical Society, and in 1889, president of the Worcester District Society.

WILLIAM B. FRIEKE, M.D., M.M.S.S., died in Cambridge, May 9th, aged thirty years. He graduated from Harvard College in the class of 1882 and from the Medical School in 1887.

BOOKS AND PAMPHLETS RECEIVED.

The Anthropometric Tables of Amherst College. 1892.
Athetosis with Clinical Cases. By Archibald Church, M.D. The Insane and the Asylums. By Horace G. Wetherill, M.D. Drug Habituuation. By Lucius W. Baker, M.D. Reprint. 1892.

Gastrectomy. By N. Senn, M.D., Ph.D., Chicago. Reprint. 1892.

Lecture.**NEW OUTLOOKS IN THE PROPHYLAXIS AND TREATMENT OF TUBERCULOSIS.**

THE MIDDLETON-GOLDSMITH LECTURE FOR 1892.

BY FRANCIS P. KINNICUTT, M.D.,
Physician to St. Luke's Hospital and the Presbyterian Hospital,
New York.

GENTLEMEN:—When your committee did me the honor to request my acceptance of the Middleton-Goldsmith lectureship of the present year, and suggested the subject, "The Present Aspect of the Treatment of Tuberculous Disease and especially of Pulmonary Tuberculosis," my first inclination was to decline. Their representations that a review of this subject was particularly desirable at the present time and would serve a practical purpose, have alone induced me to undertake a difficult task.

The lecture has been postponed beyond the customary time of its delivery, in the hope that investigations which have been carried on during the past winter in St. Luke's Hospital and in the Pathological Laboratory of the College of Physicians and Surgeons, might be sufficiently advanced to be incorporated in it. This hope, in part, has been fulfilled.

Any consideration of methods of treatment of infectious diseases, at the present time, must necessarily be in the light of modern pathology and bacteriology. Through the discoveries in this field of medicine, the term *treatment* has acquired a new significance. A large number of the infectious diseases of human beings and of animals have already been shown to have their origin in specific pathogenic living organisms; and there are strong reasons for believing that a similar etiology will be demonstrated in the near future for all diseases hitherto included in this category.

In the infancy of bacteriology, it was not unnatural to assume that the sowing of the seed was alone necessary for the production of a disease, that if once the specific germ gained access to the economy, its particular effects would certainly follow. The "possession of a self-protecting power by the organism of man and of the higher animals, which could exercise its influence within certain limits either in arresting the development of the living excitors of disease or in counteracting their poisonous products" was hardly dreamed of. To-day the splendid discoveries of bacteriological research have abundantly demonstrated that an unceasing contest is being waged between the growing power and toxic activity of the pathogenic microphage and the living organism.

In this connection, what can be of more absorbing interest than the discovery by the distinguished plant physiologist Professor Pfeffer,¹ of the group of phenomena, to which he gave the name of chemotaxis, the definite relation between vital movement and chemical action. Later, it was suggested by Dr. Leber, that the emigration of leucocytes in the human body was due to the same power. In other words, that certain harmful substances in the living tissues, embracing effete materials, living pathogenic organisms and viruses of various kinds are agreeable to a rudimentary sense of taste, as it were, in the leucocytes, which are thus allured from the media in which they commonly live, towards the attracting substance.

The mustering of the leucocytes in troops in the neighborhood of the bacterial invaders of the body, as

a direct or indirect protection to it, is almost as dramatic as it is important. This action of the leucocytes, in virtue of their chemotaxis, and the final incorporation or digestion by them of the bacteria, constitutes Metchnikoff's well-known theory of phagocytosis and phagocytic immunity.

Further, we may refer to the investigations of Büchner² and Roemer, showing the association of a general leucocytosis with febrile inflammatory processes. They found that within eight hours after the intravenous injection, in rabbits, of various proteids, the result was marked leucocytosis; the relation of white to red blood-cells on the evening of the fourth day of the daily injection of solutions of the protein of the bacillus pyocyaneus (green pus) was 1 to 38, the absolute number of the red blood-cells remaining unchanged. It should be mentioned that the office of policeman, on the part of the leucocyte is not considered proven at the present time, by many. Their work as scavengers is acknowledged, but it is believed that the true guardianship of the body resides in the body fluids; in other words, that the destruction of bacteria is accomplished by the germicidal power of the latter, and their removal only is affected by the leucocytes.

Finally, we may refer to the investigations which have shown that "while the living tissues and fluids of the body possess the power in varying degree, of arresting the development of living, disease-producing organisms, and of eventually destroying them, certain life products of the latter are capable of impairing or inhibiting this protective power."

In view of such facts, preventive medicine must necessarily embrace the means of promoting the victory of the organism in its contest, either by strengthening its defences or by weakening or destroying the power of the growing microphage.

With our present knowledge of the various media in which the specific living excitors of disease most commonly lurk, it should be a matter of reproach if we fail in securing a more efficient prophylaxis than has been possible in the past.

Previous to 1882, the pulmonary lesions of tuberculosis had been accurately described; and Villemin, as a result of his successful inoculations of animals, had declared it to be a specific infectious disease. With the announcement of Koch, on March 14th of the above year, that he had discovered not only the constant accompaniment but the cause of the tuberculous process, the infectious nature of tuberculosis was finally established and the nature of the relation between specificity of cause and specificity of process in this disease was determined.

Before proceeding further, it will be advantageous to have accurately pictured in our minds the pulmonary lesions which are directly or indirectly due to the tubercle bacillus. The list is indeed a formidable one. Miliary tubercles both single and conglomerate, larger and smaller areas of epithelioid-cell growth called diffuse tuberculous tissue, and various aggregations of these, often in a state of more or less advanced coagulation necrosis, disintegration and excavation as a result of the latter, cicatrical formation, peribronchitis and extensive inflammatory consolidations specific in nature; and finally we must bear in mind the bronchitis and lobular pneumonias probably simple (unspecific) in character, so frequently present in tuberculous lungs.

In the light shed by modern research upon the possession by the organism of man of a self-protecting power against pathogenic organisms, with a knowledge of the specific organism which causes tuberculosis and the lesions which are directly or indirectly produced by its presence in the economy, we are proportionately equipped to attempt to consider the measures, prophylactic and remedial, which have been proposed to cope with the disease.

Prophylactic measures must necessarily consist of those designed to destroy the vitality of the bacillus outside of the human body, to minimize the sources of infection and to render the tissues insusceptible to its presence.

Three possibilities suggest themselves as *specific* means for exercising a *remedial* effect. They are: (1) the discovery of a method of treatment capable of destroying the bacillus within the body; (2) of some substance, organic or inorganic, which by its introduction into the body, may so modify the action of the bacillus, as to deprive it of its harmful effects—the possible abstraction of a constituent of its protoplasm or of its metabolic products, analogous to the tetanus or pneumonic antitoxin, suggests itself in this connection; (3) the discovery of a principle capable on introduction into the economy of increasing the germicidal power of the fluids of the body by stimulating cell activity upon which it ultimately depends, or by such stimulation inducing connective tissue changes in tuberculous tissue, or both.

PROPHYLAXIS.

I shall first consider the prophylaxis of tuberculosis, so far as it relates to destroying the vitality of the bacillus outside of the human body and to minimizing the sources of infection.

With the discovery of the specifically infectious nature of a disease, the means of infection are not necessarily directly evident. In tuberculosis, a series of brilliant investigations quickly threw much light upon this point. Following Koch's discovery, it was very early shown that the bacilli were not contained in the air expired by patients suffering from pulmonary tuberculosis; on the other hand, that their sputum contained bacilli in enormous numbers. It was further shown that the bacilli were incapable of escaping from fluid media, and finally, that the sputum in the dry state, conveyed in the form of pulverized atoms by currents of air, was the most common source of infection. Successive investigations demonstrated that the stools of human beings afflicted with the intestinal form of the disease, the discharges from tuberculous ulcers, glands and bones were positive, if infrequent vehicles of infection; and, finally, that the milk of tuberculous cows, with or without disease localized in the udder, and tuberculous meat were capable of producing tuberculosis in the consumer.

It will be interesting to refer at somewhat greater length to inoculation experiments and clinical observations bearing on the above points.

The elaborate investigations of Cornet,⁸ in the Berlin Institute of Hygiene, in regard to the distribution of the tubercle bacilli in the air, are particularly instructive. The dust from twenty-one wards of seven hospitals, from three asylums, two prisons, from the living-rooms of sixty-two phthisical patients in private practice, from "out-patient" departments, from the public streets and from inhalation experiment rooms

was gathered, and its virulence or innocuousness determined by inoculation of susceptible animals. Of ninety-four animals inoculated with the dust of hospital wards, twenty became tuberculous. Virulent bacilli were obtained from fifteen out of twenty-one medical wards. Negative results, on the other hand, were obtained from the dust of the surgical wards, also from that of the streets and the inhalation rooms investigated. Of one hundred and seventy animals inoculated with dust from the living-rooms of consumptives, thirty-four became infected. As ninety-one of the one hundred and seventy died of septic disease, it is probable that the above percentage of animals in which tuberculosis was produced does not accurately represent the specific (tuberculous) virulence of such dust. The dust was taken from the walls, articles of furniture, picture-frames, etc. From the room of a consumptive in a private house, virulent bacilli were obtained six weeks after her death.

Cornet records the fact that he did not once find infective bacilli in the rooms of those patients who used only spittoons for the sputum, although especially careful search was made in these instances. Equally valuable evidence on this point is furnished by Trudeau.⁴ In his sanitarium at Saranac Lake, where rigid rules, in regard to the use of proper receptacles for the sputum, are enforced, and its efficient disinfection or destruction is accomplished, not a single employee has acquired tuberculosis during the six years since its institution.

In Dettweiler's sanitarium at Falkenstein, where presumably similar precautions are taken, a similar experience is claimed.

With such observations before us, further *clinical* statistics may be unnecessary, but are not without interest.

In response to questions sent, in 1883, by the Collective Investigation Committee of the British Medical Association to physicians throughout Great Britain,⁵ asking for their personal experience on the communicability of phthisis, 1,078 communications were received. Of these, 673 were to the effect that cases of tuberculosis originating in infection had not come under their notice. Of the remaining 405, 261 were regarded by the Committee as positive in evidence of communicability, 39 as doubtful and 105 as negative. Among the affirmative observers, 192 reported cases of probable infection of husband by wife and the converse, and in 130 of these cases there was entire absence of inherited predisposition on the part of the person infected.

Turning to our own country, the investigations of Flick⁶ are of much interest. The localization of, and mortality from, tuberculosis in one of the wards of the city of Philadelphia, for a period of twenty-five years preceding 1888, were very carefully studied by him. It is shown that while less than one-third of the houses of the ward became infected with tuberculosis during the twenty-five years prior to 1888, considerably more than one-half of the deaths from this disease during the year 1888, occurred in infected houses. Inasmuch as there were more than twice as many non-infected as infected houses in the ward, a preponderance of deaths in non-infected houses would be expected.

Cornet's investigations of the health statistics of the Catholic Nursing Orders of Prussia,⁷ may be considered as supplementary to those of the same author which have already been described. Thirty-eight con-

vents were selected, representing a yearly average of 4,028 persons, and the statistics relate to the twenty-five years preceding the year 1889. It is known that the general annual death-rate from tuberculous disease is from one-seventh to one-fifth of all deaths. Among the above orders, the enormous average mortality of 62.88 per cent. is shown to be due to tuberculosis alone. In nearly one-half the convents it even rises to seventy-five per cent., and in two "Mother Houses," it was the sole cause of death. In others, the death-rate from this disease varies from 40 to 50 per cent.

Cornet says that the different mortalities may be explained by the fact that some of the nurses are engaged in attending altogether, or, for the most part, upon surgical cases. The average age at death of the inmates is 36.27 years, lower by ten years than that of men engaged in trades notoriously the most unhealthful; that is, file-cutters, coppersmiths, locksmiths, blacksmiths, cotton-spinners, etc. If the mortality due to tuberculosis and that resulting from other diseases commonly regarded as infectious are both deducted from the death-rate in the Prussian State and in the convents, it is shown that up to the age of forty years, the death-rates in State and convents are remarkably equal. From forty to sixty years, the mortality due to non-infectious diseases is less in convent than in State. Even admitting the insanitary conditions of convent life, it is impossible to believe, with our present knowledge of the etiology of tuberculous disease, that it can produce it. On the other hand, these conditions are of the kind to lead to its rapid extension, when once introduced. It should be mentioned that the health of all persons on entering the Nursing Communities is excellent, admission being dependent upon medical certificates to this effect.

Among the numerous investigations^{8 9 10} of the infectiousness of the milk of tuberculous cows, I shall only refer to the very brilliant ones of our countryman, Dr. Ernst of the Harvard Medical School.¹¹ They surpass in their extent and importance those of Continental observers. Experimental inoculation in rabbits and guinea-pigs and feeding experiments in calves and pigs with both the milk and cream of tuberculous cows *without* disease of the udder, proved in the most positive manner that such milk is capable of producing tuberculosis in the consumer. Incidentally, in experiments with milk taken at random from the common dairy-supply of Boston, virulent bacilli were found in two instances.

If Dr. Ernst's experiments are supplemented with the clinical fact of the frequency of intestinal and mesenteric tuberculous disease in children, and with the statement made in the form of a resolution, by the United States Veterinary Association in 1889, that from ten to fifteen per cent. of the dairy stock of the Eastern States is tuberculous, this subject assumes very grave importance. Although investigations have shown that tuberculous meat as such is infective, further experiments are necessary to determine whether those parts of a tuberculous animal usually used for food and not specifically affected, are harmful.

I have been able to collect a large number of cases of probable inoculation-tuberculosis in the human being. Many of them occurred through infection of post-mortem and dissection wounds. Among others, the following are of interest:

A healthy girl of 14 years, without inherited predisposition, became locally infected through wearing

the ear-rings of a consumptive. A tuberculous infiltration of the glands and general infection followed.¹²

A male child, very vigorous at birth, began to suffer when three years old from eczema of the skin of the abdomen. Bacilli were searched for, but not discovered. After four years of age, he constantly slept with his consumptive mother, and bacilli were shown to be present in the eczematous vesicles.¹³

A student received a slight wound in dissection; a nodule appeared at its site and a swelling of the glands of the forearm followed. The glands were excised, and showed central cheesy degeneration.¹⁴

Ten Jewish boys were circumcised by the same physician only a short time before his death from consumption. There is positive evidence that the saliva of the operator came in contact with the preputial wounds. The first symptoms of infection developed ten days later. Three of the children died of tuberculous meningitis, three of marasmus, and one of intercurrent diarrhoea. Three survived, but developed tuberculous adenitis.¹⁵

Accumulated experimental and clinical investigations in demonstrating the most common sources of infection, namely, the sputum of patients suffering from pulmonary tuberculosis, the milk of tuberculous cows, and finally, though to a much less extent probably, tuberculous meat, clearly indicate the direction which prophylactic measures should take.

The enormous number of tubercle bacilli contained in the sputum of patients suffering from pulmonary tuberculosis, even admitting that many of them are dead, as Kitasato very recently has shown, is well known. In a series of investigations kindly made for me by Dr. T. Mitchell Prudden in 1891, as many as 21,460,000 were computed to be present in the daily sputum of a single patient. Nuttall's experiments¹⁶ conducted in the Johns Hopkins Laboratory, give quite similar results.

Sawizky¹⁷ has shown, moreover, that tuberculous sputum, dried and preserved under the conditions which usually obtain in the dwelling-house, preserves its infective properties for two and a half months.

Stone's experiments,¹⁸ if corroborated by further investigations apparently show that its virulence may be extended for as long a period as three years. If we further consider the exceptional resistance of the tubercle bacilli to the action of both chemical and other antisepsics, the efficient disinfection or destruction of tuberculous sputum becomes of vital importance.

Chemical Disinfection. — Carbolic acid, potassa, sulphate of copper and chloride of zinc, all in solutions of 1-500, were found by Grancher and de Gennes to be useless.¹⁹ Histological examination of the sputum so treated showed no change in the appearance of the bacilli and inoculations proved that they were still active. Later experiments²⁰ have demonstrated that carbolic acid even in ten per cent. solution and after twenty-four hours admixture with the sputum, is without effect.

Corrosive Sublimate is valueless through the coagulation produced by it of the albuminoids contained in the sputum. The experimental investigations of Schottelius and Spengler²¹ with the newer antisepsics, creolin, aseptol and lisol, of which much was hoped, have also been disappointing. Ten per cent. solutions of creolin and aseptol were found to be absolutely without effect, even after twenty-four hours.

Lisol, however, in ten per cent. solution proved to

be capable of rendering the sputum sterile in twelve hours.

These results indicate in the most positive manner that we possess no practical means at present for efficiently disinfecting sputum by chemical antiseptics.

Experiments with heat, on the other hand, have shown that the tubercle bacilli rarely survive a temperature of 80 C., and are invariably killed at temperatures varying, according to different observers, from 90 C., to 100 C.²¹ Simple rinsing of the cups or other receptacles of the sputum with boiling water is not sufficient and is not without danger to the attendant. Numerous observers report cases of infection of cuts from sputum. (V. Eisberg,²² Fleur,²³ Holst,²⁴ L. Pfeiffer²⁵ and others.)

In view of these facts, every consumptive should possess the knowledge that while his disease is in reality a menace to those about him, the foil is within his reach. He should be taught never to use a handkerchief for the sputum, never to spit upon the floor. An appropriate receptacle of glass, china or paper, partially filled with water should be provided for the sputum, which should be thoroughly disinfected or destroyed at least once in twenty-four hours. For its disinfection in hospitals, an ordinary Arnold's sterilizer, of sufficient size to accommodate all the cups of a ward, and in which they should be placed daily for a half-hour, may be used.

A far better method in my judgment, is the destruction of the sputum by fire. The method at present in successful use in St. Luke's Hospital and which is of easy application in private houses, consists in the use of paper boxes, which are daily supplied to each patient, and at the end of twenty-four hours destroyed with their contents, by fire. They are of convenient size, are very inexpensive, and the preparation used in their construction prevents all leakage. The floors and the walls of living-rooms and of hospital-wards of consumptives should be scrubbed or wiped with damp clothes, not swept or dusted. The cast-off clothing of such patients should be submitted to the action of live steam or to the degree of heat described as sufficient to destroy the tubercle bacilli.

Public sentiment, in the absence of legislation, should compel the proprietors of hotels and boarding-houses at health resorts, at least, to take such measures as can be designated with our present knowledge, for disinfecting the living-rooms of consumptives. Further investigations are urgently needed to determine the most efficient and practical means for accomplishing this object.

A further most important prophylactic measure consists in the systematic veterinary inspection of dairies, particularly those of large cities and of slaughter-houses. Commercial considerations have secured the necessary legislation for the inspection of the pork products of the United States; a consideration of the public health should be sufficient to secure a similar legislation to minimize the sources of infection of tuberculous disease.

A bill for the inspection of dairies and the slaughter of tuberculous animals, I am happy to state, will probably be introduced into the legislative houses of the State of New York during the present session. Such an example, it is reasonable to hope, would gradually be followed by the legislatures of other States.

In the meantime, in the absence of necessary legislation, the only safeguard possessed by the public

against possible infection through dairy products, consists in the sterilization of milk and cream by boiling, or through the use of steam sterilizers.*

Many of the prophylactic measures which have been mentioned have already been embodied in the form of suggestions or in laws by various governments and municipalities abroad, and the Board of Health of the City of New York has issued some admirable rules "to be observed for the prevention of the spread of consumption."

In considering the prophylaxis of tuberculosis, I have purposely confined myself to measures designed to destroy the vitality of the bacillus outside of the human body and to means for minimizing the sources of infection, in the belief that such efforts are of far greater relative value than those directed toward increasing the resisting power of the individual. I shall even go farther, and thus cease to be open to the reproach that the clinician's interest in the therapeutics of the disease is almost to the exclusion of that in its prophylaxis, and assert that infinitely more can be accomplished towards the elimination of this terrible scourge by making practical use of our present exact knowledge of its etiology and prophylaxis than by any or all therapeutic measures at present at our command. As has been well said, "It is the seed of the disease, without the implantation of which there can be no harvest of death, that we are now most able to reach and destroy." We shall fail then in our duties as true physicians, if we do not scatter broadcast among the laity this knowledge. From a full appreciation of the dangers at their doors and a knowledge of the means capable of diverting them, surely good fruit will be borne, even to the *enactment and enforcement* of laws for the protection of the public health.

In turning our attention to the remedial treatment of tuberculosis, our thoughts naturally are directed first to Koch's tuberculin.²⁶

His hypothesis of its specific mode of action is as follows: He particularly states that other explanations are possible and may be more correct. The tubercle bacilli in their growth produce in the living tissues, just as in artificial cultivations, certain substances which have various but always deleterious effects upon the living elements of their surroundings, — the cells. Among these substances is one which, in a certain concentration, destroys living protoplasm and causes it to undergo what is known as a coagulation necrosis. The necrotic tissue is unfavorable to the nutrition of the bacilli; its further development is checked, and finally in some cases its death follows. If the amount of the necrosis producing substance be artificially augmented, as he believes it to be by the introduction of tuberculin into the system, not only will the extent of the necrosis be increased and consequently the conditions of the nutrition of the bacilli be more unfavorably affected, but also more completely necrosed tissues will disintegrate and slough, and where this is possible, take with them the enclosed bacilli, carrying them outward. Large doses of tuberculin are capable of giving rise to a certain amount of pyrexia and other symptoms in healthy persons, he believes, through irritative influences exerted upon certain elements of the tissues, probably on the white corpuscles of the blood or cells closely related to them.

* Investigations conducted in the Imperial Health Bureau of Berlin demonstrate that tubercle bacilli also retain their vitality in butter and cheese, frequently for weeks.

The necrosis producing substance in tuberculin, Koch now tentatively believes to be an albumose or a substance closely related to it. Many elaborate criticisms of this hypothesis, both theoretical and based upon experimental and clinical investigations, have appeared during the past year.

In a very recent monograph by Rosenbach,²⁷ the author denies both a specific affinity of tuberculin for tuberculous tissue and the specific action claimed for it. The general reaction and constitutional disturbance following its inoculation, he believes to be due to a general irritation set up in the body, which, according to its degree, can assume the characteristics of an inflammatory action, in some cases even of a purulent type. The degree of the reaction, particularly of the fever, depends upon the predisposition of the individual to febrile disturbance. Similar constitutional disturbances have been shown to follow the inoculation of cantharid salts and the protein of other bacteria. Rosenbach asserts that the specific activity of tuberculin can only be demonstrated when it is proved that substances derived from other micro-organisms can produce fever exclusively in subjects who are the hosts of bacteria of the same kind, and further that they can evoke reactions only in tissues in which changes have occurred from their action and elsewhere remain without effect. He claims that hitherto this has not been shown. The author expresses a guarded opinion whether tuberculin produces an actual necrosis of tuberculous tissue; if it occurs, he believes it is not a coagulation (specific) necrosis, but rather is secondary to an acute inflammatory process and exudation.

A new light has been thrown on the nature and action of tuberculin through the investigations of Wm. Hunter, of England, and the German pathologist, Klebs. As early as January, 1891, the former began his investigations.²⁸ Starting with the assertion of Koch that the remarkable properties possessed by it, unfortunately for evil as well as for good, were due to a single active principle which constituted but a fractional part of the extract, he believed that the chemical behavior of this hypothetical principle, which was described by the discoverer as a derivative of albuminoid bodies, could not possibly apply to any one known chemical substance.

His studies had for their object:

- (1) To isolate the chief constituents of tuberculin and to determine their chemical nature.
- (2) To ascertain their action with special reference to their power of inducing the two most characteristic effects of tuberculin, namely, local inflammation and fever.
- (3) To ascertain how far it was possible to eliminate all substances having an injurious action, and thus to obtain remedial without injurious effects.

His results may be summarized as follows, under the heads of Composition, Action and Therapeutic Value.

The chief substances found in tuberculin are: (1) Albumoses; * (2) Alkaloidal substances; (3) Extractives, small in quantity and of unrecognized nature; (4) Mucin; (5) Inorganic salts; (6) Glycerine and coloring matter.

Having ascertained that the only substances present in tuberculin with which the active properties could be associated were albumoses, organic bases of alkal-

oidal nature, and probably various extractives, he proceeded to determine by experiments on mice and guinea-pigs, to which of the above substances, tuberculin owed its characteristic properties, remedial and otherwise.

Four modifications of the original tuberculin were accordingly prepared by him. He has given to them the designations A, C, B and CB; and these terms will be retained in the present paper.

From extensive investigations with these modifications, he feels warranted in concluding:

- (1) That tuberculin owes its activity, not to one principle, but to several; that its action in producing local inflammation, fever and general constitutional disturbance is not a simple but an extremely complex one.
- (2) That its remedial and inflammatory actions are connected with the presence of certain of its albumoses, while its fever-producing properties are chiefly associated with substances of a non-albuminous nature.

(3) By the adoption of certain chemical methods, it is possible to remove the substances which cause the fever, while retaining those which are beneficial in their action.

(4) That the fever produced by tuberculin is thus absolutely unessential to its remedial action. (He is inclined to believe that the inflammation is almost similarly unessential, although admitting that under certain circumstances it may assist the action of the remedial substance.)

(5) That tuberculin possesses a truly remedial action and that this is to be found in a protein, that is, in an albuminous substance derived from the plasma of the bacilli themselves and not formed by their action upon the surrounding tissues; and, finally, that it is possible to isolate largely this protein.

Dr. Hunter's clinical investigations, in which he has been assisted by Mr. Watson Cheyne, with the above modifications of tuberculin, have led him to assert tentatively the following proposition: Modification A differs but slightly in its action from tuberculin. Modification C differs from tuberculin in being almost completely freed from the substance which gives rise to local inflammation. It contains, however, in a special degree the fever-producing agents, which may be regarded as interfering with the remedial properties and favoring rather than retarding the growth of the bacilli. Modification CB contains the remedial substance present in C, freed from the fever-producing agents. Its use, moreover, is unattended with any of the other constitutional symptoms following the employment of tuberculin. Modification B contains the remedial properties of CB with the additional property of inducing local inflammation. Its action is free, so far as has yet been observed, from ill effects.

From the marked improvement which Dr. Hunter has seen occur in cases of ulcerative and other forms of lupus, where it is possible to watch the local changes from day to day, under treatment both with B and CB, he believes the activity and probable remedial power of these modifications to be demonstrated.

It yet remains to be determined whether the improvement noted in his cases will be more or less permanent. The absence of marked local inflammation or of necrotic changes accompanying their use leaves the mode of action of the above modifications of tuberculin a matter of more or less speculation at the present time. I shall refer later to the clinical inves-

*Albumoses, chiefly proto-albumose and deproto-albumose, along with hetero-albumose and occasionally a trace of dys-albumose.

tigations of other observers and to some personal ones with Dr. Hunter's preparations.

Professor Klebs's researches have apparently been based on the same line of thought as the above, but were made quite independently of them.²⁹ Convinced that tuberculin produced in the human being many effects which had nothing to do with its action upon tuberculous tissue, and which could be avoided without affecting the latter property, he submitted tuberculin to various chemical processes, with the view of freeing it from its alkaloidal substances. Its noxious properties reside in the latter, he believes. He claims that the extracted principle represents the secretions of the tubercle bacilli and is a pure albumose. Experimental investigations in animals indicate that the injection of large doses of tuberculinocidin, as he terms the albumose, previous to inoculation with pure cultures of the bacillus, delays the development of tuberculosis to at least twice the usual period; moreover, that a complete resolution of previously developed tubercle may occur under its use.

The best results in animals were obtained when the tuberculinocidin was injected simultaneously with inoculation of the bacilli.

In such animals killed three months later, tubercle was scarcely present, and few bacilli were found. In cases where treatment was begun six weeks after experimental inoculation and continued for twenty-five days, either complete healing or a high degree of retrogradation of the tuberculous lesions was observed.

Of 75 critically observed cases of pulmonary tuberculosis in the human being, treated with tuberculinocidin, 18.6% are claimed to have been cured, and 60% improved. In a single case of supposed tuberculous meningitis, the symptoms also improved. Cases are reported in detail by Klebs, in which a successful issue occurred, both tuberculin and creosote having previously failed to give good results. The treatment being practically unattended with constitutional disturbances or fever, there is no interference with the customary life and occupation of the patient.

So far as I am able to judge from Klebs's statements, the remedial properties of tuberculinocidin reside wholly in its germicidal power, that is, in its ability to destroy the tubercle bacillus within the human body. He expressly states that no inflammatory process or necrosis of tissue is produced by it.

If Klebs's very positive statements on the above points are borne out by further extended observations, a far-reaching and very brilliant discovery has been given to the world.

In concluding his report, Klebs remarks: "That it only remains to determine the limitations which control the cure of the disease produced by the specific bacillus, whose destruction we have succeeded in accomplishing. The first cause may vanish, and yet the pernicious results of the conditions developed from it remain. When advanced destruction of pulmonary tissue has occurred, where the general vitality has greatly depreciated, and emaciation and marked impairment of the heart's function have taken place, cure is no longer to be expected, even with the removal of the first cause of these conditions."

We have now to consider some very interesting and noteworthy investigations of Roemer and Büchner.³⁰

The former, as the result of his experimental researches, has made the surprising announcement that the same reactions can be obtained in tuberculous guinea-

pigs from inoculations with proteine containing extracts from the bacillus pyocyaneus (green pus) as with tuberculin. He found that tuberculous animals died quickly after injections of such extracts, while healthy animals lived; that lesions occurred in the liver and spleen of such animals apparently quite similar, both macroscopical and microscopical, to those described by Koch as due to the specific action of tuberculin. Büchner has corroborated Roemer's observations of the effect of injections of the proteine of the bacillus pyocyaneus and has found similar effects to follow the use of the proteine of other bacilli, namely, pneumo-bacillus (Friedlander) and the bacillus prodigious. Inoculations of healthy men with minute doses of the proteine of the pneumo-bacillus or the prodigious were followed by redness and swelling at the point of injection and a local rise of temperature which gradually disappeared, and of quite similar character in the different persons experimented upon. Constitutional symptoms were not produced, Büchner suggests, on account of the smallness of the dose administered. The pronounced local reaction in comparison with that of tuberculin, he believes to indicate a more serious action of the proteine. Büchner concludes his report of his investigations as follows: "Are the proteine extractives of the tubercle bacillus alone capable of exciting a latent irritation to an appreciable inflammation and necrosis? Are not other ordinary excitors of inflammation, especially proteinines from harmless kinds of bacteria, possessed of the same power?" The observations reported by him, he thinks speak favorably for such a possibility, and open therefore in a practical manner new, and perhaps not unimportant, outlooks.

In the light of extended experimental investigations and of numerous clinical observations, the incorrectness of many of Koch's original hypotheses and conclusions is evident. It has been shown that tuberculin contains not one, but several active principles, respectively capable of producing different effects; that whatever remedial action it may possess resides *apparently* in certain of its albumoses, while its harmful properties are seemingly due to the non-albuminoïd substances present in the extract. With the knowledge that tuberculin is the concentrated fluid medium in which the bacilli have been growing, thus presumably containing the products of their growth and the proteins derived from their bodies. Prudden's experimental studies³¹ of the action of *dead tubercle bacilli* would seem to be further corroborative of the above views. His experiments indicate that the dead bacilli, freed so far as is possible from the products of their growth, are capable of enormously stimulating cell activity and of producing lesions morphologically similar to tubercle, but which are not *indefinitely progressive and do not tend to the production of an advancing coagulation necrosis and finally do not induce an infectious disease*.

A legitimate conclusion from these observations would seem to be that the coagulation necrosis which Koch's hypothesis regards as the remedial mode of action of tuberculin, is dependent upon a metabolic product of the growth of the bacillus.

In view of the remedial effects obtained by Hunter, Cheyne, and Klebs from the use of a tuberculin presumably freed from metabolic products and the apparent demonstration by Prudden that a constituent of the protoplasm of the dead bacillus, probably a

proteine, is capable of enormously stimulating cell activity, it is justifiable to feel that much light has been thrown on a most complex question.

Whatever beneficial results were obtained from Koch's original tuberculin, I am convinced were not through, but in spite of, a production of coagulation necrosis; and that the benefit claimed to-day by many from its use in exceedingly small doses, is partly through the avoidance of such an effect. In exceedingly minute doses it is possible that the action of the cell-stimulating proteine preponderates and thereby a remedial influence is exerted.

A rather large clinical experience now extending over a period of eighteen months, leads me to reiterate an opinion previously expressed: "that tuberculin contains a remedial principle." This view is shared, among our own countrymen, by Trudeau and Von Ruck, gentlemen who have enjoyed in their sanitaria, the widest possible opportunities for thoroughly studying the subject.

In a recent communication by Schede, of Hamburg,³² than whom no Continental surgeon has a larger clinical experience, a similar opinion is expressed. In concluding this portion of my subject, I cannot but express my abiding and earnest belief that the continued and exhaustive investigation of Koch's discovery will lead either to such modifications of the original extract or to the preparation of a new one based upon a similar principle, as will place in our hands an agent specific in character and remedial in tuberculosis, in a degree hitherto believed to be unattainable.

The results obtained in the wards of St. Luke's Hospital in the treatment of pulmonary tuberculosis with modifications of tuberculin already effected, will be appended to the present lecture.

THE PATHOLOGY OF PELVIC INFLAMMATIONS.¹

BY REGINALD H. FITZ, M.D.

PELVIC inflammations relate to those of the wall and to those of the contents of the pelvis. The former affect the parietal peritoneum and the sub-peritoneal fibrous tissue, while the latter concern the uterus, tubes, ovaries, ligaments, bladder, rectum, and, sometimes, displaced abdominal contents, especially the vermiform appendix, which have entered the pelvis. At this meeting it is presumable that the discussion will be especially limited to the consideration of the inflammations of the pelvic wall and of the female genital apparatus. Since inflammation of the peritoneal or sub-peritoneal tissue of one part is likely to become rapidly extended to another, it has been found convenient to speak of a pelvic peritonitis and of a pelvic cellulitis in contra-distinction to a metritis, a salpingitis or an oophoritis, although an inflammatory process in one of the organs concerned is likely to be associated with an inflammation of its peritoneal covering or adjacent fibrous tissue.

The term pelvic cellulitis dates back to elementary ideas of the structure of connective tissue and to erroneous views of the pathology of pelvic inflammation. Then, a cellular tissue was one containing holes, such as might be inflated, for example, the subcutaneous connective tissue; now, the only cellular tissue is one which contains cells, living or dead. In former times, the so-called cellular tissue was the place where pus and abscesses were often found, and a pelvic abscess was supposed to lie either in the peritoneal cavity, an encysted or circumscribed peritonitis, or in this cellular tissue of the pelvis, pelvic cellulitis.

At present, not only is the term, cellular tissue, becoming obsolete, but pelvic abscesses are known to occur with comparative infrequency in the pelvic connective tissue. What were, formerly, supposed to be so situated are, now, known to be, for the most part, cases of pyosalpinx, pus-tubes.

But an inflammatory process may lie in the connective tissue of the pelvis. It usually arises, in the female, in that portion of the sub-peritoneal fibrous tissue near the uterus, to which the distinctive term of parametrium is applied.

This parametrium is the loose, fibrous tissue which extends from the lower half of the uterus outwards between the peritoneal layers of the broad ligaments, in front and behind towards the bladder and rectum, while, downwards, it surrounds the upper part of the vagina. It is continuous everywhere with the pelvic fibrous tissue of which it is a part, and, thus is immediately connected with the sub-peritoneal, fibrous tissue in general and with the ischio-rectal and subcutaneous tissue of the perineum. The parametrium does not extend to the upper half of the uterus. From a point corresponding to the inner os of the peritoneum is closely applied to the muscular wall of the uterus, whereas below this point, the loose, fibrous tissue of the parametrium lies between.

In the case of an inflammatory process affecting the peritoneal covering of the body of the uterus, the term

¹ Intended as introductory remarks at the meeting of the Section in Obstetrics and Gynecology of the Suffolk District Medical Society, Wednesday, January 12, 1892.

perimetritis is applied to discriminate it from a parametritis affecting the loose tissue lying between the cervical portion of the uterus and the peritoneum. These two conditions may occur quite independently of each other.

The perimetritis tends to spread to continuous and contiguous surfaces of the pelvic peritoneum, and even to portions of the intestinal peritoneum which come in contact. It rarely extends for any considerable distance into the uterine wall.

A parametritis on the contrary, not only spreads laterally in every direction, following the course of the lymph- and blood-currents, but it usually reaches to the peritoneal covering of the parametrium, and, thence proceeds to the peritoneum of the pelvis and abdomen.

From the etiological point of view most severe pelvic inflammations are the result of an infection of the surface of the genital tract from without. The infective material and its products are either carried along the surface, from without inwards, to the ends of the tubes and into the pelvis, or through the wall, usually lacerated or ulcerated, into the blood- and lymph-vessels.

It is unnecessary to say that the infective substance is now regarded as of bacterial origin and as usually introduced from without through a lack of efficient cleanliness on the part of others during parturition or at operative attempts to induce abortion or to treat genital disease. The infective or septic varieties of pelvic inflammation thus, commonly, arise. In this series are also to be included those instances of auto-infection, through lack of sufficient personal cleanliness, where bacteria and their products invade the body through the genital tract, there having been no instrumental or manipulative procedures. The most striking instance of this auto-infection is to be found in the occurrence of, even fatal, peritonitis, during and towards the close of menstruation, by the dropping of infected catamenial fluid from the Fallopian tubes. This occurrence, it is needless to say, is unduly favored by the prevailing fear of menstruating women to keep the external genitals clean by washing during the monthly flow. Other illustrations are furnished by the so-called, spontaneous origin of puerperal fever and by the suppurative peritonitis which may result from a ruptured, tubal pregnancy.

Under the infective forms of inflammation are also to be included the gonorrhoeal and tubercular varieties. The former is now universally recognized as one of the most frequent and important causes of the chronic and recurring varieties of pelvic inflammation and whose appreciation is of the utmost importance in the treatment of this affection. The tubercular inflammations are of less practical importance since the resulting initial disturbances are usually insufficient to produce severe symptoms and the more important, tubercular processes elsewhere in the body are so extensive and serious as to divert attention from the former. In the tubercular, pelvic inflammations the infection is usually from the fibrillated end of the tubes, and is ordinarily discovered after operative treatment for some other supposed disease.

All pelvic inflammations, however, are not infective, although the severe forms are of this nature. The frequent presence of adhesions between the surface of pelvic tumors, especially uterine and ovarian, and the peritoneum are instances of a pelvic peritonitis, often so mild as to have taken place without suggestive symptoms. Still symptoms of greater or less sever-

ity may be associated with these milder varieties of non-infective inflammation, and may result from the rupture of an ovarian cyst, or from a twisted pedicle. Many retro-uterine haematoceles belong in this series. Such mild, non-infective, perhaps traumatic (mechanical or chemical) varieties of pelvic inflammation largely account for the rarity with which the pelvis is found free from adhesions at post-mortem examinations.

Before the days of frequent laparotomies the pathological anatomy of pelvic inflammation was, necessarily, studied after death. The lesions then found were the fibrous and fibrinous adhesions and membranes, the collections of serum, fibrin, pus and blood, with which all were familiar as evidences of old or recent, circumscribed or recurrent, pelvic peritonitis. The tubes were not infrequently found tortuous and obliterated, thickened and dilated, their contents usually watery, though sometimes cheesy or purulent. Those days furnished the natural history of pelvic inflammations and showed what would happen if the patients were, practically, let alone. But, of late years, it has been found that our knowledge of the pathology of pelvic inflammations was capable of a wider enlargement by the study of material obtained from the abdomen during life. The contributions of chiefest importance thus furnished were the diseased Fallopian tubes. It was found that a suppurating tube was the usual cause of a recurring, pelvic inflammation. A pus-tube often proved to be the chronic pelvic abscess, which hitherto had been supposed to lie in the pelvic, fibrous tissue, and whose healing proved so obstinate, when opened through the vagina, rectum or abdominal wall. This obstinacy became explained when it was evident that the result of the operation, as then conducted, was, essentially, to establish a tubal fistula, along which a catarrhal secretion would flow when pus ceased to be formed. The study of pus-tubes obtained by the laparotomist, in connection with Neogerath's investigations, has shown that the gonorrhoeal virus is the usual cause of this lesion and the important group of symptoms associated with its presence. It is, perhaps, well to say *usual*, and not *only*, for the experience of both laparotomist and experimental pathologist agree in recognizing the frequent failure of gonorrhoeal pus, escaping from a pyo-salpinx, to infect the peritoneum, while the pus in a tube resulting from puerperal or operative infection usually possess properties of extreme virulence.

The study of the tubes removed by the laparotomist has led to another important contribution to pelvic pathology. It has made clear that the usual cause of the pelvic haematocele and of the haematoma of the broad ligament was a ruptured tubal pregnancy. The customary failure of the rupture to produce more than a bland inflammation was readily explained when it appeared that the usual seat of the rupture was through that portion of the tubal wall corresponding to the placental insertion, and was thus removed from any continuity of surface with the tubal canal which might contain infective bacteria. On the contrary, a direct rupture into and through the tubal canal would offer a satisfactory explanation for the suppuration of the haematocele which, sometimes, precedes the operative attempts at the relief of the latter.

It may be stated, in conclusion, in order to promote the object of the meeting:

That pelvic inflammations affect the wall and con-

tents, and that inflammation of the former usually results from disease of the latter.

These inflammations are simple and infective. The former result from traumatic agencies, as a ruptured cyst, a twisted pedicle, a prolonged labor or a tumor. The latter are septic, gonorrhreal or tubercular. The sepsis results from bacterial invasion under conditions associated with pregnancy and menstruation, or with attempts at diagnosis and treatment, as in the passage of sounds, the use of tents, instruments and manipulations. The pelvic abscess is usually either a pus-tube or a circumscribed peritonitis, the former far more common than the latter, especially in chronic and recurrent cases. Abscesses of the sub-peritoneal, fibrous tissue of the pelvis may occur, usually proceeding from the uterus as a suppurative parametritis and rarely attaining a size to be confounded with the previous varieties.

Both the simple and infective forms of pelvic inflammation may result in adhesions, chronic adhesive peritonitis, and in thickenings of the parametrium, chronic parametritis. The former are the chief cause of uterine displacements, the latter are less frequent, and are usually so situated as to produce but little mechanical disturbance.

Simple forms of pelvic inflammation are frequently unavoidable, and, as a rule, require simple treatment, this chiefly medical; infective forms of pelvic inflammation are largely avoidable, immediately or remotely injurious or dangerous to life and well-being, and generally demand treatment by surgical methods.

THE TREATMENT OF PELVIC ABSCESS.¹

BY ARTHUR T. CABOT, M.D.

In speaking of pelvic abscess, I refer to cases where a considerable collection of pus exists, and in which, therefore, temporizing measures seem no longer applicable, but for which a radical operation for the evacuation of the pus in some way or other is called for. I hope to hear something said about the pathology of these abscesses. Practically, as they come to the eye of the surgeon, the parts are so tied up that it is very difficult to say whether the abscess is still confined to the Fallopian tube, whether it has already opened through the wall of the tube and is contained between the folds of the broad ligament, or whether, having opened outside of the tube, it is shut in by adhesion of the intestines above, making an abscess cavity with peritoneal walls, such as we see in cases of ulcerated appendix vermiciformis. The pelvic abscess having peritoneal walls may also result from inflammation occurring in an hematocoele.

The medical journals have been full of articles advocating the treatment of these abscesses in the pelvic cavity by laparotomy. Led by Mr. Tait, a number of enthusiastic laparotomists hold that the better way of treating all of these cases is by incision through the abdominal wall. Their obvious argument is that you get a better view of the condition, can proceed more intelligently to treat it properly, and can usually remove the whole abscess cavity, with its wall. While I am inclined to assent to this position for the most

part, I am far from believing that the abdominal incision is the only treatment for these cases, or that it is in all cases the best treatment.

The advantages claimed for a treatment by laparotomy are, quick healing and the absence of relapse. If the pus-tubes can be thoroughly removed, the case heals up almost like a simple ovariectomy, and the patient is quickly well. When the tubes have been thus removed, there is naturally little, if any chance of a recurrence of the abscess. These advantages, however, are not obtained in those cases in which an abscess being found which cannot be entirely peeled out, drainage has to be resorted to, for in such a case, there is quite as much likelihood that the abscess will be chronic, or will recur, when the drainage is put in over the pubes as when it is introduced through the vagina. In those cases in which drainage is to be established, the operation through the peritoneal cavity is more dangerous than the simple opening of the abscess into the vagina. Even in some of the cases in which the abscess wall is wholly removed, the close adhesion of it to the rectum may lead to a fecal fistula. These are in some cases serious disadvantages.

Further, it sometimes happens that one removes tubes and ovaries unnecessarily. It is very difficult for an operator who has just opened the abdomen to do a radical operation and who feels that, in order to justify the operation he must obtain a permanent cure, to leave a doubtful tube on the other side. He perhaps removes a large pus-tube from one side and finds the other tube somewhat thickened. It is then often hard to tell whether this may be left, or must be removed; and in fact, Tait recommends invariably removing both tubes in these operations. In a young married woman, or in a woman who expects to be married, this may be a decided disadvantage.

The last disadvantage of the abdominal operation is that, after the removal of the tubes, the scars in the broad ligaments, which have at first shortened them, melt away, and leave the uterus with less support than before. In some of these cases I have seen a very troublesome tendency to prolapse and retroversion.

These are some of the reasons which make the abdominal operation fall short of a perfect cure. On the other hand, we know that these pelvic abscesses not infrequently seek an outlet into the vagina, and that even when they are not pointing, they are often easily felt from below. An opening made through the vagina is necessarily a dependent one and gives very good drainage. The disadvantages that are urged against an opening in this direction are, that it is slow of healing, leaving sometimes a fistulous opening; and that the abscess, when thus treated, is likely to recur. These disadvantages are ones which were attached to this operation largely in pre-antiseptic times, and do not hold in the same degree now. It has been my experience in a large number of these operations that if the drainage was kept up by a tube until the abscess had contracted down to a small fistulous tract, this fistulous opening almost invariably closed after the removal of the drainage-tube, and that the cure has been lasting.

Now, how are we to select the proper cases for one operation or the other? I should say that a localized abscess down in the pelvis, which is easily felt through the vagina, should be opened below. In some of these cases such as Dr. Chadwick has described, in which there is an almost board-like hardness of the

¹ Remarks made at the meeting of the Obstetrical and Gynecological Section of the Suffolk District Medical Society, January 13, 1892, during the discussion on "The Pathology, Diagnosis and Treatment of Pelvic Inflammations."

parts, if an abscess has formed, you may feel somewhere a softer, less resistant point, and pressure upon this is often somewhat painful. In such a case, after the vagina has been rendered aspetic, exploration with the needle may be safely made, and in case pus is found, a director can be passed alongside of the needle and upon this as a guide the incision can be made into the cavity. The incision should be a small one, and a dilator should be relied upon for afterwards enlarging the opening. Free cutting in this region sometimes leads to troublesome haemorrhage from the venous sinuses which exist about the uterus; but an opening made in the way that I have described is an almost bloodless operation, and I have never met with a haemorrhage which was not immediately stopped by the introduction of the drainage-tube.

After this operation, which I have done a good many times, I have not been troubled with a relapse in any case in which the tube was retained for the proper length of time. The mistake often made is that of taking the tube out before the abscess cavity has entirely closed down upon it. I use a T-shaped tube, cut short, so that it does not protrude from the vagina, and does not interfere with thorough vaginal douches, which are carried out with hot, antiseptic solutions two or three times a day. The tube, thus made, retains its place perfectly in the abscess, even when the patient is up and about.

When, on the other hand, the induration and hardness does not come down into close contact with the vagina, but where the Fallopian tubes can be made out as sausage-like swellings high up in the pelvis, we have a condition in which laparotomy is demanded. Between these two extremes, the judgment of the surgeon, guided by careful examination, must determine whether the pus in a given case is readily accessible from the vagina, or whether the chance of being able to thoroughly remove the pus cavity makes it wiser to approach the case from above.

The cases to which I have alluded in the above remarks are the more chronic ones. Occasionally we have a case of acute suppurative salpingitis, or an acute exacerbation in a chronic case, which may indicate the extension of inflammation to the peritoneum, and in such a case laparotomy is imperatively demanded. Dr. Chadwick spoke of the occasional difficulty of diagnosis between appendicitis and inflammation in the pelvis. This is one of the reasons which would make me prefer a laparotomy for those inflammations which extend high up in the abdomen, in order that the case may be thoroughly understood and intelligently treated.

I remember one such case in which, believing that I was doing an operation for appendicitis, I found two very large pus-tubes and a great deal of free pus in the pelvic cavity. In that case the evidence of abdominal inflammation was clear; the laparotomy was the only operation thought of, and the patient made a good recovery.

Before closing these rather desultory remarks, I wish to speak of one puzzling case, in which with every sign of an abdominal abscess, I operated and found no abscess. The patient was a girl of fourteen, who for four or five weeks had suffered from a good deal of pelvic inflammation with pain and high fever. This followed exposure from sitting on the damp ground at the close of menstruation. A hard mass was to be felt rising up out of the pelvis, well towards

the umbilicus, and the pelvic cavity was filled with a mass of bony hardness. The pain and high temperature persisted for so long that it led to the belief that there was pus somewhere in this cake of exudation. As she was running down-hill an operation was decided upon, and I made an incision over the mass, in the median line. The peritoneum was thickened and adherent to this mass, so that I did not at first open the general peritoneal cavity. After plunging a needle, and then a trocar, into the tumor in several directions in search for pus and finding none, I then opened the general peritoneal cavity above in order to get a clear idea of the topography, and found rising out of the pelvis an irregular mass of exudation which bound all the organs together, and so masked them that you could not tell where the uterus, or other pelvic contents were. No softening could be felt anywhere, and feeling very much dissatisfied with the operation I sewed up the abdomen. From that moment she made a good recovery. The mass rapidly disappeared, and we were all very much gratified, although we did not know why it should have done so.

I have since heard of other similar cases, and I have no doubt that gentlemen who are more practised in gynaecology have seen many such. It was, however, an unique experience at that time to me.

Clinical Department.

A CASE OF COLOCYNTH POISONING,

BY WM. A. HOLME, M.D., BOSTON.

As instances of colocynth poisoning are somewhat rare, I desire to put on record, through the columns of the JOURNAL, a case which occurred in my practice last year.

Miss M., a delicate young woman of twenty-five, finding herself pregnant, and wishing to induce abortion, acted under the advice of a dressmaker who recommended taking powdered colocynth in hot gin as an infallible remedy.

The amount taken, was, as near as I could judge, about a quarter of an ounce of the powdered drug in a half-tumblerful of gin. This mixture was swallowed at about ten P.M., and I was called at twelve. On arriving at the house, I found the woman on the floor in a state of collapse. The face was pale and pinched, respirations shallow, and all the extremities cold. The pulse was absent in both wrists. There had been intense vomiting and purging, the later discharges being bloody.

She was placed in bed, and surrounded by hot-water bottles, and given brandy and digitalis hypodermically. She rallied in about an hour and commenced to vomit and purge again, and complained also of great pain in the stomach. A glass of warm water was given with the hopes that it might bring up any of the drug which might still be in the stomach.

Continuing to vomit until she was well-nigh exhausted, I concluded to stop the retching by morphia. Three-quarters of a grain were required to quiet the stomach, the amount being given in a space of half an hour's time. The resulting gastro-enteritis was treated by milk diet, and the administration of powders of bismuth subnitrate and salol.

She made an uninterrupted recovery in about ten days. Strange to say, abortion did not result, as might have been expected from the indirect action on the uterus.

AN UNIQUE DISLOCATION OF THE FOOT, AND OF THE ASTRAGALUS.

BY JOHN R. HAM, M.D., DOVER, N. H.

I WAS called on April 25, 1892, to S. W., the proprietor of a portable steam-mill, who, while sawing logs, came in contact with a piece of shafting which was revolving at the rate of six hundred times a minute.

He may not have made more than one revolution when his clothing gave way and he was rescued. I found the malleoli widely separated and projecting; the foot forced directly upwards and firmly wedged between the tibia and fibula; the depth of the foot from the extremities of the malleoli was obliterated; and the movements of the foot gone. There was no fracture, nor was there any external wound.

Under strong extension and counter-extension the foot was finally loosened and pulled down from between the bones of the leg, which came together with an audible snap when the wedge was removed.

I now discovered a complete backward dislocation of the astragalus, which lay between the tendo-Achillis and the posterior surface of the tibia.

The reduction of this bone was a much more difficult matter, but after half an hour's effort aided by two strong assistants in extension and counter-extension, and when on the point of despair as to a successful issue, I succeeded in slipping the bone in place.

Ether was not used because it was not on hand and, the patient being three miles from the city, it was not thought best to delay in the reduction.

Reports of Societies.

OBSTETRICAL AND GYNECOLOGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

GEORGE HAVEN, M.D., SECRETARY.

REGULAR meeting, Wednesday, January 13, 1892, the President, Dr. C. M. GREEN, in the chair.

ANATOMICAL SPECIMENS.

DR. C. P. STRONG: I have here a very small cyst of the broad ligament which I removed this morning, and which is interesting for one or two reasons. The patient was a girl of twenty-two, who had always been perfectly well except that she had menstruated only about once in eight or nine weeks, — irregular in that respect. Until eleven weeks ago she had not known what it was to be ill at all. Then she was upon her feet a good deal, and commenced to have pains in her left side which constantly increasing, had made her an invalid so that she had spent most of her time in bed since I saw her for the first time about three weeks ago, and then made out a cyst of some kind. I thought it was a small dermoid back of the uterus. I advised operation on her at once without any treatment because the family were dependent on her efforts to earn money. I operated to-day and found this cyst lying in the broad ligament. This ovary

which was also removed, was very much larger than now appears, due to a large cyst in its interior which has been ruptured. The tubes were apparently perfectly normal.

Another interesting point is that the broad ligament of the other side is similarly affected, the only difference being that on the right side the cyst growing in exactly the same location was about the size of an American walnut. The right ovary contains numerous small cysts, but as I did not see any reason if the cysts were opened and their walls destroyed that they would grow again, under the circumstances I thought it best to run the risk of a second laparotomy at some future date and allow the ovary to remain. That ovary was considerably enlarged. I laid open the cyst and thoroughly cauterized its interior wall.

The point of interest aside from the condition of the tube and the parts on the other side being similarly affected, was the great amount of disability arising from the presence of these cysts, and the fact that they had come on so suddenly. There were no adhesions, nothing to account for the great pain from which she certainly did suffer.

THE PATHOLOGY, DIAGNOSIS AND TREATMENT OF PELVIC INFLAMMATIONS.¹

DR. J. R. CHADWICK: There are so many starting-points for inflammation in the pelvis that it is hard to speak of the diagnosis and go over the whole ground. What we have to consider generally are pelvic peritonitis and pelvic cellulitis. While the symptoms do not vary essentially between the two, my experience would teach me that they vary somewhat in degree, that is, that a pelvic peritonitis gives rise to much more violent symptoms than pelvic cellulitis. The symptoms briefly may be said to be first a chill followed by pain, constant and lancinating, and fever with, on the second or third day, more or less metrorrhagia with some distention of the bowels, sometimes a diarrhoea, not regularly. Those, I presume, would be accepted as the symptoms that are generally present.

In peritonitis of course the location of the pain in the early stage is characteristic of the part where the inflammation originates. From that point of origin the disease may spread indefinitely. Of course it involves more or less all the organs which are invested with peritoneum, habitually starting, as the pathology to-day I suppose would say, in a large number of cases from inflammation of the tubes, originating undoubtedly often from haematocele, and, as I believe, originating sometimes from traumatism; that is, I cannot satisfy myself that the cases are all attributable to the introduction of germs, though I know that is held by many.

In regard to the diagnosis, we have had the symptoms of the physical conditions. The most striking is the induration which is felt through the roof of the vagina, especially the posterior cul-de-sac. I should say, before going further, that in my experience the pelvic peritonitis is the common disease. Pelvic cellulitis is extremely rare, a statement that is in opposition to what most of our older books held. I have not found one case of cellulitis to one hundred of peritonitis according to my diagnosis. The induration which is felt by the vagina is of course limited in the case of peritonitis to the peritoneal cavity, that is, it

¹ See articles by Drs. Fitz and Cabot on pp. 491 and 493 of the Journal.

cannot descend lower than Douglas's cul-de-sac. There is furthermore an infiltration into the tissues over which that peritoneum lies. You find the peritoneum firmly adherent there, absolutely immovable, and the chief feature which is almost pathognomonic, is the board-like feel within the first two or three days of a pelvic peritonitis. I say board because it runs straight across. There is insinuation of the finger between the effusions and the walls of the pelvis as is possible when the pelvis is occupied by fibroid. Then you have a distension of the abdomen which more or less interferes with examination, but by the bi-manual examination you can pretty generally feel the extent of the effusion. The body is immovable, but by persistent abdominal pressure you can get a little intimation of an impulse through this mass of effusion. In two or three weeks the mass loses its hardness and feels cartilaginous, and from cartilaginous into less rigid feeling; finally, in the later stages, it seems as if you could not push the vagina up as far as it ought to go. You have had of course with this disease constipation either naturally or brought on by the use of morphia. There is generally some irritability of the bladder, though not always. If the effusion is in Douglas's pouch, you have the uterus shoved forward against the pubes, or if it is more lateral, transferred to one side or the other.

Then for cellulitis, the cellular tissue lies beneath the peritoneum and consequently you frequently have a cellulitis more extensive laterally and extending generally rather lower in the pelvis. It is a matter of degree, and you cannot always distinguish between the two. As the effusion is absorbed you find the uterus generally moving back into its place, but not always. It often may have contracted adhesions in the place to which it has been pushed, adhesions resulting from the same inflammation of which the effusion crowded it over. You may ultimately have the uterus retroverted or crowded down into anteversion. It may be more essentially an inflammation of the peritoneum covering the uterus, in which case the uterus may be covered with an effusion which makes it four or five times its natural size. Once in consultation I diagnosed peritonitis complicating a fibroid tumor. Two or three months afterwards the doctor wrote to me that the fibroid had disappeared entirely with the effusion. It seemed as if I had erroneously mistaken this large mass for a fibroid and it had been absorbed.

Now in the way of differential diagnosis, there are a great many things which may be mistaken for these common diseases. I spoke of salpingitis as being the starting-point of most of these attacks of peritonitis; and we have consequently a difficulty in diagnostinating between a very moderately circumscribed peritonitis and suppuration in the tube without any escape of pus.

Inflammation of the ovaries I have put down very rarely in my books in the last ten years, and it seems as if in the pathology of women the diseases of the ovaries other than cystic enlargement have disappeared pretty much, that is, the woman no longer exists on account of her ovaries, but for something else. I have seen a few, and lately very few, cases of inflammation of the ovary recognizable as a small rounded body somewhat enlarged and tender, rarely accompanied by fever or acute pain, and I do not find very many reflexes, not as many as other men apparently do.

We have, of course, in the differential diagnosis to think of all the varied diseases that may occur in the abdomino-pelvic cavity. We have to bear in mind psoas abscess which may come down and produce symptoms there, though rarely. We have to remember inflammations of each of the different organs that are there and the tissues around them, for instance, the various tissues of the kidney, dropsical kidney or floating kidney. I have found a floating kidney in the pelvis supposed to be a fibroid. Perinephritic abscess may not infrequently be taken for pelvic. You have to bear in mind all the renal colics and ureteral colics and various diseases of the bladder, which in rare instances puzzle you, as well as morbid growth. Perhaps the principal diagnosis is between these inflammatory affections and cysts of the ovaries and fibroids of the uterus. You have to bear in mind that any of these tumors are liable to inflammations within themselves as well as inflammations around them; that there may be ulceration and inflammation and suppuration inside of an ovarian cyst that will give rise to fever, and perhaps adhesions on the outside of it to the pelvis which puzzle you a good deal. Generally you can distinguish a tumor by the fact that the induration does not run straight across the pelvic floor. You may have a fibroid that is inflamed or sloughing or has inflammations around it.

Then you have the catarrhal diseases of the intestines which sometimes cause fever. There, of course, you have the diarrhea to aid you chiefly in your diagnosis, though that is not an absolute sign. You have tympanites on percussion, and you have the tenderness universal, and vomiting, and other symptoms, which generally will help you.

Intussusception, constriction of the intestine and stricture all need to be borne in mind, and morbid growths of the intestines and appendicitis. I remember very well a case I saw with Dr. G. H. Lyman in the City Hospital. A young girl had a tumor on the right side of the uterus, bigger than an apple, attended with some fever; and I think every one diagnosed an ovarian cyst with some inflammation around it. To the surprise of every one, after two or three weeks, that disappeared. She came in later on, and it was again found. Then I saw her outside a number of times, when the tumor would appear and disappear. All this happened eight years ago, before we had learned so much about appendicitis. Finally, I operated, and got down upon the intestine, which was matted together on the right side, in a mass containing a bluish place, into which I put the aspirating needle and got pure blood, which scared me, and I let it alone and put a drainage-tube down to that spot, and in three days I had a gush of pus, and the whole trouble ceased. I have seen her within a year, and she is perfectly well. I have no question that that was appendicitis. At the time of the operation I did not think it was wise to go into it especially as the tapping with the aspirator drew out pure blood.

Of course ascites and tubercular peritonitis are pretty easy to distinguish. I do not mean that you can distinguish a tubercular peritonitis as tubercular necessarily, but you can distinguish it from pelvic inflammation.

Abdominal hyperesthesia, extra-uterine pregnancy. When you come to extra-uterine pregnancy the diagnosis has been pretty well threshed out of late years. It is a very important one to make, because it is im-

portant to act promptly. I think we rarely see such a case before the tube has ruptured. Taking it after rupture, you have a certain amount of exudation, which has pushed the uterus to one side, and a very peculiar condition of the patient, subject to lancinating pains, not severe enough to be those of peritonitis, not attended with fever enough for acute peritonitis, and often subsiding for a day and letting the patient get up. With that you invariably have a little loss of blood from the uterus, continuously after the fifth or sixth week. You find the uterus crowded to one side, enlarged; and if you are so lucky as to get the decidua when it is cast off, you have the means of establishing a diagnosis of pregnancy, not always that the pregnancy is extra-uterine because there is nothing absolutely characteristic in the decidua as to whether it is extra- or intra-uterine. Taking all the symptoms together, and making sure that the uterus is empty, you can establish a diagnosis with a very strong presumption of its being correct. I have not seen very many—four or five—such cases, and I have diagnosed them all. Once or twice besides I have written in my notebooks, "Look out for extra-uterine pregnancy," where it proved subsequently not to exist. Last year I had a case where, in fact, every symptom of extra-uterine pregnancy existed. The woman had been flowing a month, and the only thing different from what would be expected was that the pain was not on the side of the induration. Seeing her with Dr. W. L. Richardson later on, we decided that we must make sure that the uterus was empty. After dilating the cervix a little, I extracted the fetus from within the uterus. I was all ready to operate on the extra-uterine pregnancy, and every symptom was characteristic except the one point already alluded to.

I have overlooked a very important class of cases which probably are the starting-point of many cases of peritonitis, that is, haematocele; and haematocele may come at any point, may be of any size, and gives rise to more or less fever, sometimes a great deal, generally very much less than peritonitis. The symptoms are all less severe. It is not always fluctuating; in fact, you can generally feel it as more or less solid. There is generally less induration around it. Dr. Cabot will not have forgotten the case he saw with me last year where a woman came from St. Paul to have a big fibroid removed. On examining I found the fibroid, but the vagina so compressed by a pelvic abscess that I could not reach the cervix. I tapped it per vaginam and evacuated a quart of pus. In about ten days it had drained pretty dry, the tube slipped out, and the next day there was a sudden access of pain, and a tumor rising almost to the right kidney, with evidences of renal irritation, that is, casts, albumen, etc. I suspected that I had withdrawn the tube too soon, so that the abscess had filled up, or that the ureter had been occluded by this inflammation, and I had to deal with a distention of the ureter or kidney. Dr. Cabot saw her with me, and we could not make out certainly, but we rather suspected there was distention of the kidney. We tapped it, and found pure blood. It was nothing but an haematocele. She was well in two or three weeks, and has remained so ever since except for the fibroid.

We must not forget cancer occurring in the pelvis outside of the uterus. I have only seen two or three cases occurring in the retro-uterine space. One I saw in consultation with Dr. Sarah M. Crawford, which

she had diagnosed as cancer for some cause that I never could make out. I found no reason for believing it was cancer. She had a firm induration, not in the acute stage of inflammation, an old effusion as I thought—behind the uterus, and I said I did not think there was any cancer; but she died of cancer originating from that point.

DR. F. H. DAVENPORT: The subject of pelvic inflammations is so broad a one that I shall merely give in outline my views as to the treatment of the more common pelvic inflammations that we meet with, namely, pelvic peritonitis and cellulitis, and the most common cause probably of pelvic peritonitis—Inflammation of the appendages of the uterus.

The pathology of these inflammations has changed much in the last fifteen or twenty years, and of course the treatment has changed as well. In the first place, before the principal origin of pelvic inflammations was recognized to be an inflammation of the tubes, the treatment was almost exclusively medical. That was the case, partly because the true pathology of these inflammations was not recognized, and partly because there was still fear of opening the abdominal cavity except in cases where there was evidence of a large tumor. With the change in the views as to the pathology, and the greater freedom in opening the abdominal cavity, medical treatment was almost entirely neglected in the large proportion of these cases. Of late years, however, there has been a reaction on the part of surgeons, generally, to limit the cases treated by purely surgical methods to certain clear indications, and under those conditions and as a result of them, the medical treatment has come rather more prominently into the foreground. At least, there has been a disposition on the part of practitioners to see if good results could not be obtained in other ways.

In acute inflammations of the peritoneum and of the cellular tissue operative measures are rarely considered. The laws of treatment are well understood and very simple; they are to insure rest and quiet on the part of the patient, and such relief to pain and to the acute symptoms present as can be given by medicines and soothing applications. The application to the abdomen of hot applications, turpentine, mustard poultices and soothing applications to the vagina when the sensitiveness will admit of such applications in the way of douches, and relief to the pain by anodynes, rest in bed and supporting treatment are the principal measures employed. In one respect, however, there has been a change in the views regarding the treatment of acute pelvic inflammations, and pelvic peritonitis in particular, and that is in the use of opium. It was formerly taught, and supposed that the safety of the patient demanded that the bowels should be kept absolutely at rest since even the peristaltic movement might set up fresh inflammation, and favor the extension of the existing inflammation to the upper part of the peritoneal cavity. With that idea, large heroic doses of opium were given and the attempt was made, and usually successfully to so paralyze the bowels that there was no action whatever, but it has been found that under these circumstances the resulting paralysis favors tympanites to such an extent that it increases the amount of pain; the patient suffers from the constipation which is caused by the treatment, and measures for the relief of the constipation are liable to start up a fresh inflammation. Therefore, especially in cases of septic origin, after the acuteness of the pain has been to some

extent controlled by morphine, the present treatment, which to my mind is the best, is to keep the bowels moved at short intervals with calomel or salines, which not only seems not to have a bad effect on the existing inflammation, but even in some cases to apparently favor the arrest of the septic process which has perhaps begun. So much for the acute forms of inflammation.

With regard to chronic peritonitis, that is, the results that we find after an acute process has subsided, in the form of thickenings and deposits of lymph on the various organs, under those circumstances the treatment that has been carried out and described for so long is apparently still the best. Through the vagina we can reach the results of peritoneal inflammation better than through the abdominal wall; therefore applications to the vault of the vagina, large copious, hot water douches, depleting measures by means of glycerine tampons are the procedures most in favor. When we meet a case where there is a large deposit of lymph, such as Dr. Chadwick spoke of, with the uterus enlarged to several times its size by a deposit of lymph, I have found the use of large blisters to the abdomen to be most efficacious in reducing the size and promoting absorption of this plastic lymph. Several such blisters applied at intervals of ten days will, if the patient be kept quiet in bed, in the majority of cases result in a more or less speedy absorption of these products.

With regard to pelvic cellulitis, I agree with Dr. Chadwick that the cases which can properly be called cellulitis are now very rare. That such an inflammation of the pelvic cellular tissue does occur I am convinced. In the first place, autopsies have shown this beyond a doubt, and, secondly, operations have been performed for the relief of pelvic abscess where the abscess has been shown to be distinctly in the cellular tissue.

The acute cellular inflammations are most often the result of puerperal septic processes, and in their acute stage they demand no special medical treatment more than has been outlined. Where they go on to suppuration, surgical measures are indicated for the abstraction and relief of the pus.

We now come to what constitutes the most frequent source of pelvic inflammation, and that is inflammation of the tube. The principles which I lay down for myself in determining in a given case whether medical or surgical treatment shall be pursued depend upon two considerations: in the first place, the condition of the pelvic organs, and in the second place, the circumstances of the patient. It is certainly a well-recognized fact, now, that it is unwise and unwarranted to remove, in every case, tubes and ovaries when we find them enlarged. A good deal is dependent upon the character of the enlargement and condition of the patient. Given an enlarged tube, in the first place our efforts should be to determine whether such tube is enlarged as a result of serous or purulent accumulation, or whether it is merely a thickening of the tube wall itself with some inflammatory deposit in the surrounding tissues. Into the differential diagnosis between these conditions I will not enter. There are, I think, in the large majority of cases sufficiently clear indications to point to the actual condition of the tube itself. When pus is present it is of course a general rule that the woman is safer with the offending organs removed, but I think that even that is a state-

ment that goes a little too far, because it seems to me that there are cases even where there is pus in the tubes that can be treated by other measures than by their removal.

A second consideration to be thought of is, whether the woman can give up the time and can afford to take such care of herself as these cases demand. If she is a working woman, dependent on her own exertions for her support, and the history has been one of progressive invalidism, starting in the first place as pelvic inflammation, and from time to time showing acute exacerbations of the trouble, each attack perhaps making her worse than before, under these circumstances it seems to me hopeless to attempt to do much in the medical way. There, I think, the surgeon should be called upon to operate and remove the tubes. Where, however, a woman can favor herself in every possible way, can avoid those sources of fatigue and trouble which might bring on a fresh attack of inflammation, and can follow out our treatment carefully, I think that even in many cases where there is pus in the tubes a good deal can be done to relieve them without operation. Recently, we had a paper by Dr. Strong on drainage of the uterus in these cases, which showed to my mind very clearly that pus in the tubes, provided the uterine opening is patent, need not necessarily call for operative treatment.

I rely mainly in the medical treatment upon the most thorough depletion of the uterus and the surrounding tissues with glycerine. To accomplish this, I use prepared wool, which has the advantage of being elastic and soft and able to hold in its meshes a large amount of glycerine. I make some small tampons of this wool and saturate them with glycerine in such a way that a tampon of the size of a hen's egg would hold about two ounces of glycerine. These I place in the upper part of the vagina and leave them *in situ* for two or three or even four days, if necessary, though I prefer to leave them in but three days, and then to remove and cleanse the vagina and replace with another tampon. In this way I accomplish two things. In the first place, I furnish a soft cushion on which the uterus can impinge as the patient moves about, which results in marked relief to pain. In the next place, it causes a profuse watery discharge which is a direct relief to the congested condition of the pelvic organs. Iodine is sometimes applied, not necessarily in every case. The effect seems to be a relief to pain. In that way I have seen not a few cases of enlarged tubes (which to me were clearly the seat of, if not a purulent at least a catarrhal salpingitis) cured symptomatically, so that the patients were comparatively well, gained flesh, were relieved of the fresh attacks of pelvic inflammation which had come on at intervals of three to six months, and able to do a great deal more, and considered themselves comfortable. In one or two instances such treatment carried out carefully has been followed in married women by conception and the birth of healthy children.

Galvanism is another method of treatment which I have employed to promote the absorption of thickenings in the pelvis which have been the result probably of old tubal disease with extension to the cellular tissue or the peritoneum. It is a method that is worth trying. One thing more. It seems to me that the danger to a woman of rupture of a pus-tube is so remote that in my opinion it is hardly an argument in favor of laparotomy and removal of the tubes

unless other conditions make it imperative. It seems to me that considering the few cases we read of in which death has followed the rupture of a pus-tube, that the woman runs no more risk from that source alone than she would from a laparotomy even in the hands of a skilful surgeon. I do not think there is more than one to three per cent. mortality from this cause alone if tubes the seat of purulent effusion are allowed to remain; therefore, as an argument in favor of laparotomy, where otherwise it would not seem advisable, I do not think it is of very much weight.

DR. A. D. SINCLAIR: I think the subject has been reviewed mostly from the gynecologist's side and not from the obstetrician's. I think it has happened to all of us who have practised midwifery a long time to meet with cases of pure cellulitis, not peritonitis nor enlargement of the tubes, but an abscess or inflammation of the broad ligament or cellular tissue immediately around the cervix. I think that men who have pursued this subject for many years, very adroit indeed and well calculated to make good diagnoses, cannot all be mistaken in that thing, and that pelvic cellulitis is not so rare as we have heard it stated tonight. I think there is a good deal of theory afloat and a good deal written upon it. I remember when there was nothing said about pelvic cellulitis. There were various names given to this condition of things,—pelvic peritonitis, abscess, peri-uterine inflammation, and a host of other names. Bernutz and Goupil had been working up the thing for many years and published a monograph in two volumes, a most admirable thing, and created quite a revolution in the minds of men engaged in gynecology and obstetrics. I read this book, as also that of August Voisin on haematocele. I believe that Bernutz had a great many opportunities for making autopsies, and, by the way, that is the thing that is most striking. I have seen a great many cases of so-called pelvic cellulitis, peritonitis, etc., but I have not had the opportunity of seeing many autopsies, I think not more than three or four in my lifetime. There are the post-mortem records of two cases in the first volume of the City Hospital Reports. These cases were evidently pelvic peritonitis, and, by the way, the other night at the Obstetrical Society there was a paper on tubercular affection of the uterus. The first case recorded in that record of cases was one where, amongst others, was a uterus and tubes crammed full, I think, with tubercular matter and other débris. To go back to Bernutz, he had opportunities to make many post-mortems; and the conclusion one would come to who read his book would be that pelvic peritonitis was the chief cause of trouble, the tubes and ovaries being at fault. Conclusive as this book was, yet the world did not change its mind very much from the opinion that it held in regard to it, and spoke of these cases as pelvic cellulitis. Of course, they were wrong and were right. There are cases of both kinds. The pendulum has swung very completely of late years towards the exclusive view of its being dependent upon tubal trouble setting up inflammation around it. Inflammation of the cavity of the pelvis and effusion and the agglutination of intestines over the effusion makes it a large abscess sometimes, containing nothing but clear fluid (sometimes purulent); but there are cases of genuine pelvic cellulitis where the cellular tissue around the cervix becomes inflamed, where the inflammation extends to the broad ligaments and the tubes

have nothing to do with it nor the ovaries. These cases where abscess take place are generally cases that occur in puerperal women. It is not very common that we find abscess in non-puerperal women. I am speaking now of my own experience. I happened to see many cases in Boston in my own early practice. I was the first person to read a paper on pelvic cellulitis in Massachusetts; and in the discussion Dr. Jackson said he could not see that the cellular tissue around the cervix was of such extent as to form such a mass as was described. That might be or might not be. We know that the finger, the seat of felon, becomes an enormous mass; and I think we have just as good opportunity of finding a pretty large mass in examining through the vagina in a case of swelling of the cellular tissue around the neck of the womb, because it would appear larger than it really is if the patient was not under ether. That there are abscesses of the broad ligament in the puerperal state I am convinced. They come on about the tenth day after confinement. There is not so high fever as in pelvic peritonitis, it is said. The pain would subside, but not the swelling, to come on again about the seventeenth to the twentieth day. There would be increased fever. Very likely the abscess would discharge into the rectum or into the vagina, which was more rare, although we know that in chronic cases vagina, rectum and bladder become involved.

As to the symptoms of this thing, one of the earliest symptoms I used to observe was pain somewhere about the hip and dysuria and tenderness. Then there was sometimes nausea and a little cough,—reflex. The treatment of those days was the applying of leeches to the anus. I have frequently applied perhaps a dozen leeches to the anus. We also used poultices of bran or Indian meal over the abdomen. Sometimes the application of a blister made with nitrate of silver,—pretty smart thing it is, too,—and hot vaginal douches. I do not think as I look back that we used vaginal douches very much at that time. These cases of so-called cellulitis got well. The pelvis cleared up completely; the uterus became quite free. These were the puerperal cases. There was another lot and I dare say those are the ones where the trouble depends upon inflammation of the tubes from various causes. Those cases may in a patient with poor constitution reduce the patient to such an extent as to produce death. The mortality from that class of cases is not, I think, quite settled, but I think it will reach 10% to 15%. At one time I could find no statistics over 5%.

About taking away the prop of the uterus, I saw an instance of that where both ovaries and tubes were removed. The woman is worse to-day than three years ago.

DR. W. W. GANNETT: In connection with the pathological relations which Drs. Sinclair and Chadwick and Davenport have considered, it seems to me each has treated the matter from his own standpoint,—Dr. Sinclair from the obstetrician's and Drs. Chadwick and Davenport from the gynecologist's. That there is a cellulitis, such as Dr. Sinclair refers to, there can be no doubt. It represents a lymphangitis and occurs in puerperal cases. The material travels through the lymphatics and causes this inflammation in the broad ligament, and those cases are very frequently seen at autopsy. The gynecologists I suppose do not see them so frequently.

I should like to ask Dr. Davenport whether he meant by rupture of pus-tubes a rupture along their course, or would he include a discharge of pus from the fibrillated end?

DR. DAVENPORT: I meant a discharge of pus from the tube in such a way as to set up fatal peritonitis.

DR. GANNETT: It seems to me that perhaps Dr. Davenport laid too little stress upon that point. I can recall quite a large number of autopsies in which a peritonitis resulted from discharge of pus from the fibrillated end. It seems to me, viewed purely from the pathological standpoint, that a tube containing pus may be a constant source of danger to the woman in virtue of the possibility of peritonitis being set up thereby.

DR. E. W. CUSHING: In March, 1887, I reported 27 cases of operation for removal of diseased tubes. Since that time I have been active to a degree which I trust has not been pernicious in that direction. I wish to speak in regard to a subject that has been but little touched on to-night, and that is the neglected cases, those that do not get well under treatment. In my hospital service, and in consultation, I am more in a way to see these cases than any others.

One cause of all these troubles, which has not been dwelt on, is too much local treatment, or rather local treatment given without due precautions as to cleanliness and as to care.

Now, it is true that there are a large number of gentlemen who are practising the treatment outlined by Dr. Davenport, and undoubtedly a good many of their cases get better. Every once in a while, however, one gets worse; and there are two or three forms which that getting worse may take. The first is the case that gets rapidly worse with violent fever, tympanites, usually much aggravated by giving large doses of opium,—cases of spreading peritonitis. Those are comparatively rapid cases.

The second class of cases are those where, with long continued tubal inflammation, the ovary is affected. The ovary and the end of the tube are glued on to the lateral wall of the pelvis forming there an abscess. The outside wall of the abscess becomes eaten through by the suppurative changes and the woman begins to run down with symptoms of absorption of pus. In my experience, as long as the pus is retained in the tube itself without forming adhesions to structures where pus is to be absorbed, there is not so much general constitutional trouble. When, however, the wall of the abscess is formed on one side by the tissues of the pelvis, there is liable to supervene a condition of pyæmia.

Another course, which is generally and wrongly supposed to be salutary, is the opening of the pus-tube into the bowel: to be sure, in many cases where the opening is low down and the woman is strong, the tube seems to discharge itself into the bowel; the process of shrinking goes on, and the patient gets well. In far too many cases they do not get well. The tube fills again and discharges, and fills again, and so at intervals of from three weeks to three months the woman goes through the cycle of fever, pain, suffering and discharge, then relief, and then the whole thing comes on again. I have had a considerable number of cases with that history.

In these three ways,—by immediate acute inflammation, by general pyæmia and by long continued wasting through repeated opening into the bowel,—

the women run down, and require operation when they are in a desperate condition. If moderate treatment does not cure the woman, if she is an invalid and if there are signs of pus as evinced by high temperature, I think operation is justifiable and indicated; and if the operation is done reasonably early, it is not particularly difficult or dangerous. The difficulty and danger are from the neglect, from the recurrent attacks of inflammation matting everything together, from old openings into the intestines which have to be found if possible, although sometimes everything is so glued with lymph that it is neither easy to find them nor to prevent the occurrence of fistula afterwards.

In regard to opening of pelvic abscess, I think that Dr. Cabot's view is judicious, except that to my mind not enough stress was laid on the necessity of removing diseased tubes where you would hardly call the malady a pelvic abscess. I fully recognize the surgical tendencies of the last few years to operate on all pelvic abscesses from above. I have tried it, and have concluded that where a collection of pus can be readily reached from below, where, in other words, the vagina is pushed down forming a fluctuating mass behind the uterus, it is a good thing to let out that pus by the vagina; let it be done with the proviso that this may be a temporary thing that there may be pus-tubes behind which may have to be removed later.

Such cases, however, form a minority of those which require operation. They are mostly post-puerperal or follow abortion. In the great majority of cases the disease is in the Fallopian tubes, and the operation should be through the abdominal wall.

It is too late to enter on the question of the manner of operating, but at another time I shall have something to say on this subject.

AMERICAN PEDIATRIC SOCIETY.

(Concluded from No. 19, page 475.)

FOURTH Annual Meeting held in Boston, May 2, 3, and 4, 1892.

SECOND DAY.—AFTERNOON SESSION.

TYPHOID FEVER IN CHILDREN UNDER TWO YEARS,

by DR. W. P. NORTHRUP, New York.

Dr. Northrup's paper, purposed to strengthen the belief that typhoid fever, as a rule, avoided the first two years of life. Clinically: At the New York Foundling Hospital there had never been a case in the observations of twenty years. Cases had been suspected, but on autopsy did not prove to be such. Pathologically: A great many institution-reared children under one year, on autopsy, show the gross lesions of typhoid, judged by the scale of adult life. The Peyer's were enormously swollen and abruptly limited at their margins, sometimes showing a partial ulceration; mesenteric lymph nodes swollen; spleen enlarged, etc. Illustrative cases were narrated showing such lesions. Bacteriological investigation showed no typhoid bacilli (Prudden).

Dr. Northrup desired to raise the inquiry, whether, in the experience of those present, typhoid fever has been observed in children under two years. He had never met it in the wards or in private practice nor in two thousand autopsies.

TYPHOID FEVER IN CHILDREN,

by DR. CHAS. WARRENTON EARLE, Chicago.

Dr. Earle reported twenty cases of typhoid fever in children, occurring in private practice in a community where typhoid fever had been comparatively rare. Of these twenty cases, ten were males and ten females.

Mortality nothing. The youngest child was two years, the oldest fifteen, average seven and a half. Highest temperature 105.5°. Duration of the disease averaged twenty-six days. It varied from seventeen to forty-five days. The pulse ranged from 90 to 180 beats per minute. Bowels constipated in three cases, slight diarrhoea in ten and severe in seven. Vomiting in a very small percentage of the cases, in one or two persistent, slight in three or four. Tympany was manifested in a considerable number of the cases. Phlebitis took place in one case in the profunda femoris vein. Inflammation of the parotid on one side in one case. Epistaxis in eleven cases; in four severe, and the remaining slight. Bronchitis present in almost all the cases; in most of the cases slight, in a few severe. Haemorrhages from the bowels in none of the cases. Rose spots in all of the cases except one which was seen late. Splenic tumor in seventy per cent. of the cases. Pain in the abdomen almost universally present. Pain in the head usually complained of by the older patients and in the beginning of the sickness. In one case speech absent two weeks, in a second five weeks. In most cases the speech was slow and somewhat indistinct. Recovery of speech took place in every case. In one it was suddenly restored, and in two where there was complete absence of speech it was restored gradually. In one case complete deafness for two or three weeks. Otitis in one case. Symptoms referable to the nervous system, delirium with stupor, in most of the severe cases. Convulsions in two cases. Periostitis in one case. Relapse in five cases. Duration of the relapses fifteen to twenty days. Highest temperature in relapse 104.5°. Epistaxis in three of the relapses. Diarrhoea in four and constipation in one.

TYPHOID FEVER IN INFANCY,

by DR. W. S. CHRISTOPHER, Chicago.

The reader had met cases which seemed to be mild cases of typhoid fever in infants, but owing to the fact of invariable recovery, the diagnosis had not been confirmed. Physical examination of the abdomen revealed some flatulence but never meteorism. Enlargement of the spleen almost always to be made out by percussion. On the skin of the abdomen there was a typical roseola. Almost invariably the spots occurred as early as the third day, and rarely exceeded eight or ten in number. Pulmonary symptoms were very important. The bronchitis, always present to greater or less degree in the adult, was exaggerated in the child, and became a prominent symptom of the disease. It seemed probable that in many instances pneumonia was but a symptom of typhoid fever. The condition of the tongue was very important. It did not enlarge, nor become flabby nor indented by the teeth when they were present. It remained of normal size and shape, and was covered by a creamy coat, leaving the sides and edges free. The front portion was rather thinner than the main portion, and the fungiform papillæ might be seen through it, but later were often hidden. The uncovered edges and tip of the tongue were bright red. Tongue always remained moist. The face

did not assume the appearance of typhoid fever. He had never seen nose-bleed. The diagnosis was to be based upon bronchitis, the peculiar tongue, the roseola and the enlarged spleen. In the absence of any one of these, he would be unwilling to make a diagnosis of typhoid fever. The fact that so few adults had the disease might be in part explained by the fact that they secured immunity through a slight and unnoticed case in infancy.

DR. KOPLIK thought the Society owed a great deal to Dr. Northrup for having called attention to the fact that certain of the post-mortem appearances which in the adult were so characteristic of typhoid fever might in children be due to other things.

DR. JACOBI asked in what conditions and diseases this change in Peyer's plaques took place.

DR. NORTHRUP, in reply, stated that ulceration was not such a constant feature, but that marked enlargement of Peyer's patches in children was a familiar sight. He had observed it in at least 150 out of 2,000 autopsies. This occurred in all kinds of intestinal diseases, in fact after almost anything.

Referring to Dr. Earle's paper, he wished to state that he did not think enlargement of the spleen could be determined by percussion. He regarded palpation as the only reliable means of determining this point.

DR. BLACKADER thought he had in rare instances met with typhoid fever in young children. He had always supposed that the freedom which young children had from typhoid fever was due to the fact that they were not brought so much into contact with the sources of infection. Their food was more frequently cooked.

He also felt that it would be very difficult to determine enlargement of the spleen by percussion. The principal symptoms upon which we had to rely were prolonged febrile reaction, rose spots and bronchitis.

DR. WINTERS said he could not recall a single instance of typhoid fever under two years of age, though he had probably seen cases. He thought the rash was almost constantly present, so that he would not be willing to make the diagnosis in young children in the absence of the rash. In some cases the spots were very few in number, while in others they were very abundant. He thought a considerable distension of the abdomen occurred in most cases.

DR. HUBER could recall only two instances of typhoid fever under two years of age, in one of which Dr. Jacobi had made the diagnosis, and in the other case there were five older children sick from typhoid fever at the same time.

DR. SEIBERT had never made the diagnosis under two years. He called attention to the fact that a severe acute gastritis with high temperature and rapid pulse might be mistaken for typhoid fever. In one such case he had examined the breast milk and made a diagnosis of gastritis, and the temperature had gone down from 106° to normal in a few hours upon withdrawing the milk from the child. In the treatment of all cases of typhoid fever he used systematic irrigation of the colon with plain water, in order to take away whatever typhoid poison had accumulated in the lower portion of the large bowel. Under this treatment tympanites subsided, and diarrhoea, if intense, got better, and insomnia seemed to be influenced by it. Whenever he had a patient with diarrhoeal distension of the abdomen he took away milk until the diarrhoea had ceased. He had never prescribed an antipyretic

in four years, and never given a bath except to wash the patient for cleanliness.

DR. ADAMS did not question that typhoid fever occurred in young children, but claimed that the diagnosis was not uniformly made. The typical symptoms of typhoid fever in adults he did not find in very young children. In the treatment he thought too much attention was paid to high temperature. A high temperature which was not continuous was not dangerous. He had seen some unfortunate results from the use of antipyretics in case of high temperature, and had come to discard as routine practice any method of treatment as far as antipyretics or drugs were concerned. He had never practised irrigation in typhoid fever. While the principle seemed good, he would hesitate to recommend it in young children: first, because the intestinal tract should be kept as quiet as possible, and, secondly, because young children resisted such treatment, unless in a very low condition.

DR. ROTCH thought cases of typhoid fever in young children were rare. The diagnosis in young babies and children had to be made the same as the diagnosis in aborted types of the disease in adults, namely, by exclusion mainly.

DR. JACOBI had made the diagnosis of typhoid fever under two years, and had seen a few autopsies. The diagnosis in most cases was first suggested by exclusion. If he saw a case with a moderate amount of fever lasting sometime, without any local symptoms to account for it, he would suspect typhoid fever. If there were two temperature curves in twenty-four hours for sometime, it was typhoid fever unless there was good reason to take it for intermittent duplex. If the fever was well tolerated it would lead to the suspicion of typhoid. When also there was a roseola, he would say that it was typhoid fever. When in addition to that the spleen could be felt under the ribs it was typhoid fever.

PRE-TUBERCULAR ANÆMIA,

by DR. B. K. RACHFORD, Newport, Ky.

Dr. Rachford based his conclusions upon examinations of the blood of 168 convent girls, from a careful inquiry into their family histories and from physical examinations. His conclusions were that family tuberculosis was one of the great sources of anæmia. Girls from tubercular stock were more likely to be anæmic than girls from non-tubercular stock in the ratio of 72 to 7. Second, that tubercular lymphatic disease caused profound anæmia, while beginning pulmonary tuberculosis might not produce anæmia. Anæmia in cases with tubercular family history without apparent lesions, might be due to tuberculosis of the deep lymphatics. Pronounced anæmia without apparent cause, was strongly suggestive of concealed tuberculosis. Third, that deep-seated tuberculosis might confer immunity from pulmonary tuberculosis. Some of these anæmic girls with tuberculous family history, even though exposed often to tuberculosis, escaped from the disease not because the anæmia protected from the disease, but the cause of the anæmia, namely, deep-seated tuberculosis, conferred immunity from pulmonary tuberculosis. Fourth, the typical anæmia of tuberculosis corresponded more nearly to simple anæmia than to chlorosis.

DR. FISHER believed that cases of anæmia or chlorosis were very often cases of true tuberculosis. He cited the case of a young woman with an obstinate

form of chlorosis, who suffered from a severe form of diarrhoea, and in the discharges tubercle bacilli were found. There was no cough, and the anæmia had existed about two years before the bacilli were found.

DR. OSLER said the paper was an admirable piece of clinical observation. He thought the conclusions were those which had already been arrived at, that the anæmia of tuberculosis was very commonly a simple anæmia, not a chlorotic anæmia, though there were some instances, undoubtedly, in the early stages of tuberculosis in which the condition was what the French writers described as chloro-anæmia.

A CASE OF SPORADIC CONGENITAL CRETINISM, by DR. CHARLES W. TOWNSEND, Boston.

The case was that of an infant eighteen months old which was an idiot, but in addition to the other clinical symptoms of idiocy showed the characteristic cretin's habit of lying in a hibernating condition for from a few minutes to a hour every day, with the eyes vacant and staring, and the respiration scarcely to be noticed. The facial expression was characteristic of cretinism — edematous thickened skin, with narrow eyes, large tongue, partly protruded from the mouth, and the bones from the forearm and leg were short and out of proportion to the large body and head. The temperature was always subnormal, 96.8°, the respiration slow, twelve to sixteen to the minute. The child died at the age of two years from some intestinal trouble.

DR. HUBER said that cases of cretinism, semi-cretinism and the cretinoid condition were rather frequent in the tenement districts in New York. In the syphilitic cases we did not get that enlarged thyroid so common in the cases that occurred in Switzerland. In such cases the thyroid was very poorly developed or absent. He had seen one or two of the semi-cretins who had attained the age of eighteen or more. They had a fair amount of intelligence, the characteristic facial expression, the long antero-posterior diameter, the large head, and were only twenty-seven to thirty inches tall.

DR. OSLER said that no case had come under his personal observation until recently, when a case was brought to him from Maryland. It was a perfectly typical case. There was no cretin in any of the idiotic asylums.

DR. HUBER, in reply to a question, stated that the cretins occurred mostly among the Russian Poles, Germans and Swedes.

THIRD DAY.—MORNING SESSION.

SYPHILITIC BRONCHO-STENOSIS IN CHILDREN,

by DR. A. SEIBERT, New York.

Dr. Seibert reported four cases of this affection which he had observed in the last three years. The patients varied in age from eighteen months to three and a half years; were the children of poor Russian Hebrews who had recently come to this country. Taking the four cases together, the following is a brief sketch of the chief symptoms and course: the disease started in the upper air passages with cough, hoarseness and aphonia. Gradually and slowly signs characteristic of stenosis appeared, to remain for weeks and months, only varying in intensity: muco-purulent expectoration from larynx and trachea; one-sided bronchitis; at last pulmonary infiltration into the tissue adjoining the right bronchus, dulness over the middle

lobe posteriorly, bases free. Chronic course three to eight months; no fever; comparatively good nourishment of patients in spite of long suffering; and at last prompt success by anti-syphilitic treatment.

Laryngoscopic examination showed marked hypertrophic swelling of the mucosa and vocal cords; no ulceration in the larynx; well marked in the oral cavity. It was clear that we had to deal with an affection of the respiratory tract that could simulate laryngeal croup. One child was intubated, and respiration remained the same after intubation. This showed that we had to look for the hindrance to respiration below the larynx. The gradual development of the cases spoke against foreign body as the cause. Tumors pressing on the bronchus could not explain the tracheitis. The general condition of the children was very good, which did not speak for extensive tubercular affection of the larynx, trachea and lung. Further more, fever was absent.

Enlarged tubercular lymph nodes might exist without fever, and might compress a bronchus; but if laryngeal, tracheal and pulmonary changes also existed, then fever and cachexia would be present. Syphilis was the only thing that would account for the clinical picture and for all the pathological processes.

Syphilitic broncho-stenosis in children was of rare occurrence, much rarer than bronchial compression by tubercular nodes.

DR. CAILLÉ, of New York, had seen a number of these cases. In two cases he had found, at autopsy, that the areas of dulness were not inflammatory foci, but aseptic spots. He thought that fumigations with calomel were indicated, in order to obtain both a constitutional and local effect. This treatment should, after a few days, be followed by iodide of potassium.

DR. HENRY JACKSON, of Boston, alluded to two cases he had seen in adults. In one there were cicatrices in the larynx, ulceration and a few small cicatrices in the mouth. There were signs of consolidation in the lungs. There was an annoying hard cough. The diagnosis of tuberculosis was made, syphilis not being considered. At a later period the diagnosis of syphilis was made and the patient rapidly recovered on anti-syphilitic treatment.

The second case presented marked signs of syphilis in surface lesions. He had ulcerated laryngitis. There was stenotic breathing, a small area of consolidation in the middle part of the right lung. The case yielded to specific treatment.

DR. SEIBERT, of New York, called attention to one form of syphilitic stenosis that would not be benefited by anti-syphilitic treatment, namely, where a diminution existed in the circumference of the bronchial tube due to constriction on the part by a cicatrix. In the majority of cases the stenosis was caused by a pathological hypertrophy of the submucosa and mucosa, and was very readily relieved.

Fumigations with calomel might be good, but he was satisfied with the old way of using iodide of potash and mercury. He usually administered the iodide per rectum.

A CASE OF DEATH FROM LARYNGISMUS STRIDULUS IN INCIPIENT RACHITIS,

by DR. SAMUEL S. ADAMS, Washington, D. C.

The case was that of a bottle-fed baby first seen at the age of four months, when it was suffering from an attack of tonsillitis. A week after recovery a severe

attack of grippe came on, which subsided after three days and was followed by bronchitis of the larger bronchi. A few days later broncho-pneumonia developed, which was soon recovered from. About six weeks later, Dr. Adams was called to see the child on account of loss of appetite and sluggish bowels. His attention was called to a peculiar noise the child made as it awoke. This was a sort of whoop with inspiration. Shortly after this, convulsions set in. A consultation was had, and the diagnosis of laryngismus stridulus, due to incipient rachitis, was arrived at. The child died suddenly a few days later, and no autopsy could be obtained. The sutures and fontanelles were normal, but the child was fat and flabby.

DR. BLACKADER, of Montreal, stated that while laryngismus stridulus was a not uncommon accompaniment of incipient rachitis in London and on the Continent, yet in Montreal it was rare, although cases of incipient rachitis were common.

DR. ADAMS, in reply to questions, stated that there was no nystagmus in this case, and no evidence of adenoid vegetations so far as symptoms went. He had not examined for them.

DR. SEIBERT called attention to the possibility of enlargement of the thymus gland being the immediate cause of death in this case. He cited a case in which a baby in perfect health had died almost instantly without any movement from being turned upon the face in the mother's lap. At the autopsy a very large thymus gland was found.

DR. JACOBI, of New York, said that, in his judgment, forty-nine out of fifty cases of laryngismus stridulus were of rachitic origin. There was every reason to look for rachitis in this case. The child had been fed on cow's milk, was a fat child, had not been a well child. Besides this, the child had had a good many convulsions, and there probably was that condition of the brain which results from rachitis. He believed that there was edema of the brain which gave rise first to the laryngismus stridulus, and, secondly, to the constantly repeated convulsions. As to the cause of death he did not think we could state positively. He suggested, as a possible cause, the so-called swallowing of the tongue, also hypertrophy of the thymus gland.

DR. HUBER, of New York, stated that cases of laryngismus stridulus with more or less softening of the occipital and parietal bones and other evidences of advanced rachitis were not uncommon in his service in the Vanderbilt Hospital and in the tenement districts. He had seen four cases in which swallowing of the tongue was the immediate cause of death.

DR. ADAMS, of Washington, stated that he had seen one or two of the convulsions, and that after an inspiratory whoop a decided clonic convolution followed. The cause of death was not clear.

DR. HUBER, of New York, reported

A CASE OF SACRO-COCYGEAL TUMOR IN A CHILD THREE WEEKS OLD; OPERATION; RECOVERY.

DR. A. JACOBI, New York, presented

A NOTE ON PEROXIDE OF HYDROGEN.

Dr. Jacobi called attention to a number of cases he had seen, in which the use of peroxide of hydrogen in diphtheria especially had produced appearances which might be mistaken for the original disease, and which appearances had readily disappeared on withdrawing

the peroxide. The disease had not only not been benefited, but had been prolonged by the use of the drug.

DR. CAILLÉ, of New York, cited a case in which, thirty-six hours after using the peroxide of hydrogen in weak solution as a spray and gargle, a whitish veil appeared in the mouth, and then beginning ulceration and a pseudo-membrane over these ulcerated spots. At the suggestion of Dr. Jacobi the peroxide was stopped, and the patient recovered.

DR. BLACKADER, of Montreal, suggested the possibility that the peroxide contained impurities of an irritating nature, these impurities being the salts and acids used in the production of the peroxide, and which in themselves must be poisonous.

DR. SEIBERT, of New York, had observed the same appearances described by Dr. Caillé as following the use of peroxide. Although peroxide was extensively advertised, he had never seen one scientific article in medical literature showing that it really did kill germs.

DR. BUCKINGHAM, of Boston, had used the fifteen-volume solution of peroxide of hydrogen in a spray in the mouth and nose. He had not been able to trace any bad results. It seemed for a time to lessen the membrane, but the membrane quickly returned. He was uncertain whether it had any benefit as far as the disease went.

DR. KOPLIK, of New York, had observed, in one case where he had used a spray of peroxide, a beefy color to the soft palate followed by a milky pseudo-membranous deposit.

DR. HUBER, of New York, had seen in a number of cases the effects which had been described.

DR. JACOBI, of New York, said the films seen were coagulated albumen, but the damage was done by destroying the epithelium, giving rise to new exudation, new diphtheritic deposits and certainly to more danger and discomfort.

THE RELATION OF RHEUMATISM AND CHOREA,
by DRs. C. W. TOWNSEND, BOSTON; F. M. CRANDALL, NEW YORK; M. ALLEN STARR, and SAMUEL S. ADAMS, WASHINGTON.

The discussion was opened by DR. C. W. TOWNSEND, who read a paper of which the following is an abstract:

Statistics as to the frequency of rheumatism in choreic cases vary very much, owing to the obscure nature of rheumatism in children, and this variation was illustrated by quotations from different writers. The questions to be considered are:

(1) Does rheumatism occur with greater frequency among choreic than non choreic children?

(2) Does rheumatism act simply as a debilitating disease in its relation to chorea, or is there an intimate relation between the two diseases?

(3) Is the heart-murmur often found in chorea, due to endocarditis, and is it liable to lead to serious heart disease?

In answering these questions, the writer considered all the cases of chorea in the out-patient department of the Boston Children's Hospital, 148 in number, from the years 1883 to 1890, a large number of whom had been seen at the hospital or visited at their homes after the original attack of chorea. He found that twenty-one per cent. of these had had rheumatism, and thirty per cent a heart-murmur, half of the latter becoming organic heart disease. That there was an intimate re-

lation between rheumatism and chorea seemed evident from the large proportion of rheumatic cases among the latter. Among non-choreic children he had found only five and one-half per cent. to be rheumatic, or twelve per cent., including the cases of so-called growing pains. Another reason for believing in the intimate relation of the two diseases was that chorea is often followed or accompanied by rheumatism, as well as preceded by it, one sometimes giving place to the other.

The occurrence of endocarditis in chorea without rheumatism was considered a strong argument against the purely neurotic theory, and one that pointed to the infectious nature of chorea.

The conclusions reached were:

(1) Fright, eye-strain, debility and school pressure, particularly the latter, which often include some of the former, are potent exciting causes of chorea.

(2) Rheumatism, although absent from the history of at least half of the choreic cases, occurs with greater frequency among choreic than non-choreic cases.

(3) There is an intimate relation between chorea and rheumatism.

(4) The heart-murmur so frequently found in chorea, sometimes associated with rheumatism and sometimes not, is in a considerable proportion of the cases due to endocarditis, and leads to organic valvular disease.

DR. CRANDALL, of New York, had concluded, after a careful study of his cases of chorea, that there was some underlying cause aside from the fright, rheumatism, etc., that there was some neurotic element underneath all this. Not every person exposed to tuberculosis contracted the disease, and not every person exposed to fright, scolding, rheumatism, etc., had chorea. Rheumatism, however, was the most universal and potent of the exciting causes.

DR. STARR, of New York, presented an analysis of 385 cases of chorea. Of these, 234 were general; 140 were unilateral; 11 extent uncertain. Distinct history of rheumatism in 70 cases. In 281 cases rheumatism denied; in 5 cases pains of doubtful nature were admitted; in 29 cases no record was made of rheumatism. Organic heart disease found in 70 cases; functional murmurs in 56 cases; heart normal in 212 cases; no statement regarding heart in 47 cases. The cases in which rheumatism was noted were cases in which a distinct attack of acute articular rheumatism had occurred. In 340 of the cases a record was made of the history of the parents as regarded rheumatism, nervous diseases and phthisis. In 58 cases one or both parents suffered from rheumatism. In 100 cases one or both parents were said to be "nervous."

DR. S. S. ADAMS regards rheumatism which holds an indirect relation to chorea, as a less important factor in its development than neurasthenia.

DR. JACOBI, of New York, said that a diagnosis of acute rheumatism was not so frequently made in little children as it ought to be, and a good many of the cases in which there was heart disease and not rheumatism had been rheumatic. We found in children of six to twelve years of age a good many fully developed cases of heart disease that must have a cause. Congenital heart disease was rare. All the cases, with rare exceptions, seen in later life were acquired, and the cause of acquired endocarditis was rheumatism. A great many cases were reported in which some pain had existed, but they had not been taken for rheumatism.

Why not? These pains had been rheumatism. The so-called growing pains were one of three things: first, neuralgic pains; second, epiphysis. These cases were not so frequent as to cover all the cases. Third, there was a large number of cases of so-called growing pains which were not growing pains at all, but positive cases of rheumatism. Cases of rheumatism with endocarditis that could not be doubted at all would frequently be found attended with very little pain about the joints, very little swelling and sometimes not very high fever. Sometimes the endocarditis came very early, sometimes late: it was very frequent. He believed rheumatic endocarditis attending even a mild attack of rheumatism was more frequent in children than in adults. He believed that there was very much more articular rheumatism in children than we had generally assumed, and that there were a good many cases of chorea which should be attributed to that.

DR. HOLT, of New York, said if we assumed that only cases with a definite history of acute articular rheumatism were to be regarded as rheumatism, the number of cases would be very much reduced; but it seemed to him that the great proportion of all these cases of endocarditis should be included as rheumatism. He had learned to be very suspicious of cases of functional heart murmur in chorea. In such cases when examined several years later well-developed heart lesions were often found. His own conviction was that the connection between rheumatism and chorea was a very close one. Other factors, of course, were necessary besides rheumatism, but certainly the rheumatic diathesis and the presence of acute rheumatism was a more powerful predisposing factor than any other single one.

DR. FISHER, of New York, had examined the blood of a patient suffering from a second attack of chorea and in whom there was a history of rheumatism. The blood contained peculiar germs resembling the streptococcus seen in a case of rheumatic endocarditis. The germ disappeared after about ten days' use of Fowler's solution.

DR. OSLER, of Baltimore, thought it quite impossible to bring all the cases of chorea into the category of rheumatism. In 554 cases he had studied from German records only fifteen per cent. had a positive history of articular trouble; and, including those with pains of any kind, the percentage was only twenty. Unless we expanded largely our conception of rheumatism in children the large proportion of the cases which had come under his observation in Philadelphia and Baltimore had no definite history of rheumatism, and the absence of the subcutaneous fibrous nodules upon which English writers had laid such stress was striking. The frequency of organic heart disease in the subjects of chorea was remarkable, and the subjects of chorea had usually a definite articular history. In 110 cases from the Infirmary of Nervous Diseases in Philadelphia there were 40 with signs of organic heart disease, and in more than fifty per cent. of these cases there had been no history of rheumatism. There was no other disease with which endocarditis was shown by autopsy to be so frequently associated as with chorea. The nature of the disease and the relationship were still doubtful, but the points brought out had been of considerable interest, and showed a larger percentage of rheumatic cases than had yet been shown in any series in this country, a percentage approaching much more to the English than to the Germans.

THIRD DAY.—AFTERNOON SESSION.

THE VALUE OF MILK LABORATORIES FOR THE ADVANCEMENT OF OUR KNOWLEDGE OF ARTIFICIAL FEEDING,

by DR. T. M. ROTCH, Boston.

DR. BOOKER, of New York, believed that the process presented by Dr. Rotch would supply us with a means of treating cases that could not take milk as ordinarily sterilized, and of treating cases in which the breast milk could not be given. The point at which the milk was sterilized, namely 167° F. was important. Sterilized milk at 212° F. was more difficult of digestion than unsterilized milk.

DR. KOPLIK, of New York, thought this low point of sterilization was very important, since if sterilized at 212° F., some children would not drink it. It tasted boiled, and the cream separated in drops of fat. He had experimented with sterilizing milk at a low point, and had succeeded well.

DR. JACKSON, of Boston, had examined specimens of the milk as delivered to the laboratory and found it contained but a comparatively small number of bacteria. As to whether milk was as fully sterilized at 167° F. as at 212° F., he had made a few experiments and found that about an equal number of bacteria developed in the milk sterilized at 167° F., and at 212° F.

DR. HOLT, of New York, said the sterilization of milk as first introduced had not met the expectations of the profession. He was delighted to find that milk subjected to a temperature of 167° F. was sterile for all practical purposes. Dr. Rotch had given us a method of artificial feeding which exceeded his expectations. He thought the Society and the profession owed him a debt of gratitude for making a start in a direction the full fruits of which we could not see for many years.

DR. BLACKADER, of Montreal, also had come to the conclusion that milk sterilized at 212° F., did not meet our practical wants. He had recently subjected milk to a temperature of not exceeding 180° F. with very good results. The milk was not altered to the same extent as before.

DR. JACOBI, of New York, said the fault was not so much with sterilization at 212° F. as it was in the fact that we expected too much. No sterilization and no handling of cow's milk would make human milk. He believed the principles of feeding laid down before would still hold good. He wished to join in the complimentary remarks as to the method of Dr. Rotch and its merits.

A SIMPLE METHOD FOR CLINICAL EXAMINATION OF BREAST MILK,

by DR. L. EMMETT HOLT, New York.

Dr. Holt showed a simple apparatus he had devised for the clinical examination of breast milk, which consisted of a lactometer and a graduated tube. Milk to be examined was either the entire specimen at a single nursing or a specimen taken as near the middle of the nursing as possible. The specific gravity was first taken; then the milk was put into the graduated tube taken up to the hundred line and allowed to stand for twenty-four hours on the physician's table, at which time the amount of cream which had risen could be read off as hundredths. A good average milk would have a specific gravity of about 1030, with about eight per

[MAY 19, 1892.]

cent. of cream, provided the specific gravity and the percentage of cream did not vary materially from these figures, it might be inferred that the amount of protein was normal. The quantity of milk must be taken into account, just as it is when a chemical analysis is made. For instance, he had seen the cream at fifteen per cent., and yet the children losing. The milk in this case was found to be scanty.

DR. CHARLES HARRINGTON, of Boston, said his experience had led him to the conclusion that the lactoscope, if properly used, was superior to other systems in the determination of the amount of fat in milk. The instruments which depended upon the liberation of the fat were so unreliable as to be in most instances practically of no value. He agreed with Dr. Holt that with a knowledge of the percentage of fat and the specific gravity the percentage of sugar and albuminooids might be determined quite accurately. In trying to get an idea of the amount of fat from the cream volume he had found great difficulty in many cases. In one case where only a thin wafer of cream appeared the milk was found to contain four per cent. He had not used the lactoscope much with breast milk.

After appropriate action relative to the death of DR. JOHN AMORY JEFFRIES, of Boston, the meeting adjourned.

Recent Literature.

Diseases of the Throat, Nose and Ear. A Clinical Manual for Students and Practitioners. By P. McBRIDE, M.D., F.R.C.P. (Ed.) With colored illustrations from original drawings. Philadelphia: P. Blakiston, Son & Co. 1892.

This work of 606 pages is, if we are not mistaken, the first in which the diseases of the throat, nose and ear are discussed in a single volume. It is fortunately not a compilation, but founded chiefly upon the author's own experience, and there is ample evidence throughout its pages that he is an accurate observer and a conscientious practitioner. He has shown great ability as a condenser. The volume, by no means bulky, contains everything of importance in modern laryngology, rhinology, or otology. It is fully up to date. It is a comfort to read page after page without meeting a single drawing of atomizers, compressed air apparatus, or of instruments of any kind. All these have wisely been left out, and much valuable space thereby economized.

Although specialists will find this a highly interesting work, its chief mission will be for students. We can recommend it to them as a thoroughly safe guide. It tells them what they want to know in a clear and reliable manner without wasting their time, as the author has imparted his facts without waste of words. The press-work leaves nothing to be desired.

The Emperor of Austria has conferred the cross of Knighthood of the Order of Leopold, with remission of the customary fees, on Professors Otto Kahler, Moriz Kaposi, and Gustav Braun, of the University of Vienna.

THE BOSTON Medical and Surgical Journal.

THURSDAY, MAY 19, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

THE LIVER IN DIABETES.

THOUGH the primary cause of this disease (whether nutritive or nervous) is still involved in obscurity, yet that diabetes is frequently associated with exaggeration of the glycogenic function of the liver is not questioned. More than a hundred years ago, Richard Meade declared diabetes to be a disease of the liver; time has shown what measure of truth there is in his statement. The immediate result of Claude Bernard's discovery of hepatic glycogenesis was to direct research to that organ as the probable seat of diabetes. The results of very many autopsies of diabetic patients have shown a remarkable concomitance between this disease and states of hyperemia, enlargement and hypertrophy of the liver. Out of twenty-seven autopsies at St. George's Hospital, Dickenson found the liver healthy in only six cases; in thirteen it was more or less hyperemic; in three it was hard and enlarged; in four it was fatty, etc. Among thirty diabetics examined after death at the Vienna Hospital, the liver was found enlarged in fifteen, gorged with blood and hardened; it was generally of a dusky brown color, and in some cases its acini were less sharply defined or even obliterated.¹ According to Klebs the congestion of the liver is an active hyperemia; dilatation of the hepatic veins and their roots such as occurs in static hyperemia, is wanting. The hypertrophy is also a peculiarity of diabetes, but the increased volume of the organ depends more on the enlargement of the gland-cells than on augmented quantity of blood. In the further progress of the disease, according to Klebs, the liver again diminishes in size, becomes withered and flabby, and often fatty degeneration takes place.

Hypertrophic sclerosis has several times been noted; Hanot and Chauffard have called attention to the presence of pigmentary granulations in the sclerous tissue (*hypertrophic pigmentary cirrhosis*). If atrophic cirrhosis has been frequently seen, this may be ex-

¹ Senator.

plained by the abuse which diabetics often make of alcohol, when, however, diabetes has lasted a long time, according to Lécorché, the congestive state entails a cirrhosis which terminates the disease.

Glenard, in summing up the results of autopsies as far as known, computes that there exists an objective alteration of the liver in sixty per cent. of cases of diabetes, and hypertrophy is met with in one-quarter of the cases.²

It is by no means agreed that all forms of saccharine diabetes are due to excessive production of sugar by the liver. The gastro-intestinal theory of Bouchardat, according to which the abnormal saccharinity of the blood is due to direct absorption of sugar from the alimentary canal, has not yet been wholly set aside, and doubtless serves to explain some cases. Bouchardat supposed the cause of the diabetes to be mal-elaboration of the carbo-hydrates owing to some digestive derangement. Other and later writers have hypothesized a failure of the liver to fix sugar and store it up for time of need. However this may be, Andral's famous case, in which mellitaria had existed with complete obliteration of the portal vein, proves the possibility of an abnormal quantity of sugar entering the blood and constituting a glycosuria independently of any action of the liver; and Wickham Legg has shown that ligation of the choledochus duct produces in the cells of the liver alterations which oppose the formation of glycogen, preventing even the production of glycosuria after puncture of the fourth ventricle; what is especially noteworthy in this experiment is that the injury above stated does not prevent glycosuria from supervening when an excess of sugar or starch is ingested.

The old writers paid much more attention than modern writers to the gastro-intestinal derangements which often precede and accompany diabetes, and get good results from a therapy and a dietetic hygiene based on data thus obtained; and this, long before any thing was known respecting the agency of the liver in glycogenesis.

That there is a very grave form of diabetes dependent on destructive lesions of the pancreas, is now being generally admitted, and without entering into any explanation of the relation of the pancreas to hyperglycemia (which is confessedly little understood), it is certain that in pancreatic diabetes hepatic alterations do not play the principal rôle. Experimentally, diabetes has been produced in animals by extirpation of the pancreas; the diabetes so obtained persists; in frogs the result is the same even after ablation of the liver (Le Gendre).

There is a very popular theory of diabetes which leaves the liver hardly any rôle in the pathogenesis—that of Bouchard. According to this, in diabetes there is a normal formation of sugar by the liver; insufficient utilization of sugar by the tissues; accumulation of sugar in the blood; accumulation of water in the blood by reason of the sugar which demands water

for diffusion and borrows it of the tissues and fluids; augmentation by this fact of the total mass of the blood; consecutive hyper-activity of the renal secretion, whence polyuria which removes the sugar and moderates the hyper-glycæmia.³

In a recent able survey of the whole subject, Dujardin-Beaumetz⁴ maintains that in diabetic patients the functions of the liver are in the main normal and physiological, perhaps even exaggerated, and he affirms that in the numerous cases of hepatic disease which he has examined, he has never seen even a temporary glycosuria appear in the course of the hepatic affection. He further contends that in the diabetic the intercurrent affections of the liver (cancer, cirrhosis, amyloid degeneration, etc.), tend to cause the sugar to disappear from the urine.

To conclude: doubtless the hyperæmia and other alterations of the liver noticed by Glenard, Dickenson and others in diabetes and referred to above, may be regarded as accompaniments or consequences of the disease rather than in any true sense the cause. True diabetes has never yet been produced by agents influencing primarily the liver.

SEX IN EDUCATION.

SIR JAMES CRICHTON BROWNE has been delivering an address before the Medical Society of London on the above subject.¹ Sir James's former investigations as to the relation of school work to headaches is still in memory. He dreads forcing in education, and fears for the immediate and prospective results of over-pressure in the English high-school system upon English girlhood, motherhood and future generations.

As the result of his own examination of a great number of brains—leaving aside other and grosser physical differences—and the examinations of others, he concludes that all available evidence points to the conclusion that the male brain exceeds the female brain in weight in his country to an even greater degree than has been hitherto supposed. That the smaller size of the female brain is a fundamental sexual distinction, and is not to be accounted for by the hypothesis that environment, educational advantages, and habits of life, acting through a long series of generations, have stimulated the growth of the cerebrum in one sex more than in the other, is made clear by the fact that the same differences in brain weight between men and women has been found in savage races. And not only is the male brain heavier than that of the female, but it has a wider range of variation in weight. The very big brains and the very small brains are encountered, just as are geniuses and idiots, giants and dwarfs, more frequently amongst men than amongst women.

Again, he finds that there is a distinctly different

¹ Lancet and British Medical Journal, May 7, 1892.

² Bouchard : *Maladies par ralentissement de la nutrition.* Chap. VII.

³ Bull. gén. de Ther., January 15, 1892.

⁴ Labadie Lagrave : *Maladies du Foie*, 1892.

distribution of brain substance in man and woman, and this he regards as the second sexual brain distinction. The frontal lobes are equally developed in both sexes; the parietal lobes, corresponding roughly with the motor area of Ferrier, are larger in the male than in the female; the occipital lobes, sensory in their functions, are larger in the female than in the male.

The third brain difference between the sexes is in the convolutional arrangement. The female brain is more symmetrical than the male, due, probably, to its comparative poverty in secondary gyri. There are, moreover, observations indicating that the gray matter of the male brain has a greater specific gravity than that of the female brain.

Still another brain difference is in the vascular supply, and vascular supply is in some degree a measure of functional activity, the flow of blood to an organ or part having always a relation to its working power. But the region of the brain which in men is most richly flushed with blood is that which is concerned, we have reason to believe, in volition, cognitions, and ideo-motor processes; while the region which in women is most vascular is that which is mainly concerned in sensory functions, and we thus see that there is a relation between the size of the cerebral arteries, and what observation has taught us as to the intellectual and emotional differences of the sexes.

Sir James finds that all through life the male brain differs from the female in capacities, aptitudes and powers. These differences assert themselves early, and are found among barbarous and civilized peoples alike, and they have a special pathological significance at the period when sexual divergence is taking place most rapidly, and when education is being pushed forward with most vigor.

This address expresses no uncertain opinions in regard to the dangerous tendencies of the modern "higher education" of women, but it is nowhere temperate. Few will probably refuse their consent to the statement that education from first to last can only be safely conducted in the light of cerebral physiology. He who unveils that light and holds it up where it must be seen is, at the present time, a benefactor.

SEVENTY-EIGHTH ANNUAL REPORT OF THE MASSACHUSETTS GENERAL HOSPITAL AND MCLEAN ASYLUM.

FROM the report of the Resident Physician of the Hospital we learn that 3,203 patients were admitted during the calendar year, of whom 1,171 were Medical and 2,032 were Surgical; 1,881 were males, and 1,322 were females; 637 paid board in whole or in part; and 2,566 were entirely free.

The proportion of deaths to whole number of results was 8.40 per cent. The number of patients received on account of accidents was 595. The average number of free patients was 186; Americans 94, foreigners 92. The average time of paying patients was 2.66 weeks, of free patients 3.76. The proportion of ward beds occupied by free patients was 81 per cent, by

paying patients, 19 per cent. The average cost per week per patient in the Hospital was \$12.54.

The total attendance of out-patients was 48,032, of whom 25,819 were new cases; the average daily attendance was 163. The out-patient quarters were enlarged by the addition of another story. The Convalescent Home has sheltered 386 patients. Donations and legacies to the amount of \$36,662.32 were received during the year.

At the McLean Asylum, there were 184 patients—88 males and 96 females—at the beginning of the year; 116 persons were admitted during the year, of whom 64 were regarded as recent cases and 52 as chronic or incurable. The average cost per week per patient was \$16.81.

Eighty-nine persons, thirty-nine men and fifty women, had never been in any hospital. Of the remaining twenty-seven persons, seventeen, four men and thirteen women, were admitted for the second time; seven persons, six men and one woman, for the third time; three persons, one man and two women, for the fourth time; and one man for the twenty-seventh, twenty-eighth and twenty-ninth times.

Of the one hundred and twenty-four persons discharged, including deaths, eighteen, six men and twelve women, were transferred or committed to other hospitals in this State, and two men and one woman to hospitals in other States.

Of the thirty-three persons discharged recovered, twenty had never before been inmates of any hospital; and of the remaining thirteen persons, ten had been in this Asylum, one in a private asylum in this State, and two in State asylums. These thirteen persons had previously made fifteen recoveries.

The average duration of illness from the beginning of attack in all cases recovered was 12.35 months, and the average duration of their residence in the Asylum was 6.58 months. The percentage of recoveries on all admissions, of persons accounted as insane, for the year 1891, was 28.45.

The voluntary cases admitted during the year numbered forty. These represented thirty-nine persons—ten men and twenty-nine women. Of these, twenty-seven were cases of melancholia, three of mania, three of delusional insanity, one of secondary dementia, two of paralytic, one of epileptic insanity, and two of general paralysis. Of these thirty-nine persons, four were committed after entering the Asylum as voluntary cases, and one was twice admitted as a voluntary case. The voluntary patients have yielded 28.2 per cent. of recoveries on the admissions of that class for 1891, thus furnishing only their due proportion of all the recoveries.

The number of persons admitted as voluntary patients under the present law is as follows: namely, 1881, 1; 1882, 11; 1883, 33; 1884, 49; 1885, 34; 1886, 29; 1887, 29; 1888, 34; 1889, 41; 1890, 58; 1891, 40;—a total of 359 persons in eleven years.

The Superintendent, Dr Cowles, comments upon these results as follows:

"There is much significance in the fact that nearly three-fourths of the voluntary patients in the last year were cases of melancholia. This presents the least serious degree of mental disorder; there is retention of intelligence that leads to the seeking or acceptance of remedial conditions in hospital care, and the doubtful cases, for whom preventive aid is most salutary, are mainly to be found in this stage of mental disease. The voluntary cases constituted almost exactly one-third of the admissions for the year, while nearly one-half in the previous year were voluntary.

"A number of interesting facts are brought out by these results of the year's work, that help to explain each other. There were not so many strictly recent cases as in 1890,—the average duration of illness of recovered cases was 12.33 months against an average of 8.31 months in the previous year,—the average hospital residence of these cases was one month longer, and the proportion of recoveries to the cases admitted was less. Consistent with these results is the lessening in number of voluntary cases, and evidence of the general fact is shown, that the wards were filled with sicker people than in the year before, who were the subjects of active hospital care."

The work of the laboratory for pathological and experimental investigations has been pursued steadily during the year. The training-school for nurses continues in efficient operation.

MEDICAL NOTES.

CHOLERA.—It is reported that cholera is now epidemic in Asiatic Russia, and a special commission has been appointed by Russia to inquire into it. It is also epidemic in the interior of Arabia, and fears have been expressed, that Europe may be invaded during the coming summer. A groundless rumor that cases had occurred in Paris caused some excitement there.

NOTORIETY NOT ALWAYS DESIRABLE.—A notorious quack in Nebraska, who advertised that he had cured twenty-five cases of diphtheria, was recently arrested by the local Board of Health for not having reported the cases.

NEW ENGLAND.

MORTALITY FOR APRIL IN BOSTON.—For the month of April the death-rate was 24.51. The total number of deaths was 938, as against 913 during the corresponding month in 1891. The principal causes of death were: Consumption, 135; bronchitis, 51; heart disease, 90; pneumonia, 102; diphtheria, 52. There were 339 cases of scarlet fever reported with twenty-five deaths.

THE CARNEY HOSPITAL APPROPRIATION.—The question of giving the Carney Hospital \$10,000 came up for a third reading in the Massachusetts House of Representatives on Tuesday. The previous favorable vote was reversed, and the bill was defeated by 106 nays to 99 yeas.

CATALOGUE OF THE HARVARD MEDICAL SCHOOL ASSOCIATION.—This Association has recently issued its second bulletin, in which the names and residences of all its members appear. The total number of members is 1011, of whom 13 are honorary; 348 are residents of Boston, 357 of other cities and towns in Massachusetts. Almost every State is represented and a few foreign countries.

MEDICAL EXAMINERS.—The Governor of Massachusetts has reappointed Zabdiel B. Adams, of Framingham, to be medical examiner for Middlesex County, and Thomas J. Walker, of Edgartown, for Dukes County. He has also appointed John S. Grouard, of Nantucket, for Nantucket County.

A MAD DOG IN LYNN.—A dog supposed to be mad caused a great deal of excitement in Lynn last Saturday. A large number of people were in the streets, waiting for the finish of a bicycle race, when a fine fox-hound was seen running about and snapping at other dogs. A cry of mad dog was raised, and the authorities summoned. The deputy marshal approached the dog with a revolver, but failed to hit him. The dog jumped at him and bit him severely. He then started to run, biting everybody in his way, followed by a patrol-wagon and a buggy containing the town authorities. He was finally caught and shot, but not until nine persons and about forty dogs had been bitten. The brain and spinal cord were sent to the Harvard Medical School for examination, and the dogs which were bitten have been condemned to be shot. The police of Lynn have been so active since this event, that the canine race will probably soon be exterminated in that city.

NEW YORK.

MORTALITY FOR THE WEEK.—The deaths reported during the week ending May 7th numbered 1,002, which is an increase of 52 over the mortality of the preceding week, and 123 above the average mortality of the corresponding week during the past five years. There were four deaths from typhus fever, which is the largest mortality from this disease since the week ending March 19th. There was a considerable increase in the deaths from measles, scarlet fever and diphtheria, the mortality from all of which was in excess of the average number of deaths reported from these diseases during the corresponding week for the past five years.

DEATHS IN 1892.—Dr. John T. Nagle, Registrar of Records, has submitted to the President of the Board of Health a comparative table showing that the deaths from January 1st to May 11th numbered 17,061, as against 16,715 for the corresponding period last year. This is an increase of only 346, and shows a decided reduction in the death-rate when the increase in the population is taken into consideration. During the same period 17,978 births were reported, as against 15,139 for the corresponding period last year, or an increase of 2,839.

BEQUESTS IN THE ASTOR WILL.—The late William Astor left very little in his will for charities. The only medical institutions mentioned were the following: The Woman's Hospital and the Home for Incurables, New York, each of which receives \$10,000, and St. Luke's Hospital, Jacksonville, Florida, which receives \$15,000.

BELLEVUE MEDICAL COLLEGE.—Dr. E. G. Jane-way has resigned his position as Professor of Practice of Medicine in Bellevue Hospital Medical College, and Dr. A. A. Smith has been appointed to the Chair. Dr. Herman M. Biggs is to take the place of Dr. Smith as Professor of *Materia Medica* and *Therapeutics*.

Miscellany.

MICRO-ORGANISMS IN THE SALIVA.

SANARELLI¹ has studied the cause of the fact that although many specific micro-organisms, such as the pneumococcus, the bacillus of diphtheria and the like are often found in human saliva, they seem seldom to cause infection, even after wounds of the mouth. He studied the action of saliva upon these bacteria as well as upon the typhoid and cholera bacilli, and comes to the following conclusions:

Human saliva is an unfavorable culture medium for certain pathogenic micro-organisms. It possesses the power of either destroying them or hindering their growth, so that the number remaining is not sufficient to cause infection. That bacillus of diphtheria and the coccus of pneumonia can live in saliva for some time. The first of these does not grow in it and finally dies, the latter although it does grow soon loses its virulence.

A REMARKABLE ANUS.

At the recent meeting of the French Surgical Congress in Paris a man was exhibited who for some time has been earning a livelihood by playing musical airs with his anus in various places of public amusement. A history of this case, and a study of his methods appears in a recent issue of the *Semaine Médicale*, by Dr. Baudouin. While still a boy this person noticed that when bathing he could by deep inspiration, draw water into his bowel. His friends encouraged him to cultivate his talent, which he did so conscientiously that before many years he could not only draw up large quantities of water, and expel it again with great force, but he also became able to draw in air. By alternately drawing in and expelling air through the anus, he imitated a number of musical instruments; a trombone, violin and a bass voice. He is able to play different tunes, so that they may be readily recognized. Physical examination reveals nothing abnormal. The aspiration is caused by a remarkable voluntary control of the lower bowel and anus, combined with the power to create a negative tension in the abdomen by well-trained muscular action. The different tones are produced mostly by an artistic expulsion of the air through the anus aided by movements of the buttocks. The lower bowel is so well

under his command that he can entirely empty it at pleasure, thus avoiding any disagreeable odor during his performances.

THE REMOVAL OF LEAD FROM THE EAR.

An unusual accident and an ingenious method of relieving it are reported by Dr. Sheild, in the *Lancet* of April 30th. A man while carrying a pot of molten lead down a ladder, fell, some of the material running down the right ear, and on cooling, filling the middle ear with solid lead plug. After the acute inflammation had passed off, the author laid the patient upon his side and poured liquid mercury into the meatus. This was repeated until the patient had lain in the aggregate sixteen hours with mercury in the ear. At the end of this time enough of the lead had been reduced to an amalgam to allow its removal by injecting a stream of water from a syringe. It is suggested that this treatment might be serviceable in cases of impaction of leaden bullets.

OBITUARY. DR. JOSEPH DRAPER.

At the annual meeting of the Connecticut River Valley Medical Association it was voted that the following obituary be sent to the *Boston Medical and Surgical Journal*:

Dr. Joseph Draper was born in Warwick, Mass., February 15, 1834. His early years were spent on a farm, which was very distasteful to him. He commenced the study of his profession with Dr. James Deane, of Greenfield, Mass., afterwards attending lectures in New York, and graduating from Jefferson Medical College in 1858. In October, 1859, he was appointed assistant to Dr. Rockwell, in Brattleboro Asylum, and remained until 1865. He was afterwards assistant and some of the time acting superintendent at the Insane Asylum in Worcester, Mass. In 1870 he was appointed assistant in the New Jersey Insane Asylum, and remained until 1873, when he returned to Brattleboro; and the growth of this institution is attributable to his zeal.

In 1881 he was given three months' leave of absence by the trustees to study abroad, and in this time he visited many of the institutions of England and Scotland, and learned much from them for the benefit of the Brattleboro Asylum. He was an active member of the State and County Medical Societies, of the Association of Medical Superintendents of American Institutions for the Insane, President of the Psychological Society, a member of the Massachusetts Medical Society, and of the Medico-Legal Society. His contributions to the literature of his profession were very numerous. Among his publications may be mentioned: "Annals of Vermont Asylum for the Insane," covering a period of fifty years of its history; "Sketch of Dr. James Deane," 1858; "Sketch of Dr. W. H. Rockwell," 1858; "Sketch of Dr. C. H. Tenney," 1874; "The Pathology of Insanity," 1875; "The Pathogenesis of Insanity," 1877; "Hysteria in Insanity," 1879; "Neurasthenia of the Ganglion Nervous Centres," 1881; "Insanity in Great Britain and the Continent of Europe," 1882; "The Responsibility of the Insane Outside of Asylums," 1883; "Vermont Asylum in the History of Brattleboro," 1880; "Insanity in Vermont, 1835-1885," 1885; "Obituary of Dr. Sumner Putnam," 1888; "The Oath of Hippocrates," 1889; "Nervous Exhaustion," 1890; "Subjective Delusions," 1890.

Dr. Draper was a prominent member of the Professional Club at Brattleboro, and has lectured before them and in other towns. He was married at Warwick, Mass., to M. J. Putnam in January, 1863, who still survives him.

¹ Centralbl. f. Bakteriol., x, 25.

THERAPEUTIC NOTES.

EUROPHEN AS A SUBSTITUTE FOR IODOFORM. — Peterson,¹ after trying a large number of the substances which have been recommended as substitutes for iodofrom, among them iodol, sozoiodol, aristol and dermatol, with unsatisfactory results, has finally found in europhen a good substitute. He uses it in the same way in which iodofrom is used, and for the same cases, and obtains excellent results.

A NEW STYPTIC. — Wright² makes a solution of fibrin ferment by treating a decolorized clot from ox blood with alcohol and extracting with water. To this is added a one per cent. solution of chloride of lime. This he has found to be not only an active styptic when applied locally, but to promote coagulation when given internally.

Correspondence.

THE PHYSICAL EXAMINATION OF STATE TROOPS. A CORRECTION.

BOSTON, May 14, 1892.

ME. EDITOR: — I beg to make a correction in my paper issued in the *Boston Medical and Surgical Journal*, May 12, 1892, "Is it Expedient to have a Physical Examination of Men before Enlisting them in State Troops?" On page 469 the statement is made, "but there has been no movement in the medical department towards an examination of enlistments." This I find, while literally true, should be modified, as it does not present the whole truth. Assistant Surgeon, C. M. Green, First Corps Cadets, M. V. M., has courteously called my attention to this misstatement, or unqualified statement. The spirit of what I intended to convey was that no movement in the medical department had been made, as a department, towards an examination of enlistments.

The facts, as presented to me by Assistant Surgeon Green, in an extract from General Orders, No. 15, from the headquarters of the First Corps Cadets, M. V. M., dated August 4, 1887, are as follows:

"Every candidate for admission to the Corps hereafter must be examined by one of its medical officers, who will, if the candidate is physically qualified to perform the duties of a soldier, give him a certificate to that effect, which certificate will be forwarded to the Committee on Elections with the application to enlist. The Committee will not present to the Corps the name of a candidate lacking such a certificate. By order."

This is the form of the medical officers' certificate:

"I certify that —— has been examined, and is physically qualified to perform the duties of a soldier in the Massachusetts Volunteer Militia. ——, Surgeon."

Assistant Surgeon Green has forwarded to me a bound copy entitled, "Standing Orders, First Corps Cadets, Massachusetts Volunteer Militia, 1890." Various marked passages in these "Standing Orders" embody the examination of enlistments.

This correction is important, as the above facts accord to the First Corps of Cadets, as an organization, the credit and honor of being the pioneers in this State in the physical examination of recruits before enlistment. I am very glad to say that in the discussion following the reading of this paper at St. Louis I did the First Corps of Cadets the justice of alluding to their requirement of a physical examination of men before enlistment.

Very respectfully yours,

HERBERT L. BURKELL,
Lieutenant-Colonel and Medical Director,
First Brigade, M. V. M.

METEOROLOGICAL RECORD.

For the week ending May 7, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:

2. Boston, Milwaukee and Pittsburgh 1 each. From cerebro-spinal meningitis New York 7, Philadelphia 3, Chicago and Brooklyn 2 each, Cleveland, Washington, Worcester, Taunton, Gloucester and Quincy 1 each. From erysipelas New York 6, Chicago 3, Philadelphia and Brooklyn 2 each. St. Louis, Milwaukee and Lowell 1 each. From malarial fever Brooklyn 3, New York 1. From typhus fever New York 4. From small-pox New York 1.

In the twenty-three greater towns of England and Wales with an estimated population of 10,188,449, for the week ending April 30th, the death-rate was 20.8. Deaths reported 4,057; acute diseases of the respiratory organs (London) 305; measles 342; whooping-cough 154; scarlet fever 41; diarrhoea 36; diphtheria 33; small-pox (London 2, Liverpool 1) 3.

The death-rates ranged from 9.9 in Brighton to 27.5 in Liverpool; Birmingham 24.9, Bradford 22.1, Croydon 10.8, Hull 18.3, Leeds 22.9, Leicester 23.5, London 19.8, Manchester 26.3, Newcastle-on-Tyne 18.4, Nottingham 15.5, Oldham 19.4, Portsmouth 11.8, Sheffield 22.1, Sunderland 24.3, Wolverhampton 21.2.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 7, 1892, TO MAY 13, 1892.

Leave of absence for six months, on surgeon's certificate of disability, with permission to leave the Department of Texas, is granted COLONEL JOSEPH C. BAILY, surgeon, U. S. A.

FIRST-LIEUT. WILLIAM E. PURCHASE, assistant surgeon, U. S. A., is relieved from duty at Fort Riley, Kansas, and will report in person to the commanding officer, Jefferson Barracks, Mo., for duty at that post.

FIRST-LIEUT. FRANCIS A. WINTER, assistant surgeon, U. S. A., is relieved from duty at Jefferson Barracks, Mo., and will report in person to the commanding officer, Fort Riley, Kansas, for duty at that post.

MAJOR DAVID L. HUNTINGTON, surgeon, U. S. A., is relieved from duty in New York City, to take effect on the final adjournment of the Army Medical Board, and will then proceed to Los Angeles, Cal., and report in person to the Commanding General, Department of Arizona, for duty as medical director of that department, relieving COLONEL JOSEPH R. SMITH, surgeon. Colonel Smith, on being relieved by Major Huntington, will proceed to San Francisco, Cal., and report in person to Commanding General of California, for duty as medical director of that department.

FIRST-LIEUT. WILLIAM F. LIPPITT, JR., assistant surgeon, U. S. A., upon being relieved from duty at Fort McPherson, Ga., will report in person to the commanding officer, Camp Eagle Pass, Texas, for duty at that post, relieving FIRST-LIEUT. OGDEN RAFFERTY, assistant surgeon, U. S. A. First-Lieut. Ogden Rafferty, on being relieved by First-Lieut. Lippitt, Jr., will report in person to the commanding officer, Alcatraz Island, Cal., for duty at that post.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 14, 1892.

H. J. BROWN and M. C. DRENNAN, surgeons, ordered to Naval Academy to examine the physical condition of candidates for admission to Naval Academy.

CLEMENT BIDDLE, passed assistant surgeon, ordered to Marine Rendezvous, Philadelphia, Pa.

H. C. ECKSTEIN, surgeon, detached from Marine Rendezvous, Philadelphia, Pa., and wait orders.

HOWARD WELLS, surgeon, ordered to the training-ship "Portsmouth."

JAMES STOUTHORN, assistant surgeon, from the "Portsmouth" and to the "Constellation."

E. H. MARSTELLER, passed assistant surgeon, from Naval Academy and to "Constellation."

JAMES G. FIELD, assistant surgeon, granted one year's sick leave.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE THREE WEEKS ENDING MAY 7, 1892.

BAILLACHE, P. H., surgeon. Detailed as chairman of Board for physical examination of candidates for promotion and appointment, Revenue Marine Service. April 26 and May 3, 1892.

MEAD, F. W., surgeon. Detailed as chairman of Board for physical examination of candidates for appointment, Revenue Marine Service. May 5, 1892.

KALLOCH, P. C., passed assistant surgeon. To proceed to Providence, R. I., on special duty. April 29, 1892.

KINYOUN, J. J., passed assistant surgeon. Detailed as recorder of Board for physical examination of candidates for appointment, Revenue Marine Service. May 5, 1892.

STONER, J. B., assistant surgeon. Ordered to examination for promotion. April 20, 1892.

DECKER, C. E., assistant surgeon. Detailed as recorder of Boards for physical examination of candidates for promotion and appointment, Revenue Marine Service. April 26 and May 3, 1892.

GARDNER, C. H., assistant surgeon. To report to commanding officer, Revenue Steamer "Kush" for duty. April 18, 1892.

PROMOTION.

WHEELER, W. A., surgeon. Commissioned as surgeon by the President. April 20, 1892.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held on Monday, May 23, 1892, at the Medical Library, 19 Boylston Place, at 8 o'clock P.M.

DR. W. M. CONANT: "Two Cases of Hernia: I, Right Inguinal Hernia, Incarcerated and Strangulated, Operation; II, Right Inguinal Hernia in a Woman, Radical Cure."

DR. J. HOMANS: "A Case of Spinal Disease."

G. G. SEARS, M.D., *Secretary.*

AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.—The second annual meeting of the American Electro-Therapeutic Association will be held in New York, October 4, 5 and 6, 1892, at the New York Academy of Medicine, 17 West 43d Street.

W. J. MORTON, M.D., *President.*

H. R. BIGELOW, M.D., *Secretary.*

APPOINTMENT.

MR. GREENLEAF R. TUCKER, S. B., who has been for the past two years Assistant Professor of Chemistry at the Massachusetts College of Pharmacy was elected on May 2, 1892, to the Professorship of the Department of General Chemistry.

RECENT DEATHS.

PLINY EARL, M.D., M.M.S.S., died in Northampton, May 17th, aged eighty-three years. He graduated from the University of Pennsylvania in 1837, and soon became widely known as an authority in mental disease. In 1864 he became superintendent of the State Hospital for the Insane in Northampton, and remained in that position until 1885. He was a member of many societies both in this country and abroad, and was the author of several monographs on insane hospitals and mental disease.

LORENZO W. ELDER, M.D., died in Hoboken, May 11th, aged seventy-two years. He had been Brigade-surgeon of the State Militia and Mayor of the City, and it was largely through his efforts that the County Board of Health was established.

Twentieth Annual Report of the Health Department of the City of Boston for the year 1891.

The International Medical Annual and Practitioner's Index for 1892. Edited by P. W. Williams, M.D. New York: E. B. Treat. 1893.

Report of the Commissioner of Education for the year 1888-89. Two volumes. Washington: Government Printing Office. 1891.

Diseases of the Nervous System. By Jerome K. Banduy, M.D., LL.D. Second edition. Philadelphia: J. B. Lippincott Company. 1892.

A Text-book of the Practice of Medicine for the Use of Students and Practitioners. By R. C. M. Page, M.D. New York: Wm. Wood & Co. 1892.

A Text-book of the Eruptive and Contained Fevers. By John William Moore, B.A., M.D., M.Ch., Univ., Dublin. New York: Wm. Wood & Co. 1892.

Rupture of the Sac of an Extra-Uterine Pregnancy through the Fibromat Extremity without Tearing the Fallopian Tube; Operation, Recovery. By Hunter Robb, M.D., Baltimore, Md. Reprint. 1892.

Lecture.

NEW OUTLOOKS IN THE PROPHYLAXIS AND TREATMENT OF TUBERCULOSIS.

THE MIDDLETON-GOLDSMITH LECTURE FOR 1892.

BY FRANCIS P. KINNICUTT, M.D.,
Physician to St. Luke's Hospital and the Presbyterian Hospital,
New York.

(Concluded from No. 20, page 491.)

TREATMENT OF PULMONARY AND LARYNGEAL TUBERCULOSIS BY THE CANTHARIDATES.

In February, 1891, Professor Liebreich, in a paper read before the Berlin Medical Society, announced that he had discovered a new remedy for the treatment of tuberculous disease.

The property of cantharidin, when taken internally, of producing an exudation of serum from the capillaries, not only of the kidneys, but also of the lungs and other organs, unattended with increased arterial tension, hyperemia or extravasation of blood, when used in sufficiently small doses, forms the basis of his theory.

The irritability of the capillaries, according to Liebreich, varies in different parts of the organism in health; in an abnormal state, such as may be assumed to be their condition at the site of local disease, this irritability is increased. By furthering such irritability by the use of the cantharidates, an exudation of serum occurs which may favorably affect tuberculous tissue in two ways: First, by stimulating cell-activity and nutrition; second, through the germicidal action of the serum upon the bacteria.

His experimental investigations apparently indicate in a measure the correctness of his theory. The remedial effects which have followed the use of the cantharid preparations, while occasionally striking, especially in the case of laryngeal tuberculosis, fall short of securing for them, it seems to me, a permanent place in the therapeutics of tuberculosis.

Their apparent action is in harmony with one of the possible means of a remedial treatment of tuberculosis. Cell-activity is stimulated and specifically diseased tissues are subjected to the germicidal action of the blood-serum artificially increased at the site of the disease. There is a failure possibly in the degree rather than in the kind of action. The preparations at present employed are the potassium and sodium cantharidates. They are administered hypodermatically at intervals of forty-eight hours or longer, and in doses of $\frac{1}{40}$ to $\frac{1}{50}$ of grain. The latter strength not infrequently caused symptoms of vesical and renal distress. Their use is contra-indicated in the presence of intestinal and renal disease, and in patients with marked hectic.

TREATMENT WITH THE SERUM OF DOG'S BLOOD.

The interesting experimental investigations of Richez and Hericourt, announced during the past year to the French Academy of Sciences,²⁰ with the serum of dog's blood in the treatment of tuberculosis, are in the line of thought that at present underlies our attempts to cope with the disease. These observers have been able to demonstrate that in rabbits inoculated with a culture of the tubercle bacillus, the evolution of tuberculosis can be arrested by subsequently subjecting the animal to injections of dog's serum.

When very virulent cultures are employed, the evolution is only delayed. Injections of a healthy animal with the serum, prevent the development of experimental tuberculosis at a later period. The effective substance has not been identified as yet, but a small dose of the serum is sufficient (half a cubic centimetre per kilo of the rabbit).

The clinical results obtained in tuberculous disease of human beings by this method of treatment, which has been fully tried in the Paris hospitals, would indicate that it also fails rather in the degree than in the kind of its action. It certainly acts as a potent stimulant to cell-activity. Whether it possesses another action is undetermined.

CHLORIDE OF ZINC TREATMENT.

I shall briefly refer to the treatment of tuberculous disease with chloride of zinc injections at the site of the disease, announced to the French Academy of Sciences in July of the past year, by Professor Lannelongue.²¹

It is based essentially on the simple fact that fibrinous induration is to be regarded as the natural curative process in tuberculous lesions. The power of the chloride of zinc to excite such sclerotic processes, when administered in sufficiently small quantity to avoid its more powerful escharotic action, suggested its use in the disease in question. Its action in experimental tuberculosis is thus described by M. Lannelongue and M. Achard. The anatomical elements of the tissues which it penetrates, are destroyed and an enormous proliferation of embryonic cells occurs, not only at the site of the injection, but for some distance around it, with infiltration of the tuberculous tissues with migratory cells to the fullest extent. M. Lannelongue suggests that the latter may destroy the bacilli through the exercise of their phagocytic function. The morbid tissue destroyed by the chloride of zinc is slowly absorbed and disappears; the embryonic cells, on the contrary, organize with great rapidity and form firm fibrous tissue, which exists in appreciable quantity as early as the day following the injection.

Twenty-two patients were subjected to this treatment by M. Lannelongue. The list embraces two cases of pulmonary tuberculosis and twenty of suppurating and non-suppurating tuberculous disease of joints and glands. Excellent results are claimed to have been obtained in a majority of the latter. An opportunity was afforded in a case of more or less fused tuberculous glands for comparing histologically, glands which had been injected and those which had been left without treatment. Excision showed caseous material surrounded by a zone of tuberculous tissue within a fibrous sheath, in each; in the injected glands, however, there was a large amount of dense fibrous tissue and firm adhesion to the investing membrane. A report of the results in the pulmonary cases was reserved until a longer period had elapsed.

While recognizing the possible utility of this method of treatment in tuberculous joint and gland disease, either as a remedial measure or as an adjunct to surgical procedures and suggesting the desirability of more extended investigations in this direction, its application in pulmonary tuberculosis, in my judgment, should be regarded with the greatest reserve. Aside from the difficulty of introducing intra-pulmonary injections in any exact way at the site of the lesion, the extent and complexity of the morbid conditions usually

present would seem to preclude the possibility of its usefulness as a method of treatment.

The technique of the method employed by M. Langelongue is to inject two drops of a ten per cent. solution, in a number of places around the periphery of the diseased part, in cases of tuberculous joints, bones and glands. Suppurating glands are thoroughly irrigated with sterilized water and the injections made under rigid antiseptic precautions. In cases of pulmonary tuberculosis, a solution of one in forty is used for the injections.

THE TREATMENT OF TUBERCULOSIS WITH CREASOTE, GUAIACOL AND CARBONATE OF GUAIACOL.

The literature of the treatment of phthisis pulmonalis with creasote, both by internal administration and by inhalation, is sufficiently familiar to those interested in the subject, to warrant the briefest reference to it.

Discovered by v. Reichenbach in 1830, it quickly secured a reputation in Germany, France, and England as a remedial agent in pulmonary disease. It however gradually fell into disuse, and was only rehabilitated in favor in 1877 through the admirable clinical paper of Bouchard and Gimbert on its beneficial effects in consumption.²⁵ Influenced by their statements, Beverley Robinson instituted its systematic use in his hospital and private practice in this city, as early as 1878, and valuable papers by him have appeared from time to time since on this subject.

In Germany, a series of publications by Sommerbrodt, Fraenzel, v. Brunn, Guttmann and others, confirmatory of the results obtained by Bouchard and Gimbert, appeared in 1887 and 1888. The literature of the subject at the present time is very voluminous, and it may be said to be exceptionally favorable to the value of creasote in the treatment of pulmonary phthisis.

Varied opinions are held in regard to its mode of action, its most efficient dosage and the best method of administration. The determination of these several points is of scientific interest as well as of practical import.

The efficacy of creasote in hindering or arresting fermentative processes in the digestive tract, so frequently present in phthisical patients and thereby promoting appetite, digestion and nutrition, is very generally admitted. Its ability to favorably affect appetite, and to increase the digestive secretions when given by the mouth, by locally stimulating the gastric and intestinal nerve filaments, is also very probable. Through the promotion of a better nutrition, the beneficial effects claimed for creasote in stimulating the resolution and absorption of the secondary inflammatory exudations in tuberculous lungs, may be explained. By its local action, antiseptic and stimulating, especially when given in the form of inhalations, a favorable influence upon the simple catarrhal processes so commonly present, is conceivable and probable. In turning our attention to any specific action which creasote may exercise upon the pathogenic cause of tuberculosis and its specific lesions, the results of experimental investigation properly should be considered.

Guttmann,²⁶ as the result of test-tube experiments, which he claimed, demonstrated the power of creasote, in solution of 1 to 4000, to greatly inhibit the growth of tubercle bacilli, and in solutions of 1 to 2000, to completely devitalize them, was led to believe that a similar specific action could be effected in the human

body by the administration of sufficiently large doses of the drug. One gramme of creasote, according to his calculations, present in the circulation, would suffice for this purpose. The experimental investigations very kindly undertaken for me by Dr. John Ely in the Pathological Laboratory of the College of Physicians and Surgeons, and which will be given in detail later, confirm the correctness of Guttmann's observations on the germicidal power of creasote.

Granting, therefore, the germicidal action of creasote *outside* of the human body, and also the possibility of administering it, without injurious effects in daily doses larger than those demanded by Guttmann's hypothesis, a seemingly fatal objection to the theory of the exercise of a germicidal action *in the economy*, is found in very recent investigations, which indicate that creasote enters at once, in the blood, into chemical combinations with certain contained albuminoids, combinations which are without specific germicidal influence. Moreover it has been wisely said that "man is not a test-tube," and no fact appears to be more clearly proved than that the germicidal action of a drug outside of the body affords little basis for correct conclusions of its therapeutic value. Experiments on animals are necessary to determine these points.

In pursuance of this idea, numerous investigators have attempted to test the anti-bacillary power, as well as other effects of creasote in tuberculosis, by the treatment of animals with large doses of this drug both before and after the production of experimental tuberculous disease. I shall refer only to the very interesting experiments of Trudeau²⁷ and Cornet.²⁸

Trudeau's experiments: Four rabbits were inoculated in the anterior chamber of the eye and in the right chest with a similar amount of pure cultures of tubercle bacilli suspended in water. Two of the rabbits were kept as "controls." Two were treated every other day with subcutaneous injections of five cubic centimetres of a ten per cent. solution of pure creasote in almond oil. The course of the eye tuberculosis in the test animals was daily compared with that in the "controls," and was seen to be entirely uninfluenced by the treatment. Tubercles became visible in the iris from the twelfth to the thirteenth day in both sets of animals. Iritis, cloudiness of the cornea and general secondary inflammatory changes were noted in all the rabbits from the eighteenth to the twenty-first day, and the sight was soon lost. All were killed two months after inoculation, and the lungs of both the test and the control animals presented the lesions of advanced tuberculosis.

Cornet's experiments were as follows: Seven strong guinea-pigs were treated with creasote, introduced into the stomach by means of a tube, in doses equivalent for the body weight of a man to rather more than two grammes daily, for a period varying from one to two months. At the expiration of this interval they, with four control animals, were either inoculated with, or were compelled to inhale, finely atomized pure cultures of tubercle bacilli, the creasote treatment being continued in the test animals. A single test guinea-pig died of pneumonia ten days after inoculation. The remaining six died respectively thirty, thirty-two, thirty-three, forty-three, seventy-seven and eighty-four days after infection. Two of the control animals were killed on the thirty-second and forty-third day after infection, the two remaining died on the sixty-first and eighty-fourth day after inoculation. All the animals, both

test and control, presented the characteristic lesions of tuberculosis and very little, if any, appreciable difference in the appearance, the degree or the distribution of these could be detected in the two sets.

Experimental investigations, therefore, show in the most positive manner that creasote, administered even in heroic doses, is incapable either of preventing the development of experimental tuberculosis, or of arresting its progress.

The theory of Bouchard, Gimbert, Jaccoud and others that creasote promotes connective tissue growth, by means of which recovery in tuberculous disease is favored, also is not borne out by experimental studies in animals.

The explanation of any favorable influence of creasote on sclerotic processes which *clinical* observations may indicate, should seemingly be sought in the improved nutrition which obtains through its use rather than by the exercise of any specific action.

Guaiacol, obtained by fractional distillation of beech-wood-tar creasote, and constituting sixty to ninety per cent. of the latter, was suggested by Sahli,²⁰ as early as 1887, as a substitute for creasote in the treatment of tuberculous disease. It represents the active principle of creasote, and may be substituted appropriately for it. As prepared in the various laboratories, it probably is not freed from all impurities.

Owing to this fact, very lately Seifert and Hoelscher²¹ have proposed the use of the carbonate of guaiacol. Carbonate of guaiacol possesses the advantages over creasote and guaiacol of being a simple, definite and crystalline substance which can be obtained chemically pure. It is a neutral salt, and is tasteless as well as odorless; it does not produce digestive disturbances; it is indifferent to gastric secretion and decomposes in the intestine into guaiacol and carbonic acid.

Many of the above characteristics of this salt have been demonstrated in its use in St. Luke's Hospital. Seifert and Hoelscher, as the result of experimental studies with guaiacol carbonate, have advanced a new and interesting theory of the mode of action of the creasote preparations in tuberculous disease. The basis of their theory apparently rests on the fact that experiments on dogs show that creasote and guaiacol do not circulate in a free state in the blood, and that they are eliminated by the kidneys in the form of the salts of ethyl sulphuric acid (etherschwefelsäure). They argue that during absorption, the active principle of creasote allies itself with the albuminoids in the blood and specifically through the agency of the sulphur contained in the albumin molecule. The blood of tuberculous patients contains in addition to normal albumin other albuminoid substances arising from the disease process, that is, the products of the tubercle bacilli. These substances constitute unstable combinations, prone to cause or undergo chemical processes, which act poisonously. The toxic albuminoids engendered by the disease, are chiefly responsible for the fever, night sweats, etc. The guaiacol by allying itself with them, renders them stable and therefore non-toxic. The chemical combinations effected by the guaiacol are without germicidal influence, and the favorable results obtained through the use of the creasote preparations in tuberculous disease, therefore, should be regarded as due in a large measure to their influence in assisting in the elimination of the toxic products of the specific disease process.

Seifert's and Hoelscher's theory in no respect militates against other favorable influences which have been ascribed to the creasote preparations, such as the probable direct stimulation of the appetite and thereby improved nutrition, etc. The observations thus far made in St. Luke's Hospital in the use of guaiacol carbonate lead me to believe that it may be substituted very favorably for both creasote and guaiacol.

INVESTIGATIONS IN ST. LUKE'S HOSPITAL WITH MODIFIED TUBERCULIN, CREA-SOTE, GUAIACOL AND CARBONATE OF GUAIACOL.

During the past winter sixty-five cases of pulmonary tuberculosis have been under my care continuously in the wards of St. Luke's Hospital. Many of these were cases of very advanced disease, without the possibility of recovery, and the treatment consisted merely in attempts to ameliorate the most distressing symptoms. Nineteen of the remaining cases were selected for treatment, respectively with Hunter's modifications of Koch's tuberculin, with subcutaneous injections of guaiacol and with creasote by the mouth. It was my desire, not so much to test the comparative merits of different methods of treatment, as to corroborate or otherwise, Cheyne's and Hunter's observations, and to determine both the practicability of employing a very large daily dosage of creasote and any advantages this method might possess over its use in smaller quantities. Seven cases of well-marked tuberculosis are embraced in the group treated with Hunter's modified tuberculin. The details of the histories of these patients and the results of treatment are given in a tabulated form for convenience of study. It will be seen that three cases have been under treatment for three months, the remainder for nearly two months. Physical examination in two of the former cases indicates no appreciable change in the pulmonary lesions during treatment. In the third case, the improvement in the signs of disease and in all other respects has been most marked. Physical examination indicates not only the dryness of the cavity but also its very evident contraction, as well as a diminution in the degree of the contiguous disease process. In the four remaining cases, there has been no improvement in one; in one, improvement has been marked; in one, it was distinct, though less marked; and in one case an *arrest of the disease*, at least temporarily, has occurred. By improvement is meant a marked diminution in the physical signs of disease.

The seventh case is certainly an example of arrested phthisis. This is of such rare occurrence in pulmonary tuberculosis of this degree, under conditions which commonly prevail in large city hospitals, as to be particularly noteworthy. A very distinct impression has been made on my mind in observing from day to day the cases treated with modified tuberculin, that its stimulation of the nutritive processes is not so marked as its effect upon the specific lesions. Creasote, on the other hand, has seemed to me to possess the former quality in a greater degree. To meet possible criticism, all the above cases have received no other treatment than tuberculin, beyond the administration of cod liver oil and, from time to time, various ferruginous preparations.

The exact mode of preparation of the modifications used is given in a note. The rules of dosage were to give 0.002 gm. for the initial inoculation and to increase by 0.002 gm. daily. The rule also was made

not to increase the dose, if any elevation of temperature followed inoculation. With the modifications B and CB, appreciable reactions did not occur in these cases. In a single case, treated with CB, a rise of temperature followed an inoculation of 0.008 gm. and an acute catarrhal process was developed at the apex of one lung. At the expiration of the tenth day, defervescence occurred, and no further ill effect has followed. For this reason, modification B has been used in all other cases but one. Trudeau has also adopted, I believe, modification B as the preferable one. Through the absence of all reaction and discomfort attending the use of B all patients treated with it have been able to be continuously about the ward and out of doors. Only the usual, very inexact, method for determining the number of bacilli in the sputum was used. Repeated examinations were made and they were found in all.

The number of cases treated with modified tuberculin, while much too small to permit the expression of a positive opinion of its power to exercise a specific remedial action, is large enough to indicate in the strongest manner the desirability of continued investigations of its apparently specifically beneficial effects.*

My desire to test the practicability of employing a very large daily dosage of the creasote preparations, and to determine, if possible, any advantage which this method might possess over their use in smaller quantities, has been fulfilled in a measure. Several of the patients selected for this treatment, presented a well-marked degree many of the symptoms, namely, hectic, sweats, etc., attributed to the toxic influence of the products of the bacillus, and were therefore well adapted to test the effect of creasote upon such manifestations.

It will be seen in a study of the tabulated report that seven cases have been treated with subcutaneous injections of guaiacol, rapidly pushed to a daily dosage of one gramme, and five cases with creasote by the mouth, also rapidly increased to six grammes daily. In four of the former cases there has been little if any appreciable change in the physical signs of disease. In one of these, however, the general condition has greatly improved and there has been a gain in weight of eight pounds. In one, the weight has decreased by one and three-quarter pounds; in one, there has been a loss of four pounds; in one, the weight has remained stationary. In two of these cases, the daily sputum has slightly increased in amount, in two, it has slightly diminished.

In the three remaining cases, there has been a progressive increase of the pulmonary lesions. No influence upon hectic, when present, has been observed.

* Method of preparation of Hauer's modifications:

Modification E. One cubic centimetre of tuberculin, five cubic centimetres distilled water, saturation with preferably large crystals of ammonium sulphate for twenty-four hours in the cold, the precipitate filtered off and freed so far as possible from any crystals of ammonium sulphate, placed in dialyzer and dialyzed just so long, and no longer, that runnings water and then in distilled water until all trace of ammonium sulphate has disappeared. One cubic centimetre added to the solution to prevent any putrefactive change; the solution thus made up to such bulk that ten cubic centimetres shall correspond to each cubic centimetre of tuberculin employed. (Title B, 10%).

Modification F. One cubic centimetre of tuberculin dropped into twenty cubic centimetres absolute alcohol, left to stand, then filtered off in a quarter of an hour, filtrate evaporated over water bath at temperature preferably not exceeding 40° C., and just sufficiently long to drive off all alcohol; residue taken up in twelve cubic centimetres distilled water; placed in dialyzer and dialyzed for two hours in running water until all trace of alcohol has disappeared to twenty cubic centimeters, including two cubic centimetres of pure glycerine used for preservative purposes. A few crystals of thymol added. (Title CB, 10%).

The above modifications were prepared for me in the chemical laboratory of the College of Physicians and Surgeons.

Night sweats, however, have been affected favorably. In a single case, suffering from chronic diffuse nephritis (confirmed by autopsy), a marked increase in the albuminuria was observed when a daily dosage of one gramme was reached. The treatment was then discontinued and the albuminuria gradually diminished. In no other case, treated either with guaiacol or creasote, has any trace of albumin appeared in the urine, in examinations made every other day. In a single case, when the maximum dose of guaiacol was reached, the urine became dark in color and very similar in appearance to urine containing carbolic-acid products.

Dr. Ely's report on the enumeration of tubercle bacilli in the daily sputum of several patients treated with guaiacol, contains observations of interest and practical import. It indicates the possibility of incorrect conclusions even from the best method at our command for this purpose; also the absence of bacilli from time to time, in the sputum of patients suffering from grave pulmonary tuberculosis.

In Cases II and IV, where there has been no apparent increase in the lesions and the general condition has remained stationary; the number of bacilli has greatly diminished.

In Case VII, in which the area of disease has slightly increased and the general condition has deteriorated, the bacilli have greatly increased in number.

In the cases treated with creasote, there has been no appreciable difference in the physical signs of disease up to the present date, in two. In these, there has been a gain of one pound and a loss of three pounds respectively.

In the three remaining cases there has been a progressive increase of the lesions. The effect of a very large daily dosage of creasote upon hectic and sweats corresponds to that noted in the use of guaiacol. Entire tolerance of six grammes (over one and one-half drachms) of creasote was exhibited by three of the five patients. One complained of slight gastric discomfort when a daily dosage of five grammes was reached, and one patient who had suffered from occasional nausea and vomiting previous to the administration of creasote, believed that these symptoms were increased by it. Several other patients at present in my wards are taking four to six grammes of guaiacol daily, without gastric or intestinal discomfort.

Carbonate of guaiacol has been used, so far as its supply permitted; and aside from the advantage of being tasteless and odorless and only being decomposed by the intestinal secretions, it has seemed to me to very positively stimulate appetite.

The clinical conclusions which I have formed from a careful study of these cases are: that both creasote and guaiacol in certain forms can be given in very large doses with entire tolerance and without injurious effects; that such dosage apparently possesses no advantages over a much smaller one, and that it has no greater effect upon hectic and night sweats; that subcutaneous injections of the drug possess no advantages over administration by the mouth; that whatever beneficial influence creasote may exert in pulmonary tuberculosis can be effected with a comparatively small dosage, and that favorable results can be expected only by its continuous and prolonged employment.*

* Creasote was administered, without exception, in the form of what are known as the "Enteric Pills" of a well-known manufacturer. The nature of their protecting envelope I am ignorant of. Personal investigations of the effect of an artificial gastric juice

TREATMENT WITH SUBCUTANEOUS INJECTIONS OF HUNTER'S MODIFIED TUBERCULIN.

No. sex, age.	Patient's history and physical examination at beginning of treatment.	Patient's weight, daily sputa, inoculation used, date when begun.	Duration of treatment weight, and sputa, to date.	Physical examination at present date.
1. Male, 42.	Profuse haemoptysis 5 years ago; pleurisy 3 years ago; night-sweats and cough since, with loss of 40 lbs. in weight. Physical signs: Slight retraction beneath right clavicle. Evidence of cavity in first interspace; also very abundant lanugine moist rales at this site. Abundant subcrepituation from first space, anteriorly. Some side and abundant subcrepituation with larger rales, over supraspinous fossa. Abundant subcrepituation over whole of scapular region. Patient apyretic.	Jan. 13, 1892; weight, 132 lbs. Sputa, 3½; daily average, "B." 0.002 gm. to increase by 0.002 gm. daily.	April 25, 1892; weight, 141 lbs. Sputa, 3½; daily average, "B." 0.002 gm. to increase by 0.002 gm. daily.	April 25th.—Physical signs: Marked retraction, directly beneath right clavicle. Signs of cavity distinctly heard and it is apparently now dry. Subcrepituation in second space; below this point, no adventitious sounds present. Posteriorly, adventitious sounds absent. No evidence of cavity or marked diminution of subcrepituation over scapular region. Patient apyretic; no night-sweats. <i>Very marked improvement.</i>
2. Male, 46.	History of 18 months; sputum occasionally tinged with blood; absence of night-sweats. Physical signs: Consolidation without crepituation over first and second right sternal and over supraspinous fossa. Posteriorly, some subcrepituation in interscapular region. Left lung, feeble respiratory murmur, with scanty subcrepituation beneath clavicle and over supraspinous fossa. Evening temperature occasionally 100°.	Jan. 14, 1892; weight, 122 lbs. Sputa, 3½; daily average, "C. B." 0.002 gm. to increase by 0.002 gm. daily.	April 25, 1892; weight, 125 lbs. Sputa, 3½; daily average, "C. B." 0.002 gm. to increase by 0.002 gm. daily.	April 25th.—Physical signs: Practically the same as at first examination. Evening temperature occasionally 100°. Condition stationary.
3. Female, 32.	History of cough and occasional hemorrhage for past 2 years. Physical signs: Dullness, with rather abundant subcrepituation in first right sternal and cavity subcrepituation in second space. Dullness, with moderate subcrepituation posteriorly, over supraspinous fossa and scapular region. Patient apyretic.	Jan. 17, 1892; weight, 105 lbs. Sputa, 3½; daily average, "C. B." 0.002 gm. to increase by 0.002 gm. daily.	April 21, 1892; weight, 107 lbs. Sputa, 3½; daily average, "C. B." 0.002 gm. to increase by 0.002 gm. daily.	April 21st.—Physical signs: Dullness with scanty subcrepituation in first space; absent in second. Dullness with scanty subcrepituation over supraspinous fossa and scapular region. Little appreciable difference from first examination. Patient apyretic. Condition stationary.
4. Male, 50.	Cough for past year; gradual loss of flesh and strength. Physical signs: Impairment of resonance over upper half of left chest, anteriorly, with fairly abundant subcrepituation over lower half posteriorly, impairment of resonance over upper half of left chest, with abundant subcrepituation over supraspinous fossa and scanty in areas over scapular region. Patient apyretic.	March 2, 1892; weight, 144 lbs. Sputa, 3½; daily average, "B." 0.002 gm. to increase by 0.002 gm. daily.	April 25, 1892; weight, 143 lbs. Sputa, less than 3½; daily average, "B." 0.10 gm. to increase by 0.002 gm. daily.	April 25th.—Physical signs: Little appreciable difference in resonance over upper half of left chest since first examination. Crepituation has almost entirely disappeared anteriorly, and is practically absent posteriorly. Patient apyretic. <i>Marked improvement.</i>
5. Male, 32.	Hemorrhage 5 years ago and another 3 years ago, very profuse. Since latter, unable to work, and has lost 40 lbs. in weight. Treated with tuberculin in Presbyterian Hospital, which was followed by temporary improvement. Physical signs: Diffuse infiltration upper lobes of both lungs, with abundant subcrepituation at apices and scattered over remainder of affected regions. Most marked right apex; occasional night-sweats. Patient apyretic.	March 2, 1892; weight, 123 lbs. Sputa, 3½; daily average, "B." 0.002 gm. to increase by 0.002 gm. daily.	April 25, 1892; weight, 119 lbs. Sputa, 3½; daily average, "B." 0.075 gm. to increase by 0.002 gm. daily.	April 25th.—Physical signs: No appreciable difference from first examination. Occasional night-sweats. Patient apyretic. Condition stationary.
6. Male, 33.	Cough for 3 months; no haemoptysis, no night-sweats. Physical signs: Impairment of resonance, with abundant subcrepituation over right infraclavicular region. Abundant subcrepituation in second and third spaces. Similar signs over whole left chest anteriorly; in less degree also over left supraspinous fossa and scapular region. Slight pyrexia; evening temperature, 100°—100°2.	March 3, 1892, treatment begun March 21st. weight, 120 lbs. Sputa, 3½; daily average, "B." 0.002 gm. to increase by 0.002 gm. daily.	April 25, 1892; weight, 131 lbs. Sputa, none. "B." 0.100 gm. to increase by 0.002 gm. daily.	April 25th.—No appreciable difference in impairment of resonance over affected regions. Subcrepitation scanty at present over right chest, and absent over supraspinous fossa and scapular region, left. Anterior, same but with appreciable difference from first examination. Patient apyretic since March 18th. <i>Improvement.</i>
7. Male, 41.	Cough for 6 months; no haemoptysis, no night-sweats; gradual loss of flesh. Physical signs: Impairment of resonance, slightly prolonged and high pitched expiration, with abundant subcrepituation in first two spaces, left; scanty, fine crepituation in second and third spaces, over supraspinous fossa beneath clavicle; over upper half scapular region, scanty crepituation after cough. Slight pyrexia; occasional evening temperature, 100°.	March 3, 1892; weight, 123 lbs. Sputa, none. daily average, "B." 0.002 gm. to increase by 0.002 gm. daily.	April 18, 1892; weight, 125 lbs. Sputa, none. Discharged, through desire and ability to go to work.	April 25th.—Impairment of resonance over first two spaces. Respiration feeble, but expiration slow and prolonged or increased in pitch. <i>Entire absence of all adventitious sounds over upper half left chest, anteriorly and posteriorly.</i> Patient continuously apyretic since March 18th. <i>Disease at present arrested.</i>

except where all the conditions necessary to the growth of tubercle bacilli were observed, so that the entry upon the envelope showed that it was partially dissolved after one hour.

Notwithstanding Guttmann's statement to the contrary, it was thought possible that the alcohol necessary for the solution of the creosote might have a disturbing influence upon the experiment.

CASE VII, tabulated on page 518 may be referred to as an example. About eleven ounces of sputum were eliminated daily. This was so viscid that its disintegration necessitated the addition of considerably more than an equal bulk of potash and water, so that the

TREATMENT WITH SUBCUTANEOUS INJECTIONS OF GUAIACOL RAPIDLY INCREASED.

No. sex. age.	Patient's history and physical examination at beginning of treatment.	Patient's weight, daily average of sputa (3), when guaiacol 1 gm. daily was begun; date.	Duration of treatment, weight, and sputa, to date.	Physical examination at present date.
1. Female 17.	Cough for 10 months; progressive loss of flesh and strength; no haemoptysis; moderate night-sweats. Physical signs: Excavation at right apex anteriorly, with consolidation below; below, large lung, consolidation with numerous large abscesses and abundant subcrepititation over whole of scapular region, below fine crepitatio. Left, anteriorly, moderate consolidation at apex, fine crepitatio. Advanced lung-disease. Marked hectic; evening temperature, 102°-103°.	Weight, Feb. 27, 1892, 70 lbs. Average daily sputa, 3 ss.-3 1/2 ss. Guaiacol, 0.05 gm. daily, to increase 0.05 gm. daily to 1 gm.	March 20, 1892, 71 lbs. Average daily sputa, 3 1/2-4 ss. Guaiacol, 1 gm. reached to-day; discontinued.	March 20th.—Physical signs: Progressive increase of lesions; night-sweats. Marked hectic; evening temperature, 102°-103°.
2. Female 39.	Haemoptysis 3 years ago; present history of cough 3 months; progressive loss of flesh and strength; no night-sweats. Physical signs: Dulness, prolonged and high-pitched expiration over left infrachlavicular region, with very abundant subcrepitatio. Same signs anteriorly over upper half of left lung. Impaired respiratory signs, in degree, anteriorly and posteriorly over upper half. Slight pyrexia; evening temperature, 100°.	Weight, Feb. 27, 1892, 91 lbs. Average daily sputa, 3 1/2-4 ss. Guaiacol, 0.05 gm. daily to increase 0.05 gm. daily to 1 gm.	April 25, 1892, 91 lbs. Average daily sputa, 3 1/2-4 ss. Guaiacol, 1 gm. daily for 27 days.	April 25th.—Physical signs: Little appreciable difference from first examination except subcrepitatio now heard over whole left lung posteriorly. No night-sweats. Slight evening temperature.
3. Female 24.	Pleurisy, right side, 3 years ago. Empyema same side 1 year ago, excision of rib; cough and frequent haemoptysis since; no night-sweats. Physical signs: Large antrum in rest right space, partly dry. Moderate consolidation, without crepitatio, in second space. Consolidation, apex, same lung, posteriorly, without crepitatio. Patient apathetic.	Weight, Feb. 27, 1892, 135 lbs. Average daily sputa, 3 1/2-4 ss. Guaiacol, 0.05 gm. daily to increase 0.05 gm. daily to 1 gm.	April 25, 1892, 141 lbs. Average daily sputa, 0-3 ss. Guaiacol, 1 gm. daily for 37 days.	April 25th.—Physical signs: Anteriorly, no appreciable difference from first examination; posteriorly, moderate subcrepitatio at apex and over upper half of scapular region. Patient apathetic; occasional night-sweats. Marked improvement in general condition.
4. Female 44.	Pneumonia 3 years ago; cough since; no haemoptysis; no night-sweats at present. Physical signs: Consolidation, with fairly abundant subcrepitatio at both apices. Subcrepitatio also present over upper half of lungs, with abundant subcrepitatio in upper third left scapular regions. Slight pyrexia; occasional evening temperature, 100.2°.	Weight, Feb. 28, 1892, 91 lbs. Average daily sputa, 3 ss.-3 1/2 ss. Guaiacol, 0.05 gm. daily to increase 0.05 gm. daily to 1 gm.	April 25, 1892, 90 lbs. Average daily sputa, 3 ss. Guaiacol, 1 gm. daily for 37 days.	April 25th.—Physical signs: No appreciable difference from first examination; no night-sweats. Occasional evening temperature, 100.2°-100.5°.
5. Female 32.	Grippe a year ago; cough since; no haemoptysis; profuse night-sweats. Physical signs: Areas of infiltration throughout upper lobe, right lung, with abundant subcrepitatio. Areas of infiltration upper lobe, left lung, with abundant subcrepitatio, of beginning; excavation at apex. Hectic; evening temperature, 101°-102°.	Feb. 28, 1892, 72 lbs. Sputa, 3 1/2-4 ss., daily average. Guaiacol, 0.05 gm. daily; increasing 0.05 gm. daily. March 1, 1892, 0.60 gm. Weight, 73 lbs.; sputa, 3 1/2-4 ss.	March 15, 1892, guaiacol by mouth, mix. miu, miu daily average. March 24th, miu daily in pill; not increasing. April 1, 1892, weight, 64 lbs. April 2, 1892, sputa, 3 1/2-4 ss.	April 1st.—Physical signs: Progressive increase of lesions; moderate night-sweats. Treatment apparently some effect on sweats, none on fever. Died April 7, 1892.
6. Female 46.	History of 10 months; a single haemoptysis; night-sweats almost continuously. Physical signs: Large antrum, apex left lung, with impaired resonance and abundant subcrepitatio to base anteriorly. Posteriorly, areas of infiltration over base. Beginning disease at right apex. Hectic; evening temperature, 101°-102°.	Feb. 28, 1892, 93 lbs. Sputa, 3-3 1/2 ss., daily average. Guaiacol, 0.05 gm. daily; increasing 0.05 gm. daily. March 1, 1892, 0.45 gm. Weight, 92 lbs.; sputa, 3 1/2-4 ss.	Treatment discontinued before maximum dose reached; no further treatment. March 24, 1892, weight, 96 lbs. March 31, sputa 3 ss.-3 1/2 ss.	March 10th.—Progressive increase of lesions. Treatment apparently some effect on night-sweats, none on fever. Died April 1, 1892.
7. Male 31.	Typical history since last November; several haemoptyses; no night-sweats. Physical signs: Feeble respiratory murmur, with abundant subcrepitatio over whole right lung anteriorly, and upper half of scapular region. Similar signs in slightly less degree over upper left lung; left lung, anteriorly and posteriorly. Pyrexia; evening temperature, 101°-102°.	March 2, 1892, 92 lbs. Sputa, 3-3 1/2 ss., daily average. Guaiacol, 0.05 gm. daily; increasing 0.05 gm. daily. March 21, 1892, 1 gm. for 2 days. Weight, 88 lbs.; sputa, 3 vij.	March 22, 1892, guaiacol enemas, gr. vi daily by rectum; miu, miu daily in pill; not increasing. April 19, 1892, guaiacol pills, myi daily in pill; not increasing. April 25, 1892, weight, 88 lbs.; sputa, 3 vij.	April 25th.—Physical signs: Very similar to that of first examination; excess subcrepitatio heard over whole of left lung anteriorly and posteriorly; no night-sweats; pyrexia. Evening temperature, 100°-101°. General condition worse.

bath at temperature preferably not exceeding 40° C., and just sufficiently long to drive off all alcohol; residue taken up in twelve cubic centimetres distilled water; placed in dialyzer and dialyzed for two hours in running stream of water. Quantity made up to twenty cubic centimeters, including two cubic centimetres of pure glycerine used for preservative purposes. A few crystals of thymol added. C. I. G. 10%.

The above modifications were prepared for me in the chemical laboratory of the College of Physicians and Surgeons.

small dosage, and that favorable results can be expected only by its continuous and prolonged employment.

* Creasote was administered, without exception, in the form of what are known as the "Esterie Pills" of a well-known manufacturer. The nature of their protecting envelope I am ignorant of. Personal investigations of the effect of an artificial gastric juice

Dr. Ely's reports of his investigations on the germicidal action of creasote on the tubercle bacillus outside of the human body, and on the enumeration of bacilli in the daily sputum of patients, treated with guaiacol, are appended.

For valuable assistance rendered me in my investigations, I desire to express my thanks to Drs. John Ely and Robert J. Devlin and to the gentlemen of the House Staff of St. Luke's Hospital, Drs. Hollis, Rogers, Bunce, and Tuttle.

DR. ELY'S REPORT ON THE GERMICIDAL ACTION OF CREA-SOTE OUTSIDE OF THE HUMAN BODY.

Shortly after the revival of interest in creasote as a therapeutic agent in tuberculosis, the question arose as to the manner in which its beneficial effect was produced. Its general preservative and anti-fermentative properties had long been recognized and made use of in the arts, and the possibility of a similar inhibiting or germicidal action upon the specific germs of tuberculosis at once suggested itself. With a view to the solution of this problem, Guttmann undertook a more definite determination of its germicidal action.

In his experiments nutrient gelatine was impregnated with creasote in proportions varying from 1:500 to 1:8000. Into this, seventeen different species of bacteria, thirteen of them pathogenic, were inoculated, at the same time similarly inoculated tubes of ordinary nutrient gelatine serving as controls. The inhibiting action of the creasote was found to vary considerably with the different species, but in general a creasote content of 1:2000 was found sufficient to prevent growth. The plan of experiment received slight modification in the case of the tubercle bacillus, blood-serum being used as the nutrient medium and the cultures, after inoculation, being placed in the thermostat at a temperature of 37° C. After several weeks, examination showed a meagre growth in the tubes which had contained creasote in the proportion of 1:16000; none in the others.

Since these experiments of Guttmann, so far as I am aware, stand quite alone, it has been thought advisable to repeat them in so far as they relate to the tubercle bacillus, but in slightly modified form. Instead of blood-serum, glycerine-bouillon and glycerine-agar have been used as nutrient media, both of which have shown themselves particularly well adapted to the growth of the tubercle bacillus; and an aqueous solution of guaiacol, the principal ingredient of creasote, had been substituted for the alcoholic solution of creasote employed by Guttmann in the preparation of his media.* These media were impregnated with guaiacol in the proportions of 1:1000, 1:2000, 1:3000 and 1:4000, and into them were introduced particles of a rapidly growing culture of the tubercle bacillus, other media, not containing guaiacol, being at the same time inoculated as controls. All were then sealed and placed in the thermostat at 37° C. At the end of seven weeks they were examined and the records tabulated below noted. It may be permissible to state here that every slightest indication of growth was carefully searched for and that no record is made except where all the conditions necessary to the growth of tubercle bacilli were observed, so that the entry

upon the envelope showed that it was partially dissolved after one hour.

* Notwithstanding Guttmann's statement to the contrary, it was thought possible that the alcohol necessary for the solution of the creasote might have a disturbing influence upon the experiment.

"No growth" in the tables below means literally what it says.

SERIES A. GLYCERINE-BOUILLON.
Inoculated March 11, 1892; Examined April 29, 1892.

Control, 4 Flasks.	1:1000, 2 Flasks.	1:2000, 2 Flasks.	1:3000, 3 Flasks.	1:4000, 2 Flasks.
1. Moderate growth, not spreading much, but heaping.	No growth.	No growth.	No growth.	Apparently slight heaping up, thought to indicate very slow growth.
2. Luxuriant growth, covering whole surface of the bouillon.	No growth.	No growth.	No growth.	Slight heaping, though somewhat questionable.
3. Luxuriant growth, covering whole surface of the bouillon.			No growth.	
4. Moderate growth, heaping.				

SERIES B. GLYCERINE-AGAR.
Inoculated March 11, 1892; Examined April 29, 1892.

Control, 4 Tubes.	1:1000, 5 Tubes.	1:2000, 5 Tubes.	1:3000, 5 Tubes.	1:4000, 5 Tubes.
1. Very luxuriant growth, heaping and spreading.	No growth.	No growth.	No growth.	No growth.
2. Abundant growth, heaping and spreading.	No growth.	No growth.	No growth.	Very slight heaping and cloudiness at edges as if growing sluggishly.
3. Moderate growth.	No growth.	No growth.	No growth.	Abundant growth.
4. Moderate growth.	No growth.	No growth.	No growth.	Very slight heaping; no apparent spreading.
	No growth.	No growth.	No growth.	Slight heaping and cloudiness at edges as if slowly spreading.

DR. ELY'S REPORT ON THE ENUMERATION OF BACILLI IN THE DAILY SPUTUM OF PATIENTS TREATED WITH CUTANEOUS INJECTIONS OF GUAIACOL.

While fully recognizing the illusive nature of conclusions as to the value of therapeutic agents based upon periodical determinations of the number of tubercle bacilli in the sputum, it has been thought desirable to make such determinations in a number of the cases treated with creasote and guaiacol.

The method employed for this purpose has been that recommended by Nuttall, the details of which are to be found in the *Bulletin of the Johns Hopkins Hospital*, Vol. II, No. 13, May, June, 1891.

Although this method is unquestionably the most accurate thus far proposed, it is nevertheless subject to great error, and the results are liable to be particularly misleading in cases in which the amount of expectoration is large and the number of bacilli small.

CASE VII, tabulated on page 518 may be referred to as an example. About eleven ounces of sputum were eliminated daily. This was so viscid that its disintegration necessitated the addition of considerably more than an equal bulk of potash and water, so that the

total amount after dilution came to be 700 cubic centimeters. Since the dropper used delivers about 100 drops to the cubic centimeter, the content of each drop (in this particular case) must be multiplied by 70,000 in estimating the total number of bacilli eliminated in twenty-four hours, and, of course, any error in the determination of the number of bacilli to the drop is similarly multiplied. And when there are only a few bacilli to each drop, all may be overlooked in counting fifty fields, or, on the other hand, a disproportionate number may chance to be seen. Thus, in Case VII, while the majority of the fields contained no bacilli, one had three. A discrepancy of 100,000 or so in a matter of small import when many millions of bacilli are present, but may be very misleading when there are only a few hundred thousand.

RESULTS OF THE DETERMINATION OF THE ACTUAL NUMBER OF TUBERCLE BACILLI IN TWENTY-FOUR HOURS' SPUTUM BY NUTTALL'S METHOD.

Case.	Date.	Quantity of Sputum.	Number of Bacilli.
I.	Feb. 21, 1892.	f 3 ix.	227,684,401
II.	Feb. 24, 1892. Mar. 23, 1892. Apr. 6, 1892. Apr. 29, 1892.	f 3 xii. f 3 ix. f 3 i. f 3 ii.	7,397,791 4,189,915 1,946,657 380,828
III.	Feb. 22, 1892. Mar. 23, 1892.	f 3 i. f 3 ii.	579,792 About 160 fields carefully gone over without finding any bacilli. Whole drop then examined systematically, and still none found. Stain good.

PNEUMONIA IN BOSTON DURING THE RECENT EPIDEMIC OF INFLUENZA.¹

BY GEORGE B. SHATTUCK, M.D.,
Visiting Physician, Boston City Hospital.

DURING the progress of the epidemic of influenza, with which, I think, we must acknowledge we have been visited this winter, I was impressed with the evident increase in the number of cases of pneumonia entering the City Hospital in my own service and in those of my colleagues, and also with the large number

¹ Read at the meeting of the Boston Society for Medical Improvement.

of deaths, especially among old people, as appearing in the daily papers and in the reports of the City Board of Health. Moreover, not a few of the pneumonias, as observed at the City Hospital, exhibited peculiarities or irregularities; they were less frank than usual in their development and in their resolution.

As I had about this time fallen a victim to your President's energy, and promised to occupy part of one of his evenings, it occurred to me I would look up these general points in a general way and give you the results, which might at least derive some interest and possibly some value from a comparison with those of a very recent previous epidemic of influenza, and those of an intervening non-epidemic year, sandwiched between the two.

But upon re-reading the contributions to the exposition of the relations between pneumonia and influenza and the mortality-rate and influenza, I found them more elaborate than I had remembered them to be. I thought, however, it was desirable that any new statements in regard to the past two years should be put in a form comparable with those previously furnished with regard to the previous epidemic. Hence, instead of letting you off with a few simple, and perhaps vague statements, I come before you with some tables, a form of setting forth facts which it has been my duty as an editor to discourage in others. The immediate cause of this unfortunate result is the zeal of your President, as before said; the remote cause is the zeal of my predecessors.

The Clinical Section of the Suffolk District Medical Society held a meeting January 15, 1890, for the discussion of influenza then epidemic in Boston, a discussion which was opened by Dr. F. C. Shattuck and closed by Dr. A. L. Mason;² at this meeting the relation of pneumonia to influenza was incidentally considered. The New York Academy of Medicine devoted its meeting April 7, 1890, to the discussion of the relation of pneumonia simply to influenza. Dr. E. G. Janeway occupied himself with New York, but his paper was not published; Dr. Wm. Pepper gave the results for Philadelphia;³ and Dr. F. C. Shattuck those for Boston.⁴

As our subject was not only the same but dealt with the same locality, it seemed better to follow the general plan of dealing with it adopted by my brother two years ago, and see how far the results would lead to similar conclusions reached by him then or formulated by Dr. Pepper from his figures and observations obtained in Philadelphia. Accordingly where there were tables — and I regret both for your sake and my own that there were so many — I have tabulated the same details for 1890-91, 1891-92, thus giving a comparison of eight years instead of six, and of two epidemic periods instead of one. For, whether or not there was a recurrence of influenza as an epidemic at any earlier period of the year 1891 than December, I think we may accept the months of December, 1890, and January, 1891, as practically free from it. I have tabulated the records of the Boston City and of the Massachusetts General Hospitals, from December 10, 1890, to February 1, 1891, and from December 10, 1891, to February 1, 1892, as a continuation of similar statistics for previous years. As arbitrary dates have to be

³ Remarks on the Frequency and Character of the Pneumonias of 1890; Medical News, vol. liii, p. 1, 1890.

⁴ The Relation of Pneumonia to Influenza in Boston: New York Medical Journal, vol. li, p. 626, 1890.

adopted to represent the epidemic limits, these are, perhaps, as good as any others. It may be that some observers would fix an earlier or a later date for the beginning or the decline of this or of the previous epidemic, but for purposes of comparison, especially in regard to diseases of the respiratory organs, it is, of course, essential to take as nearly as possible the same season of each year.

TABLE I.

Deaths from Pneumonia reported at the Boston City Hall for the Months of December and January, 1884-85 to 1891-92, inclusive.

Months.	1884-85	1885-86	1886-87	1887-88	1888-89	1889-90	1890-91	1891-92
December.	141	74	113	95	68	105	100	223
January.	103	83	91	183	92	332	139	240
Total.	244	157	204	278	160	437	239	463

Table I shows that the number of deaths returned in Boston as due to pneumonia, December and January, 1891-92, was greatly increased over the previous six non-influenza years; that this increase was about as great for December as for January; that the number of deaths for the two months exceeded that of 1889-90, by 26, though the distribution was different, there being 118 more deaths in December, 1891, and 92 less deaths in January, 1892.

TABLE II.

Cases of Pneumonia admitted to the Boston City and Massachusetts General Hospitals from December 10th to February 1st, for the Years 1884-85 to 1891-92.

	1884-85	1885-86	1886-87	1887-88	1888-89	1889-90	1890-91	1891-92
Total.	33	26	80	68	40	127	48	101
Deaths.	14	4	12	26	13	38	13	39
Mortality	42.4%	15.4%	40%	39%	32.5%	30%	27%	38%

Table II shows, from the hospital returns, that the mortality, as well as the number of cases, was largely increased, the per cent, being $5\frac{1}{2}\%$ above the average of the previous six non-influenza years, whereas it was $2\frac{1}{2}\%$ below the average of those years for the same period 1889-90. It is a curious coincidence that twenty-six fewer cases of pneumonia entered the hospitals, and twenty-six more deaths were reported at City Hall.

Table III shows by weeks that the increase in deaths from pneumonia began earlier and was more rapid this winter than last winter or the winter of the previous epidemic, and the same is true of bronchitis comparing this winter with last winter. The week ending January 2d, was the week of greatest mortality from pneumonia this winter, whereas last winter and the winter before it was a week later. The maximum mortality from bronchitis occurred the same week this winter as last winter, and the number of deaths was, curiously, the same; it was a week later than that for pneumonia. If the early increase in deaths from pneumonia was dependent upon epidemic influenza the epidemic this season should have manifested itself earlier than two years ago. Personally I should have said it developed, if anything, a little later. The editorial column of the *Boston Medical*

and *Surgical Journal*, which I understand rarely errs, under date of December 17, 1891, says: "It seems to be the general impression that epidemic influenza has once more made its appearance in the United States, though as yet it has not assumed a serious aspect. The Boston Board of Health does not officially recognize its presence in this city, but admits the apparent increase of catarrhal troubles and pneumonia during the last month," etc. The views of individual practitioners upon this point would be of value.

TABLE III.

Deaths from Pneumonia reported at the Boston Board of Health in December and January, 1889, 1890, 1891 and 1892, by Weeks.

Deaths from Bronchitis December, 1889, 1891, January, 1891, 1892.

TABLE III bis.

Total Tabulated Cases of Pneumonia at the Boston City Hospital and Massachusetts General Hospital.

	City Hospital.	Mass. Hosp.	Total.
Dec. 10, 1890, to Feb. 1, 1891	..	36	14
Deaths	..	8	13
Mortality	..	22%	28+%
Dec. 10, 1891, to Feb. 1, 1892	..	81	20
Deaths	..	34	40
Mortality	..	39%	37%

Looking from another point of view at the returns to the city authorities of the deaths from pneumonia and bronchitis, I find the following: the average of deaths from pneumonia for the month of December in the five years 1884-88, was 104; in December, 1889, the deaths were 160; in December, 1890, 100; and in December, 1891, 223; the average for the five Januaries, 1885-89, was 118.6; in January, 1890, the number was 335; in January, 1891, it was 139; and in January, 1892, 240.

In the same way for bronchitis, the average of five Decembers was 54.8; the number for December, 1889, was only 48; for December, 1890, 49; and for December, 1891, 90. For the five Januaries the average was 53.2; for January, 1890, the number was 89; for January, 1891, 48; and for January, 1892, 109.

Before tabulating the total cases of pneumonia (meaning thereby croupous pneumonia) entered at the two hospitals between December 10 and February 1, 1890-91, 1891-92, I was curious to see the proportion of cases in each. I got the following result shown in Table III bis, which includes both croupous and catarrhal or broncho-pneumonias — the number

of the latter being small—ten in all for the two years, at both hospitals.

The great increase in the number of cases, as well as in the number and percentage of deaths this winter, comes largely, therefore, from the City Hospital; and there also the proportion of males was larger—sixty-five males to thirty-two females, while at the Massachusetts there were twelve males to eight females.

TABLE IV.

Analysis of all Cases of Lobar Pneumonia admitted to the Boston City and Massachusetts General Hospitals, from Dec. 10, 1890, to Feb. 1, 1891, with Reference to the Precedence of Gripe Symptoms, Localization, Complications, and Termination—Lysis or Crisis, or Death.

	Preceded by gripe symptoms	Not preceded by gripe symptoms	Doubtful	No history	Total

December 10, 1890, to February 1, 1892.

Table IV gives an analysis of the cases of pneumonia in the two hospitals—the extent of the process, the complications and the mortality—with reference to influenza antecedents as gathered from the records.

I have not attempted to include recoveries by crisis and lysis, partly because the dividing line is very uncertain, and partly because the charts in many cases had not been entered and were not easily accessible. The results of this analysis differ materially in several important particulars—and especially as to the percentage of pneumonias preceded by influenza-symptoms—from those of a similar analysis of hospital cases in the previous epidemic published in Dr. F. C. Shattuck's paper.

The difference is probably due more to a difference of record-keeping or record-interpretation than to so great an actual difference in facts. Of the total pneumonias only 27 per cent. are recorded as preceded by influenza; 60 per cent. were not entered as preceded by such symptoms, and one per cent. doubtful. This compares with 43 per cent. preceded by such symptoms in the previous epidemic, and only 49 per cent. not preceded or doubtful.

The percentage of complications was about the same for the two epidemics, and the only other marked difference appears in the mortality which has already been alluded to.

TABLE V.

Lobar Pneumonia in Boston City Hospital and Massachusetts General Hospital, December 10, 1890, to January 31, 1890.

Age.	Cases.	Male.	Female.	Fatal.
10 and under	2	2	0	0
10 to 20	14	5	2 (14% +)	2
20 to 30	41	13	7 (17% +)	17
30 to 40	31	6	10 (32% +)	10
40 to 50	16	12	4 (25% +)	4
50 to 60	13	9	4	7 (54% -)
60 to 70	1	1	0	1
70 to 80	1	0	1	0
Unknown	8	8	0	3
Total	127	94 (74%)	35 (26%)	38 (30%)

December 10, 1891, to February 1, 1892.

Age.	Cases.	Male.	Female.	Fatal.
10 and under	1	1	0	0
10 to 20	5	5	0	0
20 to 30	23	26	17	18 (24%)
30 to 40	23	17	6	9 (29% +)
40 to 60	9	5	4	5 (55% +)
60 +	9	7	3	7 (40% -)
Total	101	71	30	39 (39% +)

The upper half of this table shows the age and sex of 127 hospital cases. Nearly 75% were males, and the mortality increased with each decade up to the fifth, remaining stationary thence to the seventeenth.

Table V gives the age and sex of the 101 hospital cases. The percentage of males was rather less than in the previous epidemic, 70+% compared to 74+%, and of females 30% compared to 26%. There were no deaths under twenty years of age, and only five cases, all of which were in males. The mortality increased pretty constantly in the next three periods of twenty years.

TABLE VI.

Fatal Pneumonia and Broncho-pneumonia reported at the Boston City Hall. Comparison between December, 1890, and January, 1891, and the average of the same months during the previous five years, with reference to age.

Age.	Avg. deaths Dec., 1884-8.	Deaths, Dec., 1890.	Per ct. of in- crease.	Avg. deaths Jan., 1885-9.	Deaths, Jan., 1891.	Per ct. of in- crease.

70 to 80	9	8	..	10.2	28	155
80 to 90	3.8	3	..	2.2	13	500

Comparison between December, 1890, and January, 1891.

Age.	Deaths, Dec., 1890.	Per cent. of in- crease.	Deaths, Jan., 1891.	Per cent. of in- crease.
10 and under	60	65	44	22
10 to 20	2	..	0	..
20 to 30	13	63	22	100
30 to 40	23	130	29	73
40 to 50	22	86	32	105
50 to 60	21	84	26	120
60 to 70	32	186	41	215
70 to 80	28	211	31	241
80 to 90	22	479	14	536
90 to 100	1	..	1	..

Table VI analyzes the deaths from pneumonia and broncho-pneumonia, as reported to the city authorities, with reference to age, and compares the deaths in December and January, 1891-92, with the same months in 1889-90, and the average of the previous five years.

There was an increase in deaths over the average deaths in December for every decade except one (10-20) up to 100, this increase culminating in the decade between 80 and 90 with 479 per cent. In December, 1889, there was no increase under twenty or over seventy, at other ages there was a marked increase over the average, but a less increase for every decade except two, 20-30 and 40-50, than in December, 1891.

In January, 1892, there was a large increase over the average for every decade except one, 10-20 — when there were no deaths — culminating in an increase of 536 per cent. in the decade 80-90, which compares with 500 per cent. increase for the same decade January, 1890; for the earlier decades the increase was smaller for January, 1892, than for January, 1890, but it was larger for the very old, that is the three decades 60-70, 70-80, and 80-90.

The very small number of deaths from pneumonia and bronchitis between the ages of 10 and 20 years in the city returns for any year is very striking.

The city returns, it may be remarked incidentally, show five deaths from bronchitis and pneumonia between the ages of ninety and one hundred in December, 1890-91, and January, 1891-92.

TABLE VII.

Fatal Bronchitis reported at the Boston City Hall. Comparison between December, 1889, and January, 1890, and the average of the same months during the five previous years, with reference to age.

Age.	Average deaths, Dec., 1884-8.	Deaths, Dec., 1889.	Average deaths, Jan., 1885-9.	Deaths, Jan., 1890.	Per cent. of increase.
10 and under	37.2	23	36.8	29	..
10 to 20	0.6	1	0.4	3	650
20 to 30	0.2	2	900
30 to 40	1	3	1.4	3	114
40 to 50	1.4	..	1.4	5	256
50 to 60	4.8	4	2.4	8	231
60 to 70	6	5	3.4	13	222
70 to 80	2.4	4	5	13	160
80 to 90	1.4	3	2.6	13	409

Comparison between December, 1891, and January, 1892.

Age.	Deaths, Dec., 1891.	Per cent. of increase.	Deaths, Jan., 1892.	Per cent. of increase.
10 and under	42	13	6	..
10 to 20	1	83	0	..
20 to 30	2	..	3	1,460
30 to 40	1	0	6	329
40 to 50	6	324	1	166
50 to 60	9	871	9	275
60 to 70	12	100	13	282
70 to 80	15	525	17	240
80 to 90	3	114	14	438
90 to 100	1	..

Table VII analyses bronchitis reported to the city, as Table VI did pneumonia, with reference to age. Deaths from bronchitis in December under ten years were increased slightly, in January there were none under twenty years; in December and January, 1889, 1890, under ten years they were less than the average, for all the other decades, except one, for both months there was irregular but considerable increase. The numbers, however, in all three years were too small to be of much value.

Having compared my figures for the present epidemic and the one free year with those published in my brother's paper for the previous epidemic and for the five free years, we will see how the conclusions to

which my figures lead, compare with those to which his figures lead him.

He says: "Conclusions can be drawn, but they do not seem to me of such a nature as to throw any really new light on influenza pneumonia." With this statement I fear I must agree. The conclusions are as follows:

"(1) Pneumonia was unusually prevalent in Boston during the height of the influenza epidemic, about the middle third of the visitation." My figures indicate that it was unusually prevalent this winter, too, but reached its culmination a week earlier.

"(2) The statistics of the Pacific Mills indicate that less than a half per cent. of those severely attacked by influenza acquired pneumonia.

"(3) Broncho-pneumonia was rare in the hospitals." I find only six cases in both hospitals this winter.

"(4) The pneumonia mortality rate was probably not increased, perhaps diminished, as compared with that of the five previous years." For this epidemic it was increased eight per cent. over the previous epidemic and five and one-half per cent. as compared with the average of six free years.

"(5) The number of cases of pneumonia not preceded by grippe symptoms was about the same as the number of pneumonias in an average year." The number was apparently greater than the number in an average year.

"(6) Pneumonia followed grippe in so large a number of cases as to show some sort of connection between the affections." In a sufficiently large number of cases.

"(7) In sixty per cent. of the cases a single lobe only was involved." In eighty per cent.

"(8) Two-thirds of the cases terminated by lysis."

"(9) Pneumonia was three times as frequent in males as in females, and the mortality rate increased with each decade." Two and one-third times.

"(10) The most striking increase in the urban deaths from pneumonia was, on the whole, between the ages of twenty and sixty and eighty and ninety. The increase under ten was slight." The increase in the urban deaths from pneumonia was greatest between the ages of sixty and ninety; it was striking, but evenly distributed between twenty and sixty; under twenty it was slight.

"(11) The gross appearances in nine cases examined after death were not specially noteworthy." Autopsies not considered.

Dr. Pepper's estimate from returns made to him by a large number (272) of practitioners in Philadelphia, of the relative proportion of croupous and catarrhal pneumonias, differs greatly from the results afforded by our hospitals. These returns indicate that the catarrhal were almost twice as frequent as the croupous. He further states that Dr. DaCosta and he saw about an equal number of catarrhal and croupous pneumonias in consultation. He notes as a peculiarity of the pneumonias during the epidemic season 1889-90 the large preponderance of cases affecting the right lung, which he estimates was affected twice as often as the left. Of 101 hospital cases in Boston from December 10th to February 1st, this winter, the right lung alone was affected in 57½%, the left alone in 32½%; but I find that of 44 cases for the same period last winter, when there was no epidemic of influenza, in 53% the right alone was affected, the left alone in 33%. Osler reports that in 100 pneumonia autopsies at the Montreal

General Hospital, not made during an influenza epidemic, the right lung was affected in 51%, the left in 32% and both in 17%. Of last winter's hospital cases in Boston 14% were double, and this winter's only 10%.

TABLE VIII.

Amount of Lung involved and region affected.	Dec. 10, 1890, to Feb. 1, 1891.						Dec. 10, 1891, to Feb. 1, 1892.						Total both years.				
	Total Cases.			Per cent.			Total Cases.			Per cent.							
		Apx.	Delirium.		Apx.	Delirium.		Apx.	Delirium.		Apx.	Delirium.

Broncho-pneumonia, 4	0	1	0	6	...	0	0	2	10	...	0	1	2				

Dec. 10, 1890, to Feb. 1, 1891, 44 cases. Dec. 10, 1891, to Feb. 1, 1892, 101 cases. Both years, 147 cases, including two of doubtful location.

Though not coming strictly under my subject, curiosity and a desire to make use of my figures led me to look into the question of apex pneumonia,—especially as I have for some time been sceptical of the current statement that it is more apt to be accompanied by delirium. In 18 apex pneumonias (17% of the total) of the influenza period, there were 9 deaths, or 50%; but 6, or 33%, were of markedly alcoholic habits, and only 5, or 28%, exhibited delirium. One case, notwithstanding the apex and the alcohol, was not delirious and got well. One case of double apex died two days after entering the hospital, this is not included. Last winter in 10 apex cases (23% of the total), five died, five had alcoholic habits, and six were delirious; that is, one only was delirious without being alcoholic.

In regard to his returns for the 1889–90 epidemic, Pepper says: "There was also an unusual proportion of cases of apex pneumonia where the entire upper lobe was completely consolidated without implication of any other part. As usual in such cases, there seemed to be a special predominance of cerebral symptoms."

Among the complications were inflammations of the ear of various degrees of severity, erysipelas, rheumatism, tuberculosis, empyema, cardiac lesions and pericarditis, melancholia, acute mania, meningitis, alcoholism, cerebral embolism, erythema, etc.

One young woman entered my service at the City Hospital with undoubted influenza. She developed an erythema of the face, then a pneumonia; she then miscarried at the fifth month; she then developed diphtheria; and she subsequently recovered her health perfectly.

I had intended to say something about the vague symptoms and ill-defined physical signs observed in some cases of pneumonia during the influenza, but I have already taken up too much of your time.

I hope some of you will favor us with your personal experiences as practitioners; some I know have seen comparatively little pneumonia this winter and others more than usual.

To sum up briefly, I should incline to the opinion that pneumonia was a sequel rather than a concomitant

or complication of influenza. Though I acknowledge that the tables presented do not offer alone sufficient support for this view.

Pepper takes this position in the following words: "The vast majority of pneumonias occurred as a sequel, rather than a complication, and they were clearly traceable to exposure to damp and raw weather while the patient had a relaxed system and while slight pyrexia persisted after the subsidence of the more marked symptoms of his influenza. Experience furnishes many instances of this fact."

Ostler, in his "Practice of Medicine," just published, speaks of pneumonia as a *complication*, and the most serious and fatal one of influenza; but at the same time states that there is, as far as his observation goes, nothing special or peculiar in the character of the pneumonia.

Through the courtesy of Drs. Mason and Folsom at the City Hospital and of Drs. F. C. Shattuck and W. W. Gannett at the Massachusetts General Hospital, I have had access to their cases; and I have to thank Dr. A. C. Jelly and my house-officers, Drs. Dudley and Towle and Mr. Edson, for assistance in abstracting the records, and the Boston Board of Health for figures furnished. My use of Dr. F. C. Shattuck's tables speaks for itself. As they were originally published elsewhere, their reproduction here commends itself additionally.

A CASE OF DOUBLE MOVABLE KIDNEY.¹

BY T. M. BOTCH, M.D.,
Visiting Physician to the Boston City Hospital.

So far as I can learn, the following case of double movable kidney is the first which has been diagnosed during life, and verified by operation, in America. It is therefore well worthy of especial record.

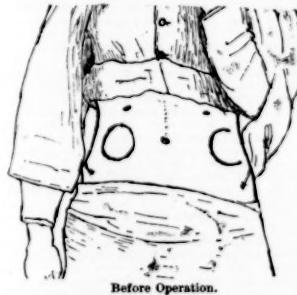

A. B., twenty-seven years of age, unmarried, entered the City Hospital on May 11, 1891. She had had no children nor miscarriages, and no diseases. The catamenia were regular but scanty. She had been subject to headaches for the last ten years, and during the last three years they had increased in severity and frequency, especially lately. The pain was described as throbbing, and was localized in the frontal and parietal regions. It was sometimes accompanied by nausea and vomiting, which was not believed by the patient to be dependent upon food. An examination of the eyes was negative.

In December, 1890, she says she felt something "shaking in her abdomen when she walked"; and near the end of the same month she experienced a sensation as if something slipped forward into the left inguinal region when she stooped over. In the latter part of January she fell violently upon the ice, in a sitting posture. At this time she noticed a resistant mass in the left inguinal region, and shortly afterward a similar one in the right. She paid but little attention to them, however, until three weeks later, when they became painful. She said they had always been movable. The pain was influenced by position and motion. It was absent when she lay quietly in bed, but returned when she moved. It was most intense when she sat down, and was referred to both inguinal regions, coccyx and back. Walking was more painful than standing. Stooping increased the pain and caused a sensation as

¹ Read before the Boston Society for Medical Improvement, February 22, 1892.

if "something were being squeezed." Reaching upwards with her right hand, caused pain in the left side; a similar movement of the left hand caused none. Coughing and laughing were painful. In addition, she complained of a feeling of weight in the abdomen.

Three or four months ago she was troubled with frequent micturition, accompanied by some pain, and lasting about a month. She has had occasional attacks of palpitation, and dyspnoea on exertion, and dizziness. The bowels were constipated. The patient was of a nervous temperament. Temperature 98.8°, pulse 80, respiration 24. An examination of the urine, on May 12th, showed: color normal, acid reaction, specific gravity 1027, clear, with a flocculent sediment, no albumen. Examination of the abdomen revealed in the right lumbar region, a tumor which was firm, oval in shape and apparently three inches by two in size, moderately tender on pressure, easily movable from the crest of right ilium, upwards under the ribs, in the axillary line; from which position it was forced downwards by coughing or deep inspiration. In the left lumbar region a tumor was felt, similar in every respect except that it was larger. Both tumors were more plainly felt when patient lay on her face or side and in the half-prone position. Percussion over the back in both lumbar regions gave resonance when the patient lay on her face.

Before Operation.

The patient was kept under observation in the ward for some weeks; at times she was confined to the bed, and at others was allowed to get up and go about, doing a little light work. Her general health improved but her symptoms continued.

In addition to other symptoms, the patient complained of much pain in the region of the coccyx, on sitting. An examination showed that it was deflected to one side, and she was transferred to the surgical side of the hospital for operation. This was performed by Dr. Gay on July 7th. The coccyx was removed and the patient made a good recovery. This was followed by a diminution of the pain caused by sitting. Later, various kinds of apparatus were tried to retain the kidneys in position but without success, and it was finally decided to perform the operation of nephro-rhaphy on both kidneys.

The first operation was performed by Dr. Burrell on September 22d. An incision was made in the lumbar region on the left side, at the outer border of, and parallel with, the extensor muscles of the spine; the dissection was carried down to the kidney and silk su-

tures were passed through the capsule of the kidney and the quadratus lumborum muscle binding them firmly together. The wound was thoroughly irrigated, packed lightly with gauze and dressed antiseptically. The patient made a good recovery.

On November 7th the second operation was performed by Dr. Bradford. An incision four inches long was made in the lumbar region, in the back, over the right kidney; extending from the lower ribs, downwards, at a distance of about six inches from the vertebral spines. The dissection was carried down to the kidney and three sutures were taken through the capsule, at the upper, middle and lower parts; these sutures were carried through the muscular substance to the outer edge of the wound and an antiseptic dressing was applied after thoroughly irrigating.

The patient was discharged December 28th in good general condition and with the wounds healed.

After Operation.

The urine chart kept from September 7th until her discharge from the hospital, showed an average daily amount of about one-half the normal quantity and at times even less.

On February 6th the patient re-entered the hospital on account of a slight discharge occurring from the right side. The examination showed one or two granulating points in the right cicatrix, into one of which a probe entered about one and one-half inches. An incision was made and a silk suture was found at the bottom and removed. A slight swelling on the left cicatrix was also opened, and a silk suture was removed.

On February 22d the patient was discharged with one side entirely healed and the other almost so.

I examined the patient on February 21st and found both kidneys in position. She complained of various nervous aches and pains, but the nausea, sense of weight in the abdomen, and headaches were relieved.

I have prepared a reference list of the cases which have been operated upon, and which is as nearly complete as the literature on the subject can make it. Dr. Landau of Berlin, and Sulzer of Basel, have written excellent papers on this subject, and I am indebted to their tables for many of the cases in my list.

One thousand three hundred and thirty-two cases of movable kidney have been collected; of these 107 occurred in males and 702 in females, that is, 86 per cent. were in females. Six hundred and sixty-eight were of the right kidney, 106 of the left kidney, and 93 of both kidneys, that is, about 77 per cent. were of the right kidney alone. This preponderance of the right over the left in lists of movable kidneys seems to be confined to females, for out of 14 cases occurring in the male sex, where the special kidney was mentioned, the right kidney was affected in six, and the left in eight. A similar list among females showed that in 80 the right was affected, in 15 both, but in only 10 the left alone. Seventy-two cases of movable kidney were first recognized, or the diagnosis confirmed, on the post-mortem table.

Although movable kidney is sometimes congenital, it is not often recognized in children. Phillips reports a doubtful case in a boy of nine years. Heirsprung reports another case in a child, and Durham mentions a case of misplacement of the left kidney in a fetus. Sulzer has collected 37 nephrectomies for movable kidney with 10 deaths. His table of nephrraphies for movable kidney is very complete, and contains 80 cases with only two deaths; 45 of these cases were entirely cured; seven were improved. In nine there was no improvement in the symptoms notwithstanding the success of the operation, and in 13 the operation did not succeed in permanently fixing the kidney. Nephrraphy of both kidneys has been performed by Hahn and also by Küster (quoted by Lindner.)

THE ESSENTIALS TO SUCCESS IN REPAIR OF THE PELVIC FLOOR IN PRIMARY AND SECONDARY OPERATIONS.¹

BY EDWARD REYNOLDS, M.D.

In this brief paper, I do not propose to touch at all upon the anatomical aspects of laceration of the perineum, except in so far as is incidental and necessary to a proper consideration of the conditions which determine success in its repair; but mean to confine myself mainly to certain aspects of this problem which, though now almost universally accepted by specialists, are as yet insufficiently realized by at least a large proportion of general practitioners. I wish first to enumerate the characteristics which are generally ad-

mitted to be essential to a successful suture, and which are common to all successful methods.

It was for a long time believed that laceration of the vaginal outlet was a tear of that supposed supporting structure, the perineal body, in the antero-posterior median plane of the body. It is only within the last few years that another and more satisfactory description has been given.

In 1883, Dr. Emmett, the father of perineorrhaphy, first announced the belief, now generally held, that for mechanical purposes the perineal body is a myth; and that the true reason for the loss of support which follows these tears, is to be found in their destruction of the integrity of the muscles and fascia of the pelvic diaphragm.

In connection with his publication of a belief in this new pathology, he described a new method of introducing the sutures; which was essentially an abandonment of the old idea that the separated tissues were to be brought together from side to side, and an acceptance of the principle that the essential characteristic of all successful methods is the approximation of the torn surfaces from above downward, and from without inward to the median line.

In a recent address, he has stated that the success of his earlier operations was in fact due to their incidental possession of the longitudinal traction, which is now admitted to be the main object of the operation, and he, in common with other gynecologists, now holds that the approximation of the tear from side to side, which is undoubtedly secured by any method of suture, is an incidental and far less necessary matter.

As the tears undoubtedly present themselves under various forms, I wish at this point to exhibit a series of diagrams which were drawn from life for me by one of the house-officers of the Boston Lying-in Hospital, and published in a paper upon the anatomy of the lacerated perineum, which I wrote for the last meeting of the American Gynecological Association.²

FIG. 1.

These figures illustrate an attempt to classify all the forms of tear which are observed in practice, as modifications of one type form, which is illustrated in the first figure. The paper for which these diagrams were originally made was an attempt to present a theoretical and mechanical proof for the necessity of approximating the tissues from above downward; but for practical purposes, a better demonstration is to be found by a consideration of the results of proper and improper methods of suture. When the sutures are inserted in such a way as to approximate the tissues from side to side, it is a matter of common observation that the result produced is substantially that which I have endeavored to represent by Figure 1, in which the line of union is narrow, and its external surface is

¹ Read before the Boston Society for Medical Improvement, February 22, 1892.

² Trans. American Gynecological Association, 1891, vol. xvi, p. 308.

almost at right angles to the lower portion of the posterior wall of the vagina. The anterior and posterior vaginal walls are but partially supported by such a result; the formation of the rectocele and cystocele goes on; the skin of the perineum so formed soon stretches and yields, and nothing has been accomplished by the operation.

FIG. 2.

When, upon the other hand, the tissues are systematically drawn together from above downward and from below upward, the form of result in well managed cases is that which is diagrammatically represented in Figure 2. The resulting surface of union is broad and deep; the external surface slopes upward and forward to form a genital furrow which is closely similar in shape to that of the normal or unaltered vulva; the posterior vaginal wall is thickened, and its anterior surface forced forward, until it is brought in contact with the anterior wall, to which it furnishes a firm support.

Such a union results almost invariably in the disappearance of sub-involution of the vagina and the arrest of the prolapse of the vaginal walls. By it the pelvic fasciae are again put upon the stretch, and converted into a firm occluding curtain for the support of the superimposed viscera; so that it may be said that the essential criterion by which the result of a perineorrhaphy should be judged, is that the fourchette of the new perineum should not only be sufficiently close to the lower edge of the symphysis, but should be upon approximately the same level with it, and that the sigmoid curve of the vagina should be fully restored.

If this result is attained, the precise method by which the sutures were introduced is a matter of unimportance; and the choice between the many methods which afford the essential requisite of drawing the tissues together from above downward, is one which depends upon the rapidity and ease with which the stitches can be introduced, rather than upon any other quality. This choice must always depend, to a certain extent, upon the idiosyncrasies of the individual operator; but it must also be regulated, both by the peculiarities of the individual case, and by the time at which the operation is undertaken.

The distorted condition of the tissues immediately after labor renders the more detailed and exact methods difficult of application; and the fact that the tissues at this time have not been distended and altered by the production of rectoceles or cystoceles, renders the adoption of such exact methods unnecessary; while, upon the other hand, the rough and ready approximation which yields excellent results in primary operations, would be entirely insufficient for a successful secondary repair.

For these reasons, I am inclined to advocate a considerable difference in the methods which should be pursued in primary and secondary operations. After

a considerable experience in the suture of the perineum immediately after labor by both methods, I have been led to believe that the attempt to approximate the whole surface of the tear with the accuracy which is necessary at a later period, is apt to lead only to distorted results; that is, to the suturing together of parts which were never separated from each other; and that the result is likely to be better if the tissues as a whole are drawn into moderately close approximation, and their exact arrangement against each other left to nature, and thus trusted to the forces of retraction and re-arrangement to which their whole substance is subjected during the few hours which follow delivery. It is, moreover, important that the method selected for use immediately after delivery should be one which permits the operator to act with a minimum of assistance.

The method which I myself pursue, and by which I am accustomed to attain, I think, upon the whole, better results than I formerly secured by more elaborate procedures, is as follows: A large, fully curved needle is threaded with silk or catgut, the second finger of the left hand is introduced into the rectum, and the forefinger of the same hand into the vagina. For a long time I employed the old-fashioned, large, fully curved surgical needle of our fathers, but of late have learned to prefer a delicate Hanks-Pearse needle, which I will pass about. The needle is then made to penetrate the skin at a point well out towards the left side of the patient's perineum, at least a third of an inch from the edge of the tear, and about opposite the antero-posterior edge of the anus; it is carried upwards and inwards with a wide sweep, entirely buried in the tissues, under the guidance of the first and second fingers of the left hand, until it crosses the median line at the point where the thicker perineal body is beginning to merge in the thin recto-vaginal septum, and is brought downward with the same wide sweep, to emerge exactly opposite to its point of entrance.

A second suture is introduced in the same manner, at the same distance from the lateral edge of the tear, and at a point which is, antero-posteriorly, half-way between the anus and the fourchette; and is carried upward to about the same point in the recto-vaginal septum. A third is introduced in the same manner, and with the same width and height, at a point about opposite, or, if anything, anterior to the situation of the fourchette.

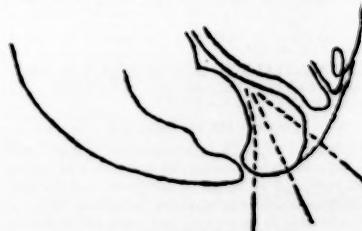

FIG. 3.

The relation of these three sutures to the tissues of the outlet, is shown diagrammatically in median section in Figure 3. When they are drawn together from side to side with moderate firmness, the edges of the tear in the median line are rolled inwards, and

disappear upwards out of sight; and on examination with the finger, it will be found that the introitus is of proper narrowness, and the sigmoid curve of the vagina fully restored.

In spite of the apparent roughness of the approximation, I have been accustomed to see it followed in the primary operation by most excellent, and even artistic-looking, results. In exceptional cases, in which the lateral prolongations of the typical Y-shaped tear extend so far up the vagina as to be necessarily crossed by these stitches, it is well to bring their ends together by a few running sutures, such as are to be described in the secondary operation; but my experience with a number of extremely prolonged tears, in which the approximation was necessarily rendered imperfect by lack of assistance, and with one extraordinarily long unsutured tear which I had the pleasure of seeing with Dr. E. J. Forster in the gynecological wards of the Boston City Hospital, to which she had been referred for the secondary operation, leads me to believe that the upper portion of these wings of the tear are likely to heal equally well without suture, provided that the lower portion is well repaired — a phenomenon which I may say, in passing, I believe can be readily explained upon mechanical and anatomical grounds.

For the secondary operation, there are three methods which are so generally applicable, and so readily and easily performed, as to be worthy of special mention.

First of these is Mr. Tate's flap-splitting operation. This possesses the important advantage that, when it is applied to late and difficult cases, it sacrifices no tissue whatsoever, and secondly, does not increase the difficulties of a second operation, should the first prove unsuccessful. By it the tissues which have been separated from each other, are brought much more nearly into apposition with each other than would at first sight be considered possible. It is valuable for cases in which the amount of tissue at the disposal of the operator is extremely small, and in which it is necessary to utilize cicatricial tissue, the capacity of which for firm union cannot be wholly trusted. In the majority of cases, it has seemed to me less useful than the methods in which the freshened surface is supplied by denudation.

The purse-string method has been highly recommended by many eminent and experienced operators. When this is adopted, an approximately oval surface is denuded, with its long axis transverse to the vagina, and the freshened surface, when made, is encircled by one or more sutures, which follow its contour, and which when drawn together, pucker up its large circular edge to a single point. I have had no experience with this method in perineal plastics, and can offer no opinion of value upon its merits. Upon theoretical grounds, it would seem to sacrifice accuracy to rapidity; yet I have no doubt, upon theoretical grounds again, that it would furnish, at least, fairly good support; and, as was said before, it has been highly recommended.

The third method to which I propose to refer, is that of Dr. Emmett, which is, however, modified by almost every operator, to suit his individual convenience and peculiarities.

For the proper performance of this operation, it is essential that the denuded area should be of exactly the right extent; and it will, perhaps, be well for me to give here a repetition of Dr. Emmett's directions for the determination of this point.

A tenaculum should be introduced into the last caruncula upon each side of the vulva, and these should be drawn upward, forward, and to the median line, by an assistant, while the operator engages another tenaculum in the median line of the posterior wall, at successively higher and higher points, until he reaches the highest point which can be drawn sufficiently far downward to meet the caruncula, when these are drawn as far up as is possible without leaving the median line. Each of these three points should then be marked by a snip from the scissors, when by bringing together successively each caruncula, and the marked point upon the posterior wall, two lateral folds or troughs will be formed, which, when their bottoms are depressed by a probe, will mark the limits of the lateral wings of the denuded surface.

The essential points in the insertion of the stitches, are that the bottom of each of the coaptation sutures should be much nearer to the median line than its points of insertion and emergence: that they should be tied in successive order from without inwards towards the median line, and that the purse-string or supporting suture, which is introduced after the others have been tied, should be passed with a wide sweep, and should pass transversely above the new-formed perineal body.

The modification of this suture which I myself employ in secondary operations, and which I believe to be as accurate as any other, and more rapid than most, is as follows:

The coaptation of the horns of the crescent is secured by a running suture, beginning at the end of the horn, and working inward; but the needle, with the free end of the thread, is carried through the preceding bight after each emergence from the tissues, in order to secure the same accuracy of adaptation which is obtained by uninterrupted sutures. I then insert two purse-string sutures, which are exactly similar to the first and third sutures which I use in the primary operation, with the single exception that they are introduced close to the edge of the tear, and then swept outward as they ascend, in order to minimize their cutting effect upon the external skin; and this I think permissible because the infolding of the median line has here been secured by the internal sutures. In primary operations, I habitually employ silk sutures, though I have uniformly obtained equally good results with catgut. In the secondary operations, I am accustomed to employ catgut for the internal sutures, and stout silver wire for the external or purse-string stitches, using the latter material for these two last stitches, because I wish to feel certain that these, at least, will preserve their integrity until after the bowels have moved; and also because, if they become relaxed by the subsidence of swelling, or by cutting through the tissues, I am accustomed to tighten them up immediately before the bowels move for the first time, and thus prevent the possibility of direct strain upon the newly-united tissues during the performance of this function.

Whichever method may be chosen, I am confident that when the profession as a whole has been sufficiently impressed with the idea that the restoration of the sigmoid curve of the vagina, and of the normal upward inclination of the genital furrow, by traction upon the tissues from above downward, and from below upward, is the only thing essential to success in the restoration of the lacerated pelvic floor, the number of

improper and useless operations, which are still constantly brought under the observation of every one interested in gynecology, will be greatly decreased, if not altogether done away with.

Clinical Department.

A CASE OF CEREBELLAR TUMOR, WITH AUTOPSY.

BY MORTON PRINCE, M.D.,
Physician for Nervous Diseases, Boston City Hospital.

The following case is here put on record, as it is desirable that all such cases should be recorded as contributions to symptomatology. It also presents one or two practical points bearing on the question of operation in cases of cerebellar tumor which are of interest.

When first seen by me, a little over a year from the beginning of the symptoms, the patient complained principally of intense headache, and of difficulty in walking, owing to a tendency to tumble. These were the salient symptoms. When first taken ill he suffered from nausea and vomiting, but had had neither for a year. The staggering was characteristic, I thought, of cerebellar ataxia. While there was no paralysis, he walked with great difficulty and caution. It seemed as if he tended to tumble to the left at this time, but this tendency could not be said to be very pronounced (the tumor was in the right lobe).

The headache which came on in paroxysms and was very severe, was located sometimes in the occipital region, sometimes in the frontal and sometimes "all over the head." The pain was described as terrible and accompanied by a bursting feeling.

He could with difficulty stand or walk without support. Although he said he felt generally weak his muscular strength was good.

Examination of the eyes by Dr. Wadsworth showed "a little indistinctness of outline of inner two-thirds of the disks, but nothing which may not be physiological; in other respects normal."

About ten months previously (December 18, 1890) the patient had entered the City Hospital. He stated, and the records substantiate his statement, that his condition at that time was about the same in kind as it was when he was first seen by me, but less severe in degree. His symptoms were vertigo, intense headache, ataxia, increased patellar and elbow reflexes. The records state that he was easily excited to tears, and could not stand with his feet together and eyes closed; that he fell to the right. The headaches, which were intense, were controlled by hydro-bromate of caffeine. There was no history of syphilis.

October 7, 1891. I recommended him for admission to the service of Dr. Bolles, with the view of trephining for the relief of the headache if it could not be controlled by medical means. It so happened that relief was obtained by caffeine, so this operation was not required. The question of operation for the removal of the tumor, which was correctly diagnosed and localized as cerebellar, was entertained and discussed at different times. The mental symptoms were quite marked and were suggestive of disease of the frontal lobes. His memory was very poor; he was emotional, easily moved to tears, and rather weak-minded.

His symptoms steadily and somewhat rapidly in-

creased in degree; and to them were added incontinence of bladder and bowels, in consequence of which he required continuous attention.

On November 9th he was discharged to his home, and died three days later.

The autopsy was made by Dr. C. M. Chamberlin, of Lawrence, who has kindly forwarded the specimen to Dr. Fitz and furnished the hospital with a statement of his findings. The right lobe of the cerebellum was occupied by a cyst about the size of a hen's egg, filled with pale limpid serum. The middle lobe was not involved, but might easily have been, and probably was compressed by the growth.

Dr. Whitney who has kindly examined the specimen for me, reports:

"The specimen consisted of the cerebellum with the pons and medulla attached. The under side of the left hemisphere of the cerebellum was occupied by a cyst measuring about six centimetres in its greatest diameter. The cyst was lined with a relatively smooth, firm, yellowish-white membrane, easily separable from the cerebellar substance, which surrounded it on all sides except the inferior. The substance of the cerebellum was compressed. Microscopic examination of the wall of the cyst showed it to be made up of a fibrous tissue rich in small cells and well vascularized, and in the inferior part the vessels were very abundant, forming almost a true telangiectasis. The inner side of the lining of the cyst contained numerous granules of blood pigment. The cyst has advanced so far that absolute proof of its mode of origin cannot be obtained; but it seems probably to be due to a hemorrhage just beneath the pia mater or in the superficial part of the cerebellar substance."

About seven years previous to the development of his first symptoms the patient, while standing on the top of a moving freight-car, was struck on the back of his head by a bridge. The accident must have been a severe one, for he was knocked unconscious, and remained so probably the greater part of a day and was disabled for some days. His statements varied so at different times regarding the severity of the accident, probably owing to the loss of memory, that more cannot be determined. The question was discussed during his illness, whether or not any close connection between this accident and the final illness was probable. The autopsy would seem to show that a hemorrhage may have been produced at that time, and may have been the origin of the cyst.

As to the feasibility of operation, although I felt there was the highest probability in favor of a cerebellar tumor, I was unwilling to advise an operation, in consequence of the unfavorable results that have hitherto attended this operation. Had I known it to be a cyst, I certainly should have advised it. Only two successful cases have thus far been reported; one of these was a sub-tentorial hydatid cyst and therefore easily emptied. In the other case the tumor was superficial and fixed to the bone.

An element of uncertainty must always attend attempts to remove a cerebellar tumor, owing to the difficulty of locating the growth within the cerebellum; and unless the growth is superficial or the tumor a cyst, the danger of shock must be great. Inasmuch, however, as such tumors are of themselves necessarily fatal, and as there is often a possibility of the growth being a cyst or superficial, it seems to me to be sound surgery to make an exploratory opening in all cases, with

the idea of attempting removal should the conditions be found to be favorable. Considering the frequency with which cysts are found following injuries, it seems to me that such an operation is particularly called for when a previous history of traumatism exists. This, however, should be done before optic neuritis has developed. If the operation had been done in this case it probably would have been successful. Cysts of the lateral lobes, if they can be diagnosed, would seem to be particularly favorable subjects for operation as lesions of these lobes may occur without disturbance of function.

Inasmuch as ataxia is known to accompany tumors of the frontal lobe, a more careful study is needed of the peculiarities of inco-ordination of movement accompanying lesions of different localities. Where optic neuritis is absent and psychic disturbances are present, as in the above case, it may be difficult to distinguish between frontal and cerebellar tumors.

Medical Progress.

RECENT PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

(Continued from No. 18, page 46.)

SURGERY OF HYDATID DISEASE.

A. S. LEBRDEFF¹⁸ and I. I. Andrieu's investigations in 1889 are said to prove that daughter-cysts transplanted in the abdominal cavity (experimentation done with rabbits) will continue to grow and multiply. Dr. Sladnitzky¹⁹ has recently confirmed this, and advocates that on that account the strictest precautions should be taken to prevent the escape of the daughter-cysts into the peritoneal cavity when operating on the parent cyst, since by their multiplication they can cause all the disturbance of the original disease. When it is evident that hydatid cysts of the liver have burst into the peritoneal cavity, abdominal section is indicated, for this same reason at once. Exploratory tapping for diagnosis of abdominal hydatids is to be considered allowable only in certain quite exceptional cases.

THE SURGICAL TREATMENT OF INTRA-PERITONEAL TUBERCULOSIS.

Czerny²⁰ makes the following report in regard to the curability of this affection. That tubercular inflammations of some membranes may subside, but the process is so often dependent on adjacent foci (glands, uro-genital tract, *et alii*), that other sequelae must necessarily follow. Pleurisy preceding tubercular bone and joint disease is found (or would be if inquiry was made) of frequent recurrence. When the nucleus of infection is limited and removable, a permanent cure is possible. He reports sixteen cases, comprising operations for ovariotomy, inguinal hernia, enucleation of uterine myoma, resection of tubercular intestine, extirpation of tubercular mesenteric glands, removal of tubercular peritoneum, etc. There were five cures: (1) miliary tuberculosis of the peritoneum, found during an ovariotomy; (2) miliary tuberculosis of the peritoneum, found during an inguinal herniotomy, reported well at end of four months; (3) a resection of a tuberculous

cæcum, well three years later; (4) extirpation of mesenteric gland; (5) tubercular ulceration of cæcum, resection, well fourteen months later. Ten of the fifteen died. The cases are worth careful study. Czerny thinks that for operative purposes there should be a distinction made between the class characterized by firm, tumor-like masses, that is, a dry, adhesive form, and the milky form accompanied by liquid effusion. The latter type is most favorable for operative results. The former has very little encouragement for the surgeon. The latter, by absorption and thickening, may be transformed into the former, as was observed in one of the reported cases. The surgery of the intestinal and lymph-gland tuberculosis is very difficult, and has been little practised; still he thinks his work justifies further trial.

THE "SCHWALBE" METHOD OF TREATMENT OF REDUCIBLE HERNIA.

Mangoldt,²¹ Dresden, has published an interesting review of Steffen's article describing this method. The Schwalbe method consists of the subcutaneous injection of alcohol (twenty to seventy per cent), by means of a Pravaz syringe, with antiseptic precautions, into the ring, as near as possible to the hernial sac; amount two to three grammes; repeated four to fourteen days, according to sensitiveness of patient and amount of reaction; these injections omitted, and recommenced after a pause of eight to fourteen days. Treatment continued till the diffuse thickening and fibrous contraction thus caused has completely closed the ring. The article describes accurately the technique of the method. The duration of the treatment varies from one month to two and a half years or more, according to the age of the patient, the size of the hernia and the diameter of the ring.

Results reported: cured (all varieties) 245 (83.62%); relieved, 19 (6.46%); not cured 29 (9.9%). A "cure" was a hernia, which was relieved so that the patient had worn no appliance for at least six or seven months, and examination by coughing, straining, standing, lying or by invagination of scrotum, was negative. The canal was not always completely closed, but the hernia never recurred, on account of the firm adhesion of the peritoneum around the inner ring. The cases of failure were in fat patients; thin patients with relaxed, flabby tissues, chronic bronchitis and emphysema, very large herniae; and where the treatment was not continued long enough. Recurrences in ten per cent. of cases due to too short treatment, chronic cough and constipation. There is no fatal case reported. One patient has remained cured fourteen years. Steffen claims to cure four-fifths of his cases. The patient does not, when cured, require a truss or bandage. The younger the patient, or the more recent the hernia, the better the prognosis and the shorter the duration of treatment. The results in patients unconfined, with three to seven days' intervals, give quicker results than daily injections of patients confined to bed. If the hernia is easily retained by bandages or truss, occupation may be continued during treatment. In rare cases the alcohol has caused urticaria, dyspnoea, vertigo, intoxication by vegetarians.

HERNIA.

A valuable résumé of the literature, chiefly German, of this subject, has been published by Wagner,²² of Leipzig.

¹⁸ Medical Chronicle, 1889, p. 215.

¹⁹ St. Petersburg Inaugural Dissertation, 1891, No. 22, p. 32. Review. Annals of Surgery, 1891, vol. xiv, p. 260.

²⁰ Beiträge Klin. Chir. 1880, Bd. vi, Hft. 1.

²² Ibid., 1891, Bd. 230, p. 167.

zig. The article is too long for more than a very abbreviated report, but some points are of especial interest. In regard to präperitoneal herniae, the following statistics are reported: Total number of reported cases (inguino-präperitoneal) 58; all but one males; ages ten to seventy-four years. The position of the testis was abnormal on the affected side in a majority of cases. Thirty-three cases were right, 14 left, 11 both right and left. Since Krölein's cases were published, there have been 30 cases with symptoms. Treatment: two relieved by taxis, 16 by operation; 12 deaths. In very few cases is the condition recognized before operation. Cruro-präperitoneal type: seven cases, all women; four recoveries; three deaths, in spite of operations, since the inner sac was not recognized.

Diagnosis: History often of importance.

Hernia is usually congenital. There is delayed or incompletely descended testicle. The fact is that symptoms persist after an apparent successful reduction; also that the reduction is difficult, and that the hernia at once recurs in spite of a wide ring, as soon as manipulation is suspended. The tumor is unusually resistant, with pain, marked tenderness and dulness of the adjacent abdominal wall. At times compression of one sac causes increased tension in the other (section of präperitoneal sac followed by fresh gush of fluid).

Differential diagnosis: From internal strangulation of a neighboring loop of intestines, reduction "en bloc," and interstitial (that is, hernia between abdominal muscular planes). In operating, Holder recommends the exposure and opening of the outer sac, then by manipulation, or, if necessary, enlarging the internal ring, the contents is reduced. If this does not render the internal sac attainable, the incision of the abdominal wall must be lengthened till it is exposed. After reduction the sac is excised, after suture of the abdominal ring.

With regard to observation on strangulated herniae, Koch, Nürnberg, reports that when the sac was excised and the stump secured by suture, but other rings were not closed by suture, in 37½% of his cases (No. 17) recurrence took place. Nussbaum operated only when truss treatment was impractical or inefficient. His radical operation was exposure of the sac, taxis, suture of the neck of the sac, its amputation, after which the amputated sac was sutured into the canal and the pillars reunited. He is reported as having from 20% to 25% of recurrences. Gangrenous herniae were excised, and an artificial anus established. He claims that the Schwalbe method (alcoholic injection) can be favorably combined with the open method, and the firm callus about the sac can be produced in a simple manner by use of the Pacquetin cautery.

Wolter reports 387 radical operations from the Hamburg hospital (72 deaths). The technique was as follows: 95 cases highest possible ligation of sac and its extirpation, pillars of ring sutured; 17 cases sac ligated, excised, pillars not sutured; 15 of these cases were femoral; 15 cases pillars sutured, but probably sac also included; in three cases only was the canal opened by incision; 11 cases modified operations; in 24 cases technique not described; in 53 cases the omentum was partly removed; in no case was the testes removed. Results: 58 cases where examination was made at considerable interval after operation, 15 recurrences; a still later investigation showed 41

definite cures. With Schiede, he considers the firmest possible union of the pillars by suture of great importance, and that the excision of the sac is of secondary importance. This view is contrary to that held by many successful operators. He also claims that the use of a truss after operation is no impediment to a permanent cure. He claims never to have seen pressure atrophy, or relaxation of the peritoneum from it, and quotes Schiede as recommending it, except where silver-rim sutures were used.

PRIMARY RESECTION OF INTESTINE FOR GANGRENOUS HERNIA.

Hab's²¹ (Magdeburg) report of 200 herniotomies is a valuable one, and well worth a perusal. One point of especial value is his contribution to the statistics of immediate resection of a gangrenous intestine when operating for hernia. In sixteen cases the intestine was resected and sutured; nine cases died and seven recovered, a much larger percentage of recoveries than is usually recorded.

HERNIA WITH INTESTINAL GANGRENE.

The question of immediate resection and suture of the gangrenous gut under these conditions is again attracting attention, and cases are accumulating where primary resection has been successful, although the majority of opinion is still in favor of treating such conditions extra-peritoneally, or by forming an artificial anus to be subsequently closed if the patient is rescued from immediate death. Two procedures have been proposed as a substitute for either of these alternatives. The first is indicated in cases where the gangrenous spot is small, and consists of folding in the affected area and suturing the intestine over it in the same way as an intestinal wound would be treated, then, if sloughing takes place, the necrotic mass is cast off into the interior of the bowel. When this method is used, the intestine is immediately replaced in the abdomen and the inguinal wound closed. The other expedient is from Helferich,²² of Greifswald, who proposes to form an anastomotic opening by so uniting the intestines above and below the gangrenous area. The latter portion is then treated outside the abdomen, and is isolated from facial circulation, the anastomotic opening being in the abdominal cavity. This opening he makes only four centimetres long. This he claims is a short operation. Later, if the strangulating intestine regains its vitality, it can be returned to the abdomen, after freeing it from the adhesions about the abdominal wound. If it becomes gangrenous, it can be resected without opening the peritoneum, and the resected ends readily closed. Helferich reports two cases illustrative of this method. One was successful. One died from collapse, but it was found that the anastomosis was complete when examined post-mortem. He claims that the method is indicated where the condition of the strangulated intestine is doubtful and gangrene threatened, rather than in cases where actual gangrene exists.

Poulsen, on the other hand, has collected 23 cases of primary resection of the intestine with immediate suture,²³ with five deaths: which is a good showing if the cases were not selected ones. These operations were done from 1884 to 1888, inclusive. His opinion is that many of the fatal cases are not published. He

²¹ Deutsche Ztsch. f. Chir., 1891, xxxii.

²² Centbl. f. Chir., 1890, Beilage, no. 25.

²³ Hospitals Tidende, K. 3, Bd. 7, pp. 349, 373.

himself at present treats these cases of gangrenous intestine by washing out the peritoneal cavity, extirpating the gangrenous sac, disinfecting its site, drawing out the gangrenous loop till healthy intestine is reached, suturing this in place in the abdominal wound, dressing with iodoform gauze, and later (one to two days) removing loop with Paquelin cautery. The artificial anus is subsequently closed.

An interesting discussion of the treatment of gangrenous hernia by the Surgical Section of the Suffolk District Medical Society, recently published,²⁴ deserves a careful perusal by those interested in this subject.

THE SYMPTOMS OF INCARCERATED OBTURATOR HERNIA.

Krölein²⁵ describes these as resembling those of ileus, that is, intestinal obstruction, together with pain in the thigh radiating from Poupart's ligament to the knee, excessive tenderness over the corresponding pectenial area, and still more marked behind the adductors in the direction of the foramen ovale. The motion of the hip is painful, and in one case there was some swelling of the leg and slight prominence of the pectenial region.

GASTRIC MYOMA.

Kunze reports a case of the removal of a subserous leiomyoma²⁶ by Rupprecht, in Dresden. The tumor was nearly equal to a fist in size, and was situated in the anterior wall near the cardiac orifice. Its removal necessitated an extensive resection of the anterior wall of the stomach, which was accurately closed by suture. The abdomen was closed. Death on the fifteenth day. Post-mortem examination disclosed a firmly closed gastric wound, without any trace of peritonitis. Cause of death, embolic pneumonia.

(To be continued.)

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. G. SEARS, M.D., SECRETARY.

REGULAR Meeting, Monday, February 22, 1892, the President, DR. FREDERICK I. KNIGHT, in the chair. DR. EDWARD REYNOLDS read a paper on.

THE ESSENTIALS TO SUCCESS IN REPAIR OF THE PELVIC FLOOR IN PRIMARY AND SECONDARY OPERATIONS.¹

DR. BAKER: I have listened with a great deal of interest to Dr. Reynolds's paper, because I think in the first place it shows the importance in recent tears of taking deep suture, which I am sure has not been fully recognized by the profession as a whole.

The importance, then, of the deep suture, which alone can give, as Dr. Reynolds has insisted upon, this sigmoid curve to the vagina, which in its turn gives firmness, strength and support to the anterior rectal wall as well as to the posterior vaginal wall. It seems to me that in the recent tears of the perineum, so far as my experience has gone, that the important

things to secure success are mainly two: first, the absolute cleanliness of the parts; and, second, with all due respect to Dr. Reynolds, the most perfect approximation of the parts. I should, I think, go a little further than Dr. Reynolds did in regard to this matter of approximation, for the reason that I believe the more nearly we approximate the parts the more nearly we simulate nature, and although this may be a little difficult on account of the ragged ends and swelling, yet still with care, and particularly if we use the suture which he lays stress upon in another way, that is, a suture which as that swelling subsides can be tightened again, I think that we have gained a very important point in regard to the success in recent cases. I have been in the habit of practising and advising in the recent years the use of deep sutures of silver wire, for, after twenty-four or forty-eight hours, when the swelling begins to subside, you can get another twist on them and thus keep the parts in perfect apposition.

Another thing I should criticise a little, and yet I know it is not the custom or habit of most operators, is the importance in any operation on the perineum, be it recent or secondary, of keeping the fingers out of the rectum. I am more and more convinced of the importance of thorough cleanliness at the time of the operation; and although we may wash out the rectum, still we cannot always control the feces that are coming down into that lower rectum, and I think we shall all the more insure a perfect result if we observe the aforesaid rule during operations on the perineum.

I am very much pleased and impressed with the way in which Dr. Reynolds has presented the importance of this subject; and although I think that many operators nowadays are looking with a great deal of interest at the more rapid method of operating by the flap-splitting which has received the name of Tait's operation, why I am not altogether sure, because I remember two surgeons of this city who were operating by flap-splitting on the perineum years and years ago, almost before I had heard the name of Tait. Dr. Beach was, I know, doing virtually the same thing Tait is doing, and Dr. Warren was splitting from above downwards, so that I do not think we need to go further than to term it a flap-splitting operation. I have been disappointed in that operation for the reason that it did not seem to accomplish all I desired in cases in which I have used it. In the series of cases in which I tried it, and I gave it a fair trial, not getting the good results I had expected, I felt desirous of being sure that I was getting all the advantage that could be obtained from it and therefore I asked one of Mr. Tait's pupils to operate on some cases with his method, which he did and the results were not, it seemed to me, entirely satisfactory. I think that in recent tears if we can observe thorough cleanliness and a good approximation of the parts it matters comparatively little what the other steps of the operation are.

I cannot altogether agree with the unimportance of the teeth in the upper part of the vagina; although I know they tend to heal readily, yet still I think there is a great tendency to the formation of more cicatrical tissue if left to nature than if the parts are cleansed and sutures taken.

I think that Dr. Reynolds's diagrams also show exceedingly well the inadvisability of practising any one way of doing an operation on any great number of cases. As we are called to perform more and more operations we shall see that one way of operating on

¹ See page 225 of the Journal.

²⁴ Boston Medical and Surgical Journal, 1892, vol. cxxvi, 297.

²⁵ Bruns, Beitr. z. Klin. Chir., 1890, Bd. vi, Hft. 1.

²⁶ Arch. f. Klin. Chir., 1890, xi, 3, p. 753.

a tear that has occurred on one way is the best, and another way is better for another case. Supposing this tear or separation of the fascial attachment has occurred on one side of the perineum, what is the use of going on and denuding as we would a perineum where both sides have been sutured. In such a case I should say we should do virtually a one-sided operation. I think the diagrams show that we should vary very much our operations, methods of denuding and closing the wounds.

DR. CHADWICK: Dr. Reynolds's study of this lesion has made him so familiar with the subject and his language is so clear that he does not leave much to be said. In the primary operation I think there is no question that he is right about the direction in which the sutures should be put. There are one or two little practical points which are perhaps well to mention. With regard to the finger in the rectum, the distance between the rectal wall and the vagina is so slight that to my mind it is absolutely essential that the finger should be in the rectum when you introduce the needle. It would be more serious to have the needle go through the rectal wall and make a fistula than to run the risk of infection. Of course you should disinfect the finger every time you withdraw it from the rectum.

The point to which those sutures converge at the top is a point where there are no very solid tissues. When they are tightened they pull away from that point, especially in a recent operation when the parts are edematous and torn, and it seems to me well to put the suture through the vaginal wall to get a *point d'appuis* to hold the upper angle of the suture. Another point would be that the sutures should be made very deep, and go behind the torn surface deeply into the muscular tissue of the perineum in order to hold. The superficial tissues are ready to slough and very friable.

With regard to the secondary operation I have operated after Tait's method and with very satisfactory results. I think the operation should be restricted to that class of cases where there is no great prolapse of the posterior vaginal wall. It takes no account of the prolapse of the wall, and I have seen in some of the early cases I did the posterior wall roll out over my approximated surface out of the vaginal outlet after I had got a perfectly good union; in other words, I think that if the vaginal wall is prolapsed and rolled out and been distended it must be excised to a certain extent to reduce the calibre of the vagina and prevent subsequent rolling out. In the class of cases where there is no great prolapse of the walls it seems to me that this operation gives as good results as you can get.

DR. REYNOLDS: As regards the use of the finger in the rectum, I personally think it is unwise to put the finger in the rectum for any but the primary operation. In that I am in the habit of putting the second finger into the rectum; I leave the thumb and first finger outside, never take that middle finger out until the three sutures are in, and then disinfect the finger at once and tie. In a rapid, rough operation like that I think that by this procedure you gain the advantages of the use of the finger without its disadvantages.

As regards the primary operation I should like, if there is time, to state briefly on what I founded my statement that I thought a comparatively rough and ready approximation was the better. I agree with

Dr. Baker that the essential part of the whole operation is to get accurate apposition, but I disagree in that I think that a comparatively rough gathering of the tissues together in such a way that the surfaces can slide slightly on each other leads to better and more exact apposition in cases operated on immediately after labor, than any careful suture I have been able to adopt. For some years in the cases that I have sutured in the wards of the Lying-in Hospital, where I have the best of light, two house-officers, and half-a-dozen nurses to assist me, I have done the perineum as I would do in the secondary operation, inserting the sutures as I would in the secondary operation with every attempt to make the apposition exact, and I confess my results have not been as good as in private practice where I have had no assistance and have adopted the rough method. I think that is because the tears are almost never symmetrically alike on both sides. They are differently stretched on the two sides by labor, they are differently bruised and paralyzed, the muscles immediately after the tear retract in differing degrees; and I believe that when you attempt an exact apposition you generally secure an inaccurate one, that is, you draw together tissues which were never separated from each other; but if you take all the muscular and fascial tissues near the tear into a wide sweeping suture, and bring them together *en masse*, I think that as the tissues restore themselves after labor the ensuing retraction of the muscles will bring them more closely into an exact apposition than can be done by art.

As regards the criticism that you cannot use one operation for so many forms of laceration, that certainly is very true. I did not think there would be time to go into all the forms, but in all of them I think that putting in at least two broad supporting sutures that will act as a splint and take the levator ani muscle off from the denuded point is a good point to remember. The fibres of the levator ani act obliquely from behind forwards and from above downwards, and during defecation the function of these fibres is to draw up the anal orifice as the faeces come down, so we can see how the new line of union running in a direction perpendicular to them must not only be drawn upon from before backwards but also from below upwards by their action, and it seems to me that the two sutures I have mentioned are important and yield good results.

DR. GEO. B. SHATTUCK read a paper on
PNEUMONIA IN BOSTON DURING THE RECENT EPIDEMIC OF INFLUENZA.²

DR. F. MINOT: In my experience with influenza during the last two winters, I observed that a certain proportion of cases were considered by the attending physician as pneumonia, although they had none of the physical signs of that disease; that is, no chill, no dulness, no characteristic expectoration, and no bronchial respiration. In fact the typical signs of pneumonia were absent. In those cases there were signs of oedema of the lungs, often to a very great extent, but without the dulness, and those cases would sometimes improve temporarily under the effect of nitro-glycerine to a remarkable degree, although most of them were fatal in the end. I cannot help thinking therefore that the statistics which are not based upon hospital returns are not altogether safe as a criterion

² See page 518 of the Journal.

for estimating the proportion of cases complicated with croupous pneumonia. In the hospital returns of course there can be no doubt, but among general practitioners a certain proportion of cases of edema of the lung is confounded with pneumonia.

DR. CUTLER: I have had very little experience with pneumonia in my own practice this year. I have seen a number of cases in consultation and they were peculiar in that the onset of the disease was rather slow and the course was protracted. I think that it is my observation that rather more cases of quite young children had pneumonia than I had ever seen before. In fact until within a year or two I do not think I have ever seen a case of pneumonia in a very young child. This winter I have seen several. Also the temperature chart has been peculiar, and instead of following out the usual course has been very much more irregular. As far as the prostration is concerned I should say that perhaps that was a little more marked than one sees it usually in ordinary cases. I have had no experience in the hospital cases, and only a limited one in private practice.

DR. MASON: My experience has been the same as Dr. Shattuck's at the City Hospital and relating to the same cases largely. It is only by the presentation of such carefully-prepared tables that we can form an accurate opinion of these accompaniments of influenza, or the extent to which influenza directly or indirectly causes increase in the death-rate of Boston from pneumonia and bronchitis. It seems to me difficult to allot the exact proportion of cases that may be accompaniments of influenza and those which are sequelae as they would follow any exhausting disease. I have found it very difficult with hospital patients, particularly, to find out whether they had a definite history of a previous attack of influenza or not, coming into the hospital very ill, with no friends perhaps who could speak for them, but I have been inclined myself, both this year and two years ago, to regard pneumonia as a necessary and fatal accompaniment of epidemic influenza rather than as a sequel. That I think was the view taken in earlier epidemics by Graves, Watson, and other distinguished physicians in the former part of this century, and certainly there are patients who, after a day or two of preliminary symptoms, are stricken down by an acute attack of lobar pneumonia. To be sure the same thing happens in non-epidemic seasons so that it is a very difficult matter to decide by figures, but if we had not influenza with us I think it is quite certain we should not have pneumonia at least to anything like the same extent.

In regard to the apex pneumonia I suppose the delirium was more common in children than in adults. A child with any form of pneumonia is apt to be delirious.

The complications which were most fatal in pneumonia were empyema, alcoholism and Bright's disease. I have seen cases at the City Hospital in which the empyema developed before the process of resolution had fairly begun. Two years ago I think there were about a dozen such cases which entered the medical wards, all of which fortunately became convalescent from the pneumonia and the empyemas were drained successfully.

DR. GOSS: My experience was necessarily limited. It seemed to me that in this epidemic there were much more frequent troubles with the respiratory organs than two years ago. There were a great many more cases

of bronchitis and pneumonia, and my opinion is that these affections were accompaniments or complications rather than sequelae; often the pneumonia being insidious in its approach perhaps and not as frank as in the ordinary croupous pneumonias which we see at other times.

DR. J. H. MCCOLLUM: It is an interesting fact, bearing on the subject of pneumonia after influenza, that at the Suffolk County Jail during the first epidemic, in which there were 125 cases, in no instance did pneumonia supervene. During the second epidemic of this disease, in which there were 80 cases, there was a like freedom from pneumonia. The explanation of this immunity from pneumonia is, without doubt, due to the fact that as soon as the first symptoms of influenza appeared the patients were confined to their cells and remained there until they were well.

I think that the influence of influenza on the death-rate of Boston is not fully appreciated. During 1891 the percentage of deaths from this disease to the total mortality was twenty-nine one hundredths of one per cent., while that of scarlet fever, one of the most prevalent of diseases, was only sixty-one one hundredths.

There is a striking statement in the report of the State Board of Health of two years ago, that directly or indirectly the first epidemic of influenza caused more deaths in Massachusetts than the great epidemic of small-pox in 1872 and 1873. Referring again to pneumonia at the jail, Dr. McCollum stated that there were very few cases at any time, that the physical condition of the prisoners was such that they would be extremely susceptible to an attack of pneumonia.

DR. ATHERTON: I think that papers like this one ought to be encouraged, since they are so valuable.

In regard to pneumonia, I have seen very little of it in the last epidemic. In the first epidemic it seemed to me that the neuro-muscular symptoms were more marked than the respiratory, and much more so than the gastric. Perhaps the doctor would not agree with me in regard to there being a relapse in the last year, but I do feel as if I had seen symptoms very marked and constant of subacute character, beginning February and March and lasting through the spring, and a second relapse about the last of December. The symptoms I saw last spring were decidedly neuro-muscular in character and respiratory too. This year the respiratory symptoms were far more prominent in every way. Except in regard to the pneumonia, the respiratory symptoms were confined largely to the upper air-passages, laryngitis, serious sore throats, pressure about the chest, and all those symptoms, partly, perhaps, connected with the nervous system.

DR. J. S. GREENE: As to the matter of concomitant versus sequelae, two of the hardest cases I have had commenced as a sharp attack of pleurisy, and developed pneumonia simultaneously with influenza.

DR. GEO. B. SHATTUCK: I was very much interested in hearing what Dr. McCollum had to say. I think it is a fair contribution to the question raised. There are certainly other people who are quite as hygienically situated as our friends in the jail, and who still get pneumonia after influenza or with influenza because, I should say, they did not take care of themselves.

In regard to apex pneumonia I fancy that children are always liable to delirium, cerebral excitement, with all pneumonias as with all acute febrile attacks.

With reference to the question as to whether pneumonia is a sequel or a complication or concomitant I

do not wish to dogmatize about it. I simply think it is a fair question for speculation and I am rather inclined to the former view. I did not intend to say that there had been no recurrence of epidemic influenza during the year 1891 before December; but that I thought we might consider that the months of December, 1890, and January, 1891, had been free from it in this neighborhood. I did not wish to express an opinion in regard to the spring months.

DR. GAY showed

A COLLECTION OF CALCULI RECENTLY REMOVED FROM A BLADDER BY LITHOTOMY.

The man, aged sixty-nine, had been disabled from business for five years. In the earlier period of his illness he was repeatedly sounded for stone, at one time it being done under ether, but nothing was found till recently. The stones are hard, smooth and of a light fawn color. Fourteen were shown varying in size up to an inch and a quarter in diameter. Two ounces were crushed and removed by Bigelow's method. There being no apparent limit to the number in the bladder, lateral lithotomy was done, and the remainder removed. The entire amount weighed five and a half ounces. He died of uremia and exhaustion in a week.

DR. ROTCH reported

A CASE OF DOUBLE MOVABLE KIDNEY.³

DR. MINOT: I should like to know the interval between the operation and the last time the patient was examined, and whether the kidneys were in place.

DR. ROTCH: The operation was done in June last. I examined her yesterday. The kidneys were in place.

DR. MINOT: I think what is needed is a table, if possible, containing the results for a considerable length of time afterwards. My impression is that Guttner speaks of several cases where the operation had succeeded, but after a time the former condition returned.—I refer to the operation of sewing the kidney. I think Guttner gives several instances of that condition in children under twelve years of age. The great proportion of cases on the right side in women is generally ascribed to the pressure of the corset and it would seem as if that was the most probable cause. The kidney slipping out from its capsule and getting beneath the liver, its relations to the liver are entirely changed, and the pressure of the corset forces it down and aids in the displacement; and even before the kidney has moved from its bed, the pressure upon the liver from the corset would tend to force it in a measure out from its capsule.

Resolutions on the death of DR. HENRY I. BOWDITCH were presented and passed.

Recent Literature.

A Practical Treatise on Fractures and Dislocations.

By FRANK H. HAMILTON, A.B., A.M., M.D., LL.D. Eighth edition, 850 pages, 507 illustrations. Revised and edited by STEPHEN SMITH, A.M., M.D. Philadelphia: Lea Bros. & Co. 1891.

The work of Dr. Hamilton is so well known that a description is almost unnecessary. Its numerous editions are convincing proof, if any is needed, of its value and popularity. It is pre-eminently the authority on

³ See page 522 of the Journal.

fractures and dislocations, and universally quoted as such. In the new edition it has lost none of its former worth. The additions it has received by its recent revision make it a work thoroughly in accordance with modern practice, theoretically, mechanically, aseptically. Its new editor has discarded matter now irrelevant, and separated clinical data from the abstract portion of the work by different type, so that it may be readily distinguished. Modern ideas and new facts have been introduced when indicated. The list of illustrations shows marked change and improvement, for one hundred and five new ones have been added to increase the efficiency of this valuable means of imparting information respecting methods and details.

The original arrangement of this volume, as regards classification, has been retained unchanged: Part I (498 pages) being devoted to the discussion of fractures, while Part II (347 pages) treats of dislocations.

Part I opens with a description of fractures in general, and treats of their character, etiology, clinical history, diagnosis, repair, prognosis, treatment, complications, and possible sequelæ. It is an interesting and very instructive chapter, and would be more so had more information been given under "Repair of Broken Bones," respecting *rate* of union. "Treatment" is well discussed; and "Delayed or Non-Union" attracts especial interest.

Specific fractures are next treated. They are classified anatomically. All possible fractures of individual bones with their causes, symptoms, diagnosis, treatment and complications are satisfactorily considered. As above, the only addition possible would be more specific facts with regard to the time required for union. Such data are of great importance when the duration of treatment is in question; and there is such a difference of surgical opinion at present on this point, especially with reference to these lesions affecting the lower extremity, that such data would seem indicated. How soon it is safe to omit apparatus, and similar considerations are of great importance in actual practice, and have not apparently received the amount of attention given to many other portions of the work.

Part II, describing dislocations, has an arrangement analogous to Part I. Like it, little can be said except in commendation. The article entitled "Dislocation of the Head of the Radius Downward (by elongation)" is a good example of the manner in which the editor has performed his task. This lesion is frequently unrecognized in practice and unmentioned in surgical literature, even in works on dislocations. Here an entire section is devoted to it, which lacks completeness only in that the writer has paid more attention to the French literature of this subject than to the valuable English and American articles of the past five years.

The task of writing a complete treatise on a subject of such magnitude is no easy one. Dr. Smith has aimed to make the present volume a correct exponent of our knowledge of this department of surgery. In examining this volume one is at once struck with the evidence of the vast amount of labor its compilation and reconstruction must have necessitated. The more one reads the more one is impressed with its completeness. The subject is one of great importance, the different lesions very numerous, the generalization of statistics and clinical data difficult and laborious, the mass of material at the disposal of such a writer enormous. Yet the work has been accomplished; and has been done clearly, concisely, excellently well.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, MAY 26, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERM: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

THE INFLUENCE OF EMOTIONS IN THE PRODUCTION OF ORGANIC DISEASE.

WHETHER organic diseases of the heart may result from mental causes is more doubtful than that arterial disease may so originate. Much has been written of late on the influence of emotions in the development of arterio-sclerosis in general and of arterio-sclerosis of the heart in particular. This morbid condition has been referred to increased arterial tension, and one of the causes of this high tension is mental emotion. The condition of a person under intense emotion is that of vascular spasm; "the face is pale and covered with sweat, the extremities are cold, the pulse is small, weak and miserable, an indescribable anguish constricts the heart, whose beatings, precipitate and tumultuous at first, may be suspended in a state of syncope." That there is spasm of the arterioles here has been proved by the application of Mosso's plethysmograph to similar cases.

"Let us suppose," then, says Huchard, "that the emotions are repeated, are perpetuated, as is the case with many politicians, financiers, or others involved in business schemes, who lead restless, anxious, worried lives, and then you will understand why it is that their arterial system, in a state of permanent hypertension must in the long run be doomed to the lesions of arterio-sclerosis."¹

Dr. Clifford Allbut mentions the case of a young man whose pulse-tracing during twelve months of domestic anxiety showed, in comparison with that before and after, a marked and persistent increase of tension (Lys).

The dependence of angina pectoris upon degenerative vascular changes in the heart-muscles has been shown by recent writers, as Lauder Brunton and Huchard; the latter, especially, in his brilliant work on "Diseases of the Heart," calls attention to the influence of mental disturbance in producing increased

tension and arterial degenerations. Other results of atheroma, such as aneurism and cerebral hemorrhage can be shown logically to follow emotional causes sufficiently intense and sufficiently prolonged. Dr. Graham Lys in recent numbers of the *London Lancet* (April 23-30, 1882), has considered the subject in its relation to other morbid states; such as Graves' disease, dyspepsia, jaundice, diabetes, renal cirrhosis, chorea, cancer, etc.

With regard to Graves' disease, he affirms that assuming, as we are bound to do, "that an antecedent mental state may fairly be held responsible for the subsequent morbid developments there will be difficulty in refraining from the belief that the exophthalmos and goitre are in some way referable to the palpitation." "Slight thyroid enlargement is comparatively so common in girls who suffer only from intermittent palpitation that there is little difficulty in referring it to this cause, and the exophthalmos is the least constant and least developed of the three."

"It can hardly be contested," he says, "that in every case of this disease a morbid mental state of constant character precedes its development; the prominent features of that mental state are depression with extreme irritability."

There can be no question that indigestion follows mental disturbance; the latter, if prolonged, may entail severe and even incurable dyspepsia. Dr. Lys thinks that this may be due to an arrest of the secretion of gastric juice. Hutchinson has dwelt on the influence of emotion in some of the secretions, and has instanced cases of persistent dry mouth following some mental shock. Beaumont directly observed the arrest of the gastric secretions by anger and other severe emotions. Probably, also, movements of the stomach may be inhibited by emotion; irritability or sluggishness of the bowels is often referable to mental disturbance according to its kind; the latter disorder reaches its climax in the extreme constitution of melancholia.

Many instances are on record of simple jaundice following mental emotion; the question how this can happen, has thus far not been explained. Dr. Lys does not venture any explanation, but supposes that the jaundice must be due "to some influence on the hepatic cells, which, while leaving them competent in some degree to complete the formation of bile-pigment, interferes with the excretion of it." He alludes to the fact that acute yellow atrophy of the liver often follows immediately mental shock, and runs its course rapidly.

Diabetes, mellitus and insipidus, is acknowledged by all authors to follow as a direct result of mental anxiety or shock. Fagge quotes from Herman Weber the case of a gentleman who became diabetic on two separate occasions, at an interval of nine years, under the pressure of intense anxiety from impending commercial ruin, recovering, on each occasion at a turn in his circumstances. Dr. Lys thinks that cases of diabetes mellitus are rare without some history of mental dis-

¹ Huchard: *Maladies du Coeur et des vaisseaux*, Paris, 1889.

turbance, more or less striking, immediately preceding the attack. Diabetes insipidus is a much rarer disease, but mental shock and emotion are mentioned among its causes. The pathology of both forms is readily referable to vaso-motor dilatation from mental disturbance.

Dr. Lys refers to the fact that granular kidney has, from time to time, been attributed to mental anxiety. Dr. Clifford Allbut has asserted as an undoubted clinical fact that renal cirrhosis is often caused by prolonged mental anxiety; he suggests that the change might be such derangement of the nutrition of the kidney as occurs in the liver in diabetes. Dr. George Johnson, writing afterwards, says that the explanation of this view is that mental anxiety is a cause of dyspepsia, and functional albuminuria often depends upon the excretion of some abnormal products of imperfect digestion; and this has been mistaken for organic Bright's disease. The question whether granular kidney and arterio-capillary fibrosis may not be themselves, primarily, like the cardiac hypertrophy and arteritis deformans associated with them, the result of increased tension, is one which Dr. Lys thinks may still be reasonably entertained.

As for chorea, its pathology seems to be as inexplicable as that of any disease known. There can be no doubt that it is often due to fright, equally irresistible is the evidence which attributes it in some cases to irritation. Dr. Lys thinks that many diseases, as rheumatoid arthritis and phthisis, depend on mental trouble only as one means of failure of general health. Other paroxysmal affections, such as asthma and migraine, undoubtedly often own mental shock as the exciting cause of individual attacks. As for purpura, we can readily credit that increased tension due to mental cause, might be the determining agent in producing hemorrhage. The frequent dependence of amenorrhoea and menorrhagia on mental causes is well known. Alopecia and canities as a result of fright and anxiety are no fiction of the poets.

Dr. Lys asks finally, What is the relation of malignant disease to emotional causes? He feels the want of positive facts here, he can only refer to the conclusions which many who have had the largest experience with disease have arrived at. "Too often," says Sir James Paget, "cancer quickly follows deep anxiety, deferred hope, disappointment." Dr. Murdoch says: "I have been surprised at the frequency with which patients suffering from primary cancer of the liver have traced the commencement of their ill-health to protracted grief or anxiety. The cases have been far too numerous to be accounted for on the supposition that the mental distress and the cancer have been mere coincidences." He quotes Drs. Snow and Erichsen to the same purport.

"It might be thought," says Dr. Lys, "that all the mental trouble did was to lower the general health; but cancer is not observed with anything like the same frequency when the general health is lowered from other causes — such as want. Many cases might be quoted in which the development of cancer has

followed mental trouble in a singularly striking way; but no individual instance can go far in carrying conviction; it is rather the fact that the association is so very constant that carries weight."

MEDICAL NOTES.

TYPHOID FEVER IN CHICAGO. — The number of deaths from typhoid fever in Chicago was high during the past winter, but the rate has gradually decreased since then. There were ninety deaths from this cause during the second week in January, whereas the total for the month of April was only fifty-six.

AMERICAN PEDIATRIC SOCIETY. — At the recent meeting of this Society the following officers were elected for the ensuing year: President, A. D. Blackader, M.D., Montreal; First Vice-President, J. M. Keating, M.D., Colorado Springs; Second Vice-President, C. W. Earle, M.D., Chicago, Ill.; Secretary, S. S. Adams, M.D., Washington, D. C.; Recorder, William P. Watson, M.D., Jersey City; Treasurer, C. W. Townsend, M.D., Boston; Member of Council, T. M. Rotch, M.D., Boston.

PRECAUTIONS TAKEN TO PREVENT EPIDEMICS. — Since the recent outbreak of typhus fever in New York, the health authorities of New York and Boston have cooperated in keeping track, as far as possible, of recently-arrived immigrants. All immigrants arriving in New York, who give Boston as their destination, are entered upon a list which is sent to the Boston Board of Health. This Board is usually able to find these persons and to keep them under observation for some time, so that in case of the appearance of any infectious disease they may be quickly isolated and other necessary precautions taken.

AN ANTI-HOMEOPATHIC PRIZE ESSAY. — Dr. G. M. Gould, of Philadelphia, offers a prize of \$100 for the best essay showing "The Ridiculous Pretensions of Modern Homeopathic Practice." An essay should not contain over 15,000 words, and in simplicity and directness should be adapted to the commonest lay understanding. Papers should be sent Dr. Gould on or before January 1, 1893, type-written, without the name of the author, but accompanied by a sealed letter, giving the author's name with motto or *nom-de-plume*. The essays will be given to a competent committee, and when their decision is reached the sealed letters of the authors will be opened, and the prize sent the winner. The essay will then be cheaply but well printed in large quantities, and supplied physicians at the cost of printing.

NEW JERSEY LAW REGULATING MIDWIFERY. — A law has been passed in New Jersey that every person practising midwifery shall possess a certificate from the State Board of Medical Examiners. All now practising are allowed to obtain a certificate without examination, others must pass such examination as the board shall require. The board may refuse or

revoke certificates for improper conduct or for failure to report births or puerperal fever. No person may advertise as a midwife without a certificate, but any one may give gratuitous service in case of emergency. Legally qualified physicians are not obliged to take out a midwife certificate.

AN OFFICIAL DOSE TABLE.—At a recent meeting of the Académie de Médecine in Paris, Dr. Peltier proposed that the Academy issue a yearly table of the maximum doses of dangerous drugs for different ages, and that a law be advocated that no physician who keeps within the limits of the doses in the list shall be prosecuted for poisoning. If, on the other hand, a dose is prescribed larger than the maximum of the official list, the prescriber does so at his own risk.

POISONING OF A RACE HORSE.—Much sensation has been caused in the racing world in England by the announcement that Orme, a famous thoroughbred colt belonging to the Duke of Westminster, has been poisoned. A large reward was offered by his owner for any information that would lead to the detection of the poisoner. The *Lancet*, after reviewing the symptoms, arrives at the conclusion that they do not warrant a belief that the horse was suffering from anything which could not be attributed to natural causes.

GLANDERS IN GREAT BRITAIN.—It appears that the number of cases of glanders in horses has diminished during the past two years. All cases should now be reported under the contagious disease (animals) act; the annual reports issued by the government show that in 1891, 1,357 outbreaks were reported; in 1890 only 937; while in the previous year there were over 2,000 cases in London alone. Glanders is very much less prevalent than formerly. In the pre-railway days, when horses were so extensively employed in road traffic of all kinds, it was a veritable plague, and there were few stables in which it did not exist. Horses suffering from it were regularly worked, and in the cavalry and artillery corps it was extremely rife. It occasioned great losses in horse establishments, and there can scarcely be a doubt that many people also died from it, though its nature in them was not suspected.

NEW ENGLAND.

MASSACHUSETTS MEDICAL BENEVOLENT SOCIETY.—The Legislature has empowered this society to hold real and personal property up to \$150,000 in value.

THE NEED OF AN ISOLATION HOSPITAL IN LYNN has been noticed during the past few weeks in connection with three or four cases of scarlet fever which have occurred in non-residents of the city.

BEQUESTS.—By the will of the late Dr. Pliny Earle of Northampton, the city will receive \$50,000 to be devoted to the Forbes Library, and the town of Leicester \$6,000 for the erection of a library.

THE HARVARD MEDICAL SCHOOL ASSOCIATION will be glad to send to graduates of the Medical Department of Harvard University, in any part of the

world the catalogue of its members, to which we referred last week. All graduates of the School are eligible to membership in the Association, the object of which is to unite all alumni and to advance the interests of the School and of medicine. The entrance fee and the annual assessment are merely nominal.

NEW YORK.

A COLORED MEDICAL STUDENT.—Dr. William T. Merchant, a colored physician from West Virginia, came on to New York early in April to enter the Post-Graduate Medical School, but, on account of his color, it is said, he was not admitted; and after waiting for a number of weeks he sought the advice of Colonel Robert Ingersoll, who was authorized to take the case into the courts, if necessary. Colonel Ingersoll wrote a letter to Dr. Roosa, the President of the college, and the Faculty have now decided to admit Dr. Merchant.

POLITICAL MEDICAL APPOINTMENTS.—At the same time that Dr. Janeway resigned his professorship at Bellevue Hospital Medical College, he gave up his position as attending physician to Bellevue Hospital and consulting physician to the Board of Health. It is stated that his reason for this action was on account of his dissatisfaction at the partisan course, as he believes, of the Board of Health, in discharging without proper cause Colonel Prentiss, for many years Counsel to the Board, and Dr. Ewing, the Sanitary Superintendent. As Bellevue College, as well as Bellevue Hospital, is to a considerable extent under the control of the municipal authorities, he desired to free himself from all connection with the latter. Dr. H. M. Silver has been appointed Demonstrator of Anatomy at Bellevue in the place of Dr. Briggs, promoted to the professorship of Materia Medica and Therapeutics.

Miscellany.

THE ABUSE OF COCAINE.

NORMAN,¹ in a paper in the *Journal of Mental Science*, on the subject of the cocaine habit, comes to the conclusion that this drug is more insidious than morphine. It fastens upon its victims more readily and its hold is at least as tight. It is treacherous, and easily produces break-down both in the moral and intellectual spheres. It is intensely toxic, bringing about destructive tissue change after a comparatively short period of abuse. In the last respect it differs from alcohol and morphine which may be long indulged in, in considerable quantities, without giving rise to serious structural change. In chronic cocaine poisoning marasmus appears early and develops with extreme rapidity; convulsions are not uncommon; and chronic poisoning in animals produces degeneration of the cells of the medulla and spinal cord, also in the nerve cells of the heart ganglia and in the liver cells. The great danger of cocaine lies in the fact that it is the most agreeable and alluring of all narcotics. It produces little or no headache and nausea, and a pleasant effect is

¹ *Lancet*, May 7.

produced with a comparatively small dose; but toxic symptoms are rapidly developed, and within three months of the commencement of the habit, there may be marked indications of degeneration.

METHYLENE-BLUE IN MALARIA.

In the JOURNAL of March 3d, we referred to some experiments made by Dr. Thayer at the Johns Hopkins Hospital in which apparently striking results were obtained in malaria by the use of methylene-blue. Further trials of this drug have shown that it cannot be considered a substitute for quinine. Dr. Thayer's conclusions are as follows:¹

Methylene-blue has a definite action against malarial fever, accomplishing its end by destroying the specific organism; but it is materially less efficacious than quinine, failing to accomplish its purpose in many cases where quinine acts satisfactorily.

The action appears to be rapid, the chills disappearing or the temperature, in the remittent cases, falling to normal during the first four or five days; but later, however, if a sufficient number of organisms have resisted the drug, they appear to develop again directly under its influence, causing a return of the symptoms.

Methylene-blue seems to have no advantages over quinine which would warrant its further use.

LEPROSY IN MINNESOTA.

DR. CHR. GRONVALD, in a short communication embodying the report of the committee on leprosy of the Minnesota State Board of Health, summarizes the results of that Board in the study and care of leprosy in the State. The disease exists in the State among the Scandinavians from infected localities.

There are medical correspondents everywhere in the State, who report all suspected cases to the State Board of Health, which then makes particular inquiries through its standing committee on leprosy, composed, since 1872, of the author and the Secretary of the Board. In 1891 there are eighteen lepers known to live in Minnesota, of whom ten had the anesthetic and eight the tubercular form of the disease. All known lepers are registered and kept under observation, and all suspected cases carefully looked into. The history of these cases has been very thoroughly studied. No further isolation than the use of their own beds and utensils is required, and this their own good sense and that of their relatives, as a rule, secures. The State Board of Health and the local boards have abundant power to enforce the strictest isolation, if found needful; but there has not been any occasion for the use of such power, as the disease is limited to the immigrants, and has never appeared in the descendants of lepers, nor in any one born in the State. It is under constant and careful observation, and has been for the last eighteen years under the care of the State Board of Health.

Dr. G. A. Hansen, of Bergen, who in 1888 went to the Northwestern States to study leprosy among the Scandinavian immigrants, reported that of about 160 lepers who had immigrated into Wisconsin, Iowa and Minnesota, thirteen were known to be alive; and with perhaps a few exceptions, all the others were dead.

¹ John Hopkins Hospital Bulletin, May.

Of all the descendants of lepers, and this includes the great-grandchildren of some, not a single one became leprosus.

JOHN AMORY JEFFRIES. RESOLUTIONS OF THE BOSTON MEDICO- PSYCHOLOGICAL SOCIETY.

The members of the Boston Medico-Psychological Society recognize, in the death of Dr. John Amory Jeffries, the loss of a valued associate and friend.

Bringing to the study of medicine a mind already trained in biological research, in the few years of his professional life he had made actual additions to medical knowledge, and, with the opportunities that were opening before him, he gave promise of much greater achievements. Medicine has lost one of its zealous and scientific students.

Although neurology was only one of the studies in which he was interested, he had already done work worthy to be compared with his investigations in bacteriology and ornithology. His last work was done for our Society, and we would express not only our personal loss but the loss which the medical profession has sustained by his untimely death.

In expressing our own sorrow at the death of one whose attainments were so high, whose promise was so great, whose zeal was so ardent, and whose friendship was so sincere, the Society would extend its sympathy to his family.

THERAPEUTIC NOTES.

ANTIPYRIN AND THE BACILLUS OF DIPHTHERIA:—Vianna¹ reports a series of experiments of antipyrin upon the Klebs-Löffler bacillus. In the proportion of two and one-half per cent., it prevents their development, and in five per cent. it kills them in twenty-four hours. As well as hindering the growth of the micro-organism, the author believes that it destroys the toxic properties of their products.

HICCOURT AND THE PHRENIC NERVE:—Lelio² reports excellent results in the treatment of hiccough by pressure over the left phrenic nerve. This is not a new method, but in the opinion of the author has not received proper attention. Digital pressure is made as long as is necessary in the interval between the heads of the sterno-cleido-mastoid muscle of the left side.

HYDROCHLORIC ACID FOR VOMITING:—Alkiewicz³ recommends small and frequent doses of hydrochloric acid, well diluted, for the treatment of vomiting due to various causes.

LACTIC ACID AS A PROPHYLACTIC OF GOUT:—Berenger-Ferand⁴ describes this method which has recently attracted attention in France. The patient is given half a drachm of lactic acid a day for three or four weeks. It is taken in one dose in the morning. At the end of this time it is stopped for ten days, and then taken again in the same manner. This is continued for several months or even years.

THE ANESTHETIC PROPERTIES OF COCAINE:—Bignon⁵ calls attention to the fact that cocaine, in slightly acid solutions, loses much of its anesthetic property, but this is entirely restored by neutralizing the acid. The maximum intensity of cocaine as an anesthetic occurs when the alkaloid is suspended in a

¹ Bulletin Médical, March 30th.

² Acad. des Sciences.

³ Nowiny Lekarskie.

⁴ Bull. Gen. de Therap., December 30th.

⁵ Bull. Gen. de Therap., 1891, 170.

slightly alkaline solution. This may be accomplished by the use of carbonate of sodium, but this must be added at the time when it is used, otherwise the cocaine in suspension will collect at the bottom of the bottle and cannot easily be suspended again.

INFLUENCE OF PURGATIVES ON BILE. — Lowenstein⁶ finds that aloes, rhubarb, cathartic acid, jalap, gamboge and podophyllotoxin do not increase the secretion of bile if given in large doses. Absence of bile in the intestine lessens the purgative effects of the last three drugs, and increases the effects of aloes and rhubarb.

TO MEASURE THE CAPACITY OF THE STOMACH. — Forlanini⁷ measures the capacity of the stomach by passing a sound and distending the organ with air introduced at a known pressure, about seven centimetres of water. The air is then withdrawn and its volume measured. By this method the result of treatment can be definitely ascertained.

Correspondence.

VIRGINIA MEDICAL LAW.

We have received the following letter from the Secretary of the Medical Examining Board of Virginia, in regard to our note on the Virginia Medical Law which we corrected in the issue of May 12th :

MR. EDITOR: — A quack from your city was recently prosecuted by the Medical Examining Board of Virginia, in the Hustings Court of this city, for practising without complying with the "law regulating the practice of medicine and surgery in Virginia."

The case was decided against the Board upon the ground that the law was defective in that it failed to make specific provision for the registration of certificates of non-residents. The Court distinctly affirmed the constitutionality of the law in a letter to the President of the Board, setting forth the basis and scope of the decision. I quote the letter (Judge S. B. Wills) above alluded to, bearing date of 14th April, 1892.

"(1) I decided that the Legislature of the State has a right to pass laws regulating the practice of medicine in this State. Such a law comes clearly within the police power of the States.

"(2) That the Legislature has a right to require non-residents to comply with the terms upon which it allows citizens of our own State to practice (129 U. S., Dent v. West Virginia).

"(3) That the Legislature, not having provided a place where the non-resident physician may record the certificate required by law as a prerequisite to obtaining a license for practising medicine, etc., has imposed upon him a condition which it is impossible for him to perform, and therefore, discriminates against him — such a condition amounting, in fact, to prohibition."

Such is the basis of this decision, and it cannot possibly apply in any other jurisdiction than that of the city of Richmond.

Some of the ablest lawyers of Virginia state that they believe the decision would be reversed by the higher courts.

This decision only applies to transients, and the law remains in full force with the single exception.

Very truly yours,

JACOB MICHAUX, M.D.,
Secretary of Board of Medical Examiners of Virginia.

⁶ Bull. Gén. Théráp., November 15, 1891.

⁷ Rif. Med., October 24, 1891.

A MEDICAL DIRECTORY HUMBUG.

BOSTON, May 23, 1892.

MR. EDITOR: — A man is now going about this city ostensibly delivering some sort of a medical "Directory," and presenting an order blank for the same, bearing the ostensible signature of the physician. Attached to the same blank is the professional or visiting card of the physician called upon.

Careful examination of the slip shows that the price to be paid was two dollars, while this sum has been obliterated and in one corner of the slip the cost is \$2.50 or \$3.00. The sum to be collected has therefore been "raised" to this degree.

Yours truly, B.

DANTE REPORTS A CASE.

BOSTON, May 21, 1892.

MR. EDITOR: — Bandoni's case of the man with the remarkable anus, cited in the JOURNAL of May 19, is not without a precedent, albeit a bad one. In the "Divine Comedy" we read of Barbariccia, leader of a band of demons:

"Egli avea del cul fatto trombetta. . . .
Nè già con si diverse cannella
Cavalier vidi muover, nè pedoni,
Nè nave a segno di terra o di stella."

"He had made a trumpet of his rump. . . .
But never yet with bagpipe so uncooth
Did I see horsemen move, nor infantry,
Nor ship by any sign of land or star."

K.

Deaths reported 2,968; under five years of age 1,094; principal infectious diseases (small-pox, measles, diphtheria and croup,

diarrhoeal diseases, whooping-cough, erysipelas and fevers) 433, acute lung disease 517, consumption 343, diphtheria and croup 143, scarlet fever 80, diarrhoeal diseases 60, measles 45, typhoid fever 10, malarial meningitis 10, whooping-cough 15, fever per se 12, erysipelas 8, malarial fever 5, small-pox 2.

From measles New York 36, Chicago 5, Milwaukee 2, Cleveland and Pittsburgh 1 each. From typhoid fever Chicago 16, Pittsburgh 11, Philadelphia 8, New York, Boston and Washington 2 each, St. Louis, Lowell and Cambridge 1 each. From cerebro-spinal meningitis New York 7, Worcester 4, Lynn 3, Washington 2, Chicago, Boston, and Cleveland, 1 each. From whooping-cough New York 7, Chicago, Philadelphia and Milwaukee 2 each, New Bedford and Malden 1 each. From erysipelas New York 2, Chicago, St. Louis, Boston, Cleveland, Milwaukee and Washington 1 each. From small-pox New York 2.

In the twenty-eight greater towns of England and Wales with an estimated population of 10,188,449, for the week ending May 7th, the death-rate was 19.7. Deaths reported 3,841; acute diseases of the respiratory organs (London) 297, measles 237, whooping-cough 152, diphtheria 43, scarlet fever 42, diarrhoea 41, fever 25.

The death-rates ranged from 14.3 in Halifax to 28.3 in Sunderland; Birmingham 19.0, Bradford 18.5, Croydon 17.2, Leeds 19.2, Liverpool 24.2, London 18.9, Manchester 18.4, Nottingham 16.0, Portsmouth 19.5, Sheffield 22.8, West Ham 17.3, Wolverhampton 18.7.

METEOROLOGICAL RECORD.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICES SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 14, 1892, TO MAY 20, 1892.

A board of medical officers to consist of Lieut.-Col. WILLIAM H. FOREWORD, surgeon; Major JOSEPH R. GIBSON, surgeon; Captain HENRY S. TURNER, assistant surgeon, is appointed to meet at West Point, New York, June 1, 1892, or as soon thereafter as practicable for the physical examination of the cadets of the graduating class at the U. S. Military Academy and such other cadets of the academy and candidates for admission thereto as may be ordered before it.

The leave of absence granted MAJOR JAMES P. KIMBALL, surgeon, U. S. A., is extended one month.

Leave of absence for two months to take effect June 25, 1892, or as soon thereafter as his services can be spared, is granted FIRST-LIEUT. HENRY A. SHAW, assistant surgeon, U. S. A.

WILLIAM N. SUTER, assistant surgeon, U. S. A., to be assistant surgeon, with the rank of Captain, May 16, 1892, after five years' service in accordance with the Act of June 23, 1874.

FIRST-LIEUT. THEODORE F. DEWITT, assistant surgeon, U. S. A., resigned May 16, 1892.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 21, 1892.

S. W. HORWITZ, medical director (retired), granted six months' leave to go abroad.

P. A. LOVINGER, surgeon, detached from U. S. S. "Philadelphia" and granted two months' leave of absence.

R. P. CRANDALL, passed assistant surgeon, detached from the Naval Laboratory, Brooklyn, N. Y., and to the U. S. S. "Philadelphia."

E. S. BOGERT, Jr., assistant surgeon, detached from C. S. S. "Blake" and to the Naval Laboratory, Brooklyn, N. Y.

J. A. GUTHRIE, assistant surgeon, detached from Port Royal Station, S. C., and to C. S. S. "Blake."

H. C. ECKSTEIN, surgeon, granted leave of absence for six months.

MASSACHUSETTS MEDICAL SOCIETY.

ONE HUNDRED AND ELEVENTH ANNIVERSARY.

Meetings will be held in the building of the Massachusetts Charitable Mechanic Association, on Huntington Avenue, Boston.

TUESDAY, JUNE 7, 1892.

Section in Medicine, 2 p. m.—"The Relations of Bacteria to Influenza," by Dr. Henry Jackson, of Boston. "Pneumonia in the Recent Epidemics" by Dr. W. E. Fay, of Boston. "The Nervous and Mental Sequels of Influenza," by Dr. P. C. Knapp, of Boston. "A Revision of the Medical Nomenclature Employed in the Vital Statistics of Massachusetts," by Dr. S. W. Abbott, of Wakefield. Drs. R. H. Fitz, C. F. Folsom, A. L. Mason, J. H. McCollom, J. J. Minot, F. C. Shattuck, G. B. Shattuck, will take part in the discussions.

Section in Surgery, 2 p. m.—"Pathological and Clinical Investigations into the new Antiseptic Dermatol," by Dr. A. K. Stone, of Boston. "The Diagnosis and Treatment of Fott's Fracture of the Ankle," by Dr. L. A. Stinson, of New York City. Discussion by Dr. H. L. Burrell and others. "Acute Intestinal Obstruction: The Symptoms and Diagnosis," by Dr. F. C. Shattuck; "The Surgical Aspects," by Drs. John Homans, J. C. Warren, G. W. Gay, M. H. Richardson, J. C. Irish, A. T. Cabot.

Section in Obstetrics and Gynecology, 2 p. m.—"Résumé of 100 Cases at the Knowles Maternity, Worcester," by Dr. G. O. Ward, of Worcester. "Alexander's Operation," by Dr. W. M. Conant, of Boston. "Hydatidiform Moles," by Dr. G. A. Craigen, of Boston. "The Treatment of Inflammatory Diseases of the Fallopian Tubes, with Cases," by Dr. Edward Reynolds, of Boston.

The Shattuck Lecture, 8 p. m., by J. F. Alleyne Adams, M.D., of Pittsfield.

WEDNESDAY, JUNE 8, 1892.

At 9 a. m.—"The General Practitioner as a Gynecologist," by Dr. W. H. Pierce, of Bernardston. "An Outbreak of Trichinosis in Colorado," by Dr. F. H. Drew, of Shelburne Falls. "The Treatment of Compound Fractures by Modern Methods, with a demonstration of 'putting up' adapted to private practice," by Drs. H. L. Burrell and E. W. Dwight, of Boston.

The Annual Discourse, 12 p. m., by Frank W. Draper, M.D., of Pittsfield.

RHODE ISLAND MEDICAL SOCIETY ANNUAL MEETING.

The eighty-first annual meeting of the Rhode Island Medical Society will be held in Tillinghast's Assembly Rooms, 223 Westminster Street, Providence, on Thursday, June 2, 1892, at 10 o'clock, a. m. The Annual Address by the President, Dr. William H. Palmer, at 12:30. The annual dinner will be served in the adjacent hall, the Trocadero, following adjournment. Dinner tickets can be obtained of the Treasurer, Dr. George L. Collins. W. R. WHITE, M.D., Recording Secretary.

REDUCED RATE TO DETROIT.

The Boston and Albany Railroad will make rate of fare and one-third on the certificate plan from all coupon ticket stations to Detroit and return on account of the meeting of the American Medical Association. Tickets giving purchasers the benefit of reduction may be purchased June 3d to 7th inclusive. The rate per berth in sleeping car from Boston to Detroit is \$4.50. For sleeping-car reservations and full information in relation to train service, etc., address J. L. White, City Passenger Agent, 232, Washington Street, or A. S. Hanson, General Passenger Agent, Boston, Mass.

RECENT DEATHS.

JOHN MESSENGER, M.D., died in New York, on May 19th, at the age of seventy-three. He was born in Vermont and graduated from the College of Physicians and Surgeons, New York, in 1852.

MYRON N. BARCOCK, M.D., of Saratoga Springs, N. Y., died May 21st, aged seventy-three.

ALVIN JENKINS, M.D., M.M.S.S., died in Great Falls, N. H., May 3, 1892, aged seventy-nine.

WILHELM BRAUNE, M.D., Professor of Anatomy in the University of Leipzig, died April 29th.

Original Articles.

SOME OF THE RECENT ADVANCES IN BACTERIOLOGY.¹

BY H. C. ERNST, M.D.,

Assistant Professor of Bacteriology, Harvard Medical School.

THE amount of time that has been devoted to the solution of the various problems presented by our increasing knowledge of the micro-organisms is easily accounted for by a glance at what the development of this knowledge seems to promise. In the first place, the theories that are the result of the work already done, furnish what appears to many to be, the first rational explanation of what the infectious diseases are, how they are propagated, and suggest many ways by which they can be combated.

Theory, inference, and experiment all show with apparent conclusiveness that the micro-organisms are concerned in the production of many, if not all, of the infectious diseases. To deny such a conclusion at the present time, is to deny the power of the logical sequence of events to prove a case, and such a denial is nowhere, I believe, seriously attempted by any with sufficient training to speak with authority.

In searching for an explanation as to how the bacteria accomplish the results that are daily seen to be the result of their growth, these are the methods usually accepted: (1) By mechanical action; that is to say, the growth of the invading organisms to such an extent, and with such rapidity, as to block up or cut off the natural channels of communication with the affected part. Such an effect may be seen in many of the preparations from parts attacked by the bacillus of anthrax. (2) By such vigorous growth and strength of attractive power as to appropriate to themselves, and take away from the tissue-cells, the nutrition intended for the latter; as a result, producing a destruction of the tissue-cells by the process called necrosis. This effect is seen as the finish of the change in tuberculosis. (3) By the production, either directly, or by the combination of the elements remaining after the bacteria have taken what may be necessary for their development, of new basic compounds that play an exceedingly important part in the production of the harmful effects of disease, or, as is becoming more evident every day, in guarding the system from further invasion and protecting it from a future attack of the same disease.

It cannot be said that we have yet come to understand the action of these new compounds; but certainly a beginning has been made, and it is to some of these beginnings and the results that seem to be promised that I wish to call attention.

The general knowledge already obtained has taught an almost inestimable amount of important fact to the scientific mind, and has put preventive medicine upon a sound basis that has not belonged to it before. It may almost be said that if the knowledge we already have might be universally and intelligently applied, the problem of stamping out infectious disease would be solved; but such an application is impossible for many reasons, and it probably never will be so. It is not possible so to appeal to the average mind, that the isolation and strict treatment of a dear friend, even suffering from an acknowledged infectious disease, will

be allowed or bearable, and it is necessary, therefore, to search for something more.

This further advance has been in the minds of all those connected with the later methods of experimentation, and lies in the direction of attempts to prevent the appearance of the symptoms of an infectious disease after exposure to its virus or the arrest and cure of those symptoms after they have made their appearance.

Such attempts have, of course, been made from the time when medicine began, but have met with the smallest amount of success, so far as the use of drugs, as the term is commonly used, is concerned. The first efforts, with a knowledge of the bacteria and their action as a basis, were those in which the attempt was made to secure the attenuation of the virus of the disease, and then applying this modified virus in an attack against the full disease. The idea underlying this is the substitution of a disease of a milder type for that of the full strength, the attack of the milder form being supposed to protect the system against the virulent. This effort had been successfully carried out for years in the common vaccination against small-pox, in which case a disease of a similar type (cow-pox) is substituted for the far more fatal and disfiguring one of small-pox. Nature furnished the milder form of the disease, and the virulent as well, and accident showed the proper method of combining them; in the series of experiments of which I now speak, Nature also furnished the virulent disease, but it has been sought to *create* a milder type that would afford protection against the stronger.

Such attempts have been carried on with much enthusiasm, and with, at least, partial success in such diseases as anthrax (called malignant pustule in man) and rabies. They represent the direction in which the efforts of Pasteur and his followers were earliest turned; and the success obtained, together with the facts revealed in regard to disease, urges their continuance. They have not thus far, however, seemed to define any general principle upon which further work may be based, nor do their results seem to serve for a foundation for reasoning, except in regard to the individual case that the experiments cover.

The further development of our knowledge has led to experiments in a different direction; and, as a result of these, came the application of Koch's remedy, tuberculin, the work with which made so much excitement during the last year. This material is obtained from a different source, and illustrates a different principle from any of the preceding. It is the product of growth — not of the bacilli themselves — and consists essentially of the nutrient material in which the bacteria have grown, freed by filtration from the bacteria, but containing all the new elements that have resulted from their growth. The unfortunate necessity for a premature trial of this material has clouded the results and prejudiced the judgment of many observers so that its true value is not yet by any means worked out.

So far as actual cure of the disease against which it is directed, little has been accomplished by its use; which is not surprising when we remember that, as used, it was in its crudest form and made up of many ingredients the nature of which is but just becoming recognized. There are many points in regard to it still to be worked out; the hurtful ingredients are to be separated, and the healing agency, if present, to be isolated and tried, before this method of reaching the

¹ Read before the Boston Society of Natural History.

end in view is to be thrown aside as useless. As it is, there seems to be strong reason to feel that it may serve as a valuable aid to diagnosis in the early stages of the disease, especially in cattle,² as a recent writer points out after a complete review of all the reported experiments in this particular direction; and it certainly appears from the more recent records that a certain amount of definite good has been accomplished in the actual treatment of tuberculosis with it.

The employment of this material illustrates the second method by means of which it has been sought to secure curative effects in infectious disease; that is, by the application of the products of bacterial growth in the laboratory, to the destruction of the organisms that produced them, or at least to the arrest of the development of these organisms.

But certain facts shown by experiment several years ago, and constantly developed since that time, have put inquiries upon a new track, one which forms the third branch of the inquiry, and that seems to promise much as the result of its intelligent following out.

It is upon these facts that the newer theories in regard to immunity depend, and it is to the application of what is learned in forming these theories to the treatment of disease that especial interest lies.

It is a long time since the theory that immunity might be due to the presence of a deterrent substance in the blood entered the minds of scientific men,—this substance being something that would prevent the growth of the invading bacteria,—but it has been an exceedingly difficult matter to secure evidence upon such an important point. The first experimental researches were negative (Grawitz and Gamaleia); but, in 1884, Grohmann showed that fresh serum exerted an attenuating influence upon the bacilli of symptomatic anthrax; Fodor found that fresh blood destroyed them; while Nuttall established the fact that organic fluids (like serum, aqueous humor, pericardial fluid), really possessed the power of destroying bacteria, and that this germicidal action was taken away by raising these fluids to a temperature of above 50° C. Buchner showed that this power rested solely in the serum, and that the breaking up or mixing in of the blood-corpuscles masked or diminished its activity. He also showed that repeated freezing divided the serum into layers of which the lowest was the most active against bacteria; that this power of the serum is destroyed if diluted with distilled water or if it be dialyzed against it. After Buchner, the most important work has been done by Ogata and Iasuhara, and Behring and Kitasato in showing the great influence of the fluid portions of the animal tissues in the acquisition of immunity. According to the work of these authors, immunity is due to the action of albuminoid substances, called by Hankin, defensive proteids, which have the power of destroying pathogenic bacteria, of attenuating them, and of destroying their toxic products.

It is necessary that one should have a clear idea of these defensive proteids to understand what extreme importance is to be attached to their discovery and the prosecution of researches upon them.

First, in regard to "germicidal proteids." Certain animals have in their blood and the other fluids of the body substances endowed with a very considerable germicidal action; and an example that has been better studied than some others is found in the blood of the white rat. These animals are refractory to inocu-

lation with anthrax, and the reason for this immunity so virulent a disease has been found (Behring), to exist in the fact that the animal's blood-serum destroys the bacterium. By comparative tests, it was shown that two and a half cubic centimetres of rat's serum would have the same germicidal action as would the same quantity of corrosive sublimate in the strength of 1 to 1,000, or of carbolic acid 1 to 50. To appreciate this, it is necessary to consider another quality, the toxic action of these materials upon the animals; when it appears that the sublimate and carbolic acid will kill the animal in a dose five to seven times smaller than is necessary to secure their germicidal action and cannot therefore be thought of for internal antisepsis, whilst the germicidal protein is present in quantity sufficient for its perfect activity in the serum of the perfectly healthy white rat. This is the most striking and valuable property of these defensive proteids,—that they are the least toxic of all germicides known, leading up to the far more important fact that it seems possible to employ them in active measures for the treatment and cure of infectious disease.

Many points are still to be made out; for instance such an apparent contradiction as that the serum's germicidal power does not in all cases correspond with the natural immunity of the animal that furnishes the serum, but thus far investigation has only served to show that these apparent discrepancies can be easily explained.

The second class of these proteids is made up of the "attenuating" varieties, the existence of which was first suggested by the fact that the bacteria of symptomatic anthrax were attenuated in virulence when injected into animals refractory to the disease, at the same time that their vitality was not interfered with. It is to the work of Ogata and Iasuhara that we owe the first experimental determination that this attenuating property lay in the serum of the animals experimented upon, and not elsewhere. Such an attenuating action upon bacteria would explain very naturally the immunity of the animals in whose blood it was found; and the authors by further experiment showed that this property remained to the serum *after* its removal from the body of the animal in which it was formed, and could be made to serve as a retarding influence, and even as a curative agent, in animals inoculated with true anthrax.

The existence of these attenuating proteids has been confirmed by other observers in the case of anthrax and in other diseases, and the establishment of the facts would be exceedingly important if this were all; but further research has shown the existence of a third class of these proteids. We know now, not only that there are germicidal and attenuating, but also "antitoxic proteids"; and their discovery is the most important of all. The former classes act directly upon the bacteria themselves,—either by actually destroying them or by so limiting their development in the animal body that their growth becomes a matter of slight moment as affecting the health of the individual attacked.

The first announcement of results in this direction was made by Behring and Kitasato, in 1890, at the time of the excitement in regard to tuberculin, and was so overshadowed by this excitement that their true importance was but tardily recognized. They had found that the blood of rabbits protected against tetanus had the power of destroying the toxic alkaloid of teta-

² See Eber's article, *Cent. f. Bact.*, 1892, p. 263.

nus, tetanin, in the lifetime of the animal attacked, and that by the application of this fact it was not only possible to protect an animal against an inoculation of the tetanus bacilli, but also to cure it after this inoculation and the appearance of the symptoms of the disease.

The importance of such results, especially as they have been repeated and confirmed by independent observers, can hardly be overestimated. They mean an absolute revolution in our ideas, and a possibility of reaching the long-sought goal, — the successful treatment of diseases that have heretofore compelled the attendant to stand helpless before their progress.

Almost in the same week with the announcements of Behring and Kitasato with reference to tetanus, came those of Frenkel and Brieger upon diphtheria. Tizzoni and Cattari have completely confirmed the work upon tetanus; and, if later reports can be trusted, the method of cure has been successfully applied in man in six cases of tetanus (lock-jaw) that there is no reason to suppose would have terminated otherwise than fatally, as such cases almost invariably do.

Similar results have been obtained in animals in the case of some of the suppurative bacteria,— in anthrax, in swine-erysipelas; and the variety and extent to which experiment must go in the elucidation of the points brought up by these new facts is almost unlimited. At the same time, there is more reason than ever to feel that investigation is upon the right track, and that finally the promise that now looks so fair, will be fulfilled, and that there will be means secured at last for the successful combating of the effects of the most virulent of the diseases of modern times. For, as will be readily seen, we have at last caught sight of materials, effective for the destruction of the bacteria or their toxic products, that at the same time will leave the animal tissues unharmed after their application. Thus far, we have been able to employ for such a purpose, only materials that were in themselves destructive to the vital organism, and the remedy when effectively employed has been worse than the disease.

THE THIRD YEAR OF THE INFLUENZA EPIDEMIC.²

BY J. H. AYER, M.D.

I FEEL that no apology is needed for presenting the often-discussed subject of influenza believing that every contribution of facts *made at the time*, which a discussion brings out may be of value to us and to future students of the epidemic.

We are grateful to Dr. Rush for his description of the epidemic as he saw it in Philadelphia a century ago; and we regret that his contemporaries did not write out their experiences for our benefit.

Dr. Rush stated that epidemic influenza visited Philadelphia in the autumn of 1789 and lasted six weeks. It relapsed in April, 1790, but less severely, and remained till the early part of June. It finally disappeared the following winter in the form of a mild relapse.

Now, a century later, it had been predicted by the profession as well as the laity that a reappearance of epidemic influenza in this — the third year — would not be a serious matter. On the contrary, however,

its course has been severe, and it has proved disastrous in many of our homes.

Influenza, in this neighborhood, became epidemic about December 20, 1889, lasting more than seven weeks. It relapsed about January 1, 1891, and continued till the early part of June. The present relapse began early in December, 1891. Since the middle of February there have been very few new cases, but yet in March, there was still sufficient evidence of its presence in our midst.

The mortality statements of the city of Boston show that the first attack was most fatal between December 28, 1889, and January 18, 1890; the second attack was most dangerous to life in May, 1891; the third attack (the present relapse) showed the greatest number of deaths between December 6, 1891, and January 30, 1892.

The disease has not been entirely absent from our midst (in all probability), since December, 1889, although for successive months sporadic cases only have been present.

What have been the characteristics of the different attacks?

In past epidemics of influenza, the symptoms have been dissimilar. Dr. Rush, in his account, says: "It was remarkable that those who had the disease chiefly in the breast last year, complain now chiefly of their heads; while those whose heads were affected formerly, now complain of their breasts."

The epidemic, as we have seen it, has shown a diversity in the relative importance of the neuro-muscular, respiratory and gastric symptoms in the different attacks.

The first attack was pandemic and acute. The analysis made by Dr. Clouston showing that 97 per cent. suffered from neuro-muscular symptoms, 77 per cent. from respiratory symptoms, and 55 per cent. from alimentary symptoms was perhaps applicable to cases in this vicinity; the neuro-muscular symptoms being the most prominent and causing most suffering.

The second attack, which came in the form of a relapse a year ago, did not attack the whole community at once, but occupied more time in seeking out its portion. There was perhaps no alteration in the proportion of the three classes of symptoms, for the neuro-muscular type was still the prominent one, but its symptoms were less acute and more prolonged. The depression of the nervous system and the accompanying and subsequent exhaustion were the marked features at this time. Neuroasthenia, with depression of spirits, apprehensiveness and mental instability stood out in such broad relief in cases noticed last spring that many German authors described influenza as a *Nervenkrankung*.

The present attack (second relapse), which started at the beginning of the third year, has been marked by increased importance of the respiratory symptoms. My notes of patients who have recently undergone a second or third attack show a decided change in type. It seems to me that the respiratory symptoms are now relatively more prominent than neuro-muscular symptoms have been in the past.

We will briefly consider the symptoms of the present attack:

(1) *Neuro-Muscular Symptoms.* — Very few patients have suffered from influenza this year without being conscious of muscular and neuralgic pain. Migraine, sciatica, lumbago, and pleurodynia have been com-

¹ Read before the Boston Society for Medical Observation, March 7, 1892.

mon; delirium, meningitis, and a tendency to the psychoses have not been entirely absent, but, on the whole, the nerve symptoms have not been sufficiently severe to impress the observer with the theory that influenza now is essentially a "nerve disease."

There has been less depression of spirits and less worry. The apprehensiveness I have seen this year has not been an unmixed evil, as it has caused patients to take proper care of themselves, and to follow implicitly the physician's advice regarding confinement to the house.

Irregularity of the heart's action of nervous origin has, perhaps, been more prominent this season, and also spasmodic cough, which will be mentioned later.

Again, this year, I have noticed a tendency to persistent localized pain from very slight accidents.

(2) *Respiratory Symptoms.* — We feel that catarrhal irritation of the upper air passages has been the most prevalent form, although from the middle of December to the end of January it seemed almost impossible among the elderly and debilitated to keep the catarrhal trouble from extending to the lungs, and there were at that time numerous cases of acute bronchitis and pneumonia, dangerous from the outset.

The symptoms in the majority of cases, however, has been those of laryngitis, tonsillitis, and bronchial catarrh. I have seen less extension of catarrhal symptoms to the middle ear or to the nasal fossae. Hoarseness of several days' duration, the feeling that there is a "lump in the throat" causing slight dyspnoea, and a harsh, hacking, spasmodic cough have been the causes of frequent complaint.

As with this cough, one rarely finds important signs in the chest on physical examination, it is necessary to consider these symptoms as partly catarrhal and partly nervous in character. I saw a marked case of neuro-respiratory symptoms early in the present relapse, where there was "constriction of the chest" coming on suddenly, and often waking the patient out of a sound sleep with dyspnoea and spasmodic cough.

(3) *Alimentary Symptoms.* — In looking over my cases I have been surprised to find how little prominence has been shown by gastro-intestinal symptoms of late. In very few cases was vomiting present at the outset, and with only one patient was gastric irritability the most prominent symptom throughout the attack, and here I suspected the existence of organic disease of the stomach. In several cases, however, there was bilious vomiting during some portion of the attack.

Intestinal diarrhoea was noted in a few cases only, and in none was it an important symptom.

I feel that the relative importance of symptoms connected with the digestive canal has been much diminished of late.

Immunity. — There seems to be no rule as to the susceptibility to repeated attacks. The majority of the members of this community have not suffered from three distinct attacks of epidemic influenza, and a goodly number have never been affected.

Susceptibility of Age and Sex. — Elderly people, although they have suffered more severely from the effects of this year's epidemic, may not necessarily have been attacked in larger proportion than in preceding years. In a home for aged people in this city all the inmates, twenty-one in number, were attacked last spring, thirteen of them severely, but all but three escaped this year's attack.

Foreign writers have stated, that a larger proportion of children have suffered from influenza during the present season. It does not seem to me that this has been the case in this neighborhood, although sixteen deaths from influenza under the age of five years have been reported during the last three months in this city.

It has also been stated, that a much larger proportion of women has been attacked during the present relapse, and the mortality-rates of the city would seem to confirm this statement. I think I have seen a like number of cases in both sexes.

Ruhemann, in Berlin, makes the statement that those whose occupations obliged them to be in the open air — soldiers, letter-carriers, policemen, firemen and doctors — were more susceptible the first year; but that now a much larger proportion of those with indoor occupations (especially women), are affected.

Febrile Disturbances. — Probably few cases of late have been ushered in by a well-marked chill, but chilly sensations lasting several days have been frequently noted. High temperatures at the outset have not been common except with acute lung trouble. A temperature of 106.2° was noted in one case at the very outset, which proved fatal in thirteen hours, from pulmonary congestion. In most cases of late, the thermometer has been principally valuable in indicating the new phases in the progress of the case.

Suddenness. — Unlike the epidemic attack of two years ago it has been rare for severe symptoms to appear at the onset. We have seen very few patients suddenly struck down by the epidemic. Convulsions have been rare at the outset.

Eruptions. — Probably there has been less erythema, erysipelas, and herpes zoster than in previous attacks. Authors have referred to the puzzling difficulty in making an early diagnosis between some cases of influenza and scarlet fever. I saw recently a very irritable child suffering from influenza with severe throat symptoms, where there was at times a suspicious redness of the skin, which, however, was found to disappear when the child could be examined in sleep.

Chronic Cases of Influenza. — *Origin have not necessarily been unfavorably influenced by the recent relapse.* — I can mention, in proof, a severe case of neurasthenia and sciatica, of over two years' standing, where the greatest gain has been made during the past season.

I see frequently a patient who has suffered severely with muscular and articular rheumatism since he was taken down with influenza December 25, 1889, but who has improved more rapidly during the past winter than in any time during the past two years.

A patient with albuminuria following painful influenza of the neuro-muscular type has been under my observation twenty-two months. His debility and prostration have left him, and he is able to work, as a jig-sawer, his full time daily; but the urine still contains a trace of albumin and a few casts and occasionally a decided trace of sugar. He has no symptoms of kidney disease, and during the past winter has been as well and as strong as ever.

These three patients were all of middle age and were not attacked by the recent relapse of influenza.

Recurrence and Persistence of Symptoms. — There has been a marked tendency to recurrence, and we have never felt certain that the disease has taken

its farewell of the patient. There has been so much exhaustion that progress, when uninterrupted, has been very slow — especially in elderly and feeble patients. Many patients have sent for their physician merely to ask, "Why don't I improve more rapidly?" but the delay in recovery does not seem to depress them so much as it did last year, and they are not unhappy, when they are told they must be content, with a slight gain from week to week.

Prognosis, like everything else connected with influenza, has been uncertain. Many of my cases have turned out unexpectedly well, the danger which seemed imminent from threatening cardiac failures and intense prostration having generally been overrated.

In Regard to Treatment, I wish to say but one word — in favor of oxygen in the acute pulmonary affections of the asthmatic type.

OPERATIVE TREATMENT FOR THE RELIEF OF CHRONIC SUPPURATIVE AFFECTIONS OF THE MIDDLE EAR: REPORT OF THREE CASES.¹

BY FREDERICK L. JACK, M.D.,
Assistant Aural Surgeon, Massachusetts Charitable Eye and Ear Infirmary.

CHRONIC suppurative inflammation of the attic of the tympanic cavity may justly be considered a serious trouble. Especially is this true if the disease begins during childhood and continues for a long period. In many instances caries of one or more of the ossicles, is present, with or without disease of the bony walls of the attic, and the small space in the cavity is crowded with granulation-tissue or polypoid growths, causing defective drainage and consequently retention of septic matter. Exacerbations are in many cases frequent, and at these times the possibility of extension of the middle ear inflammation to the meninges of the brain or mastoid antrum in a constant source of danger. In the majority of instances the hearing power is practically gone, but a point of far greater importance is the danger to life itself. Indeed, a fatal termination is to be expected in a considerable number of these cases. In the light of what has been demonstrated within a few years, and realizing the possible effect of neglecting or ineffectually treating such a trouble, does it not seem somewhat surprising that the disease is allowed to progress unchecked when surgical interference has proved very successful in the majority of instances? The result of the operation has been either rapid cure or at least such improvement as to make the disease amenable to after-treatment.

I desire, therefore, to call attention to what has been done in aural surgery towards the relief of this class of almost hopeless cases. I believe it to be of general interest, for the rule of procedure is the common-sense surgical one of removing diseased bone or whatever obstruction is found to free drainage.

As far back as 1877, Dr. Kessel, of Jena, published the report of a case in which he removed the drum membrane, malleus, incus and stapes.² He cited this case to show that the ossicles could be removed without danger. As to the pathology of the affection, Professor S. Moos, of Heidelberg, is of the opinion that the hammer is most frequently affected, and that often before caries can attack the anvil, it is exfoliated,

being loosely held in place by the adjoining ossicles and tissues. The stapes is most rarely affected. He further states that he has never observed or seen described a case of primary caries of these bones; that the mucous membrane must first be diseased before caries can attack the ossicles.³

On July 20, 1886, Dr. Samuel Sexton, of New York, in a paper read before the annual meeting of the American Otological Society, described "A New Operation for the Radical Cure of Chronic Purulent Inflammation of the Middle Ear Tract." Previous to that, a paper written by Dr. Schwartz, in 1885⁴ gives a résumé of the literature of operations on the transmitting mechanism of the ear. Since that time the application of this line of surgery has developed very rapidly.

I have endeavored to summarize the results in the few recorded cases since Schwartz's paper in 1885; and I add the report of three cases operated upon by myself for chronic suppuration of the middle ear.

In 1887 Dr. Sexton reported nineteen cases of this disease, with results as follows: In five cases a cure took place in less than one month; in two cases, in two months; in two cases, in three months; in one case, in six months. In five cases, still under observation, there was slight improvement; in three cases still under observation, there was no improvement; in one case the treatment was not continued. He does not mention in any case the duration of the otorrhoea, except in a general way, that it had long continued. The malleus alone was removed in six cases and the malleus and incus in ten. He estimated that the hearing power was increased from 75 to 100 per cent. in the cases cured.

Dr. Burnett, of Philadelphia, before the American Otological Society last July, reported a case of seven years' duration in which he excised the drum membrane and malleus. In thirteen days the discharge from the ear ceased. Three months from the time of the operation a cicatricial membrane was found over the promontory. No discharge. Hearing increased from nothing to whispered words at fifteen feet.

In my search for information as to the frequency of purulent inflammation of the superior portion of the tympanic cavity, I found, in a paper by Dr. Alexander Randal, of Philadelphia, "Notes on the Shrapnell Perforation,"⁵ a total of 120 cases among ten thousand patients — somewhat small number. If, however, to this number is added those cases with perforation of the drum membrane, my impression is that the number would be largely increased.

From 1885 to 1890 inclusive, there were treated at the Massachusetts Charitable Eye and Ear Infirmary for chronic purulent middle ear disease 3,795 cases out of 21,818 patients applying for treatment. Among 8,337 of all cases seen in the last two years, from 1889 to 1890 inclusive, there were noted 1,020 patients with chronic purulent trouble, and of these 94 cases of perforation of the fiscid membrane, — almost 10 in every 100 cases. This is practically the same ratio per thousand for all ear patients as that reported by Dr. Randall, and illustrates the relative frequency of this affection in suppurative middle ear disease.

Although without statistics to substantiate any fig-

¹ Archives of Otol., March, 1885.

² Deutsche Chirurgie, Stuttgart.

³ In two of these cases suppurative inflammation seemed to continue in one because of caries of the anvil, and in the other in consequence of the retention of the incus which could not be found.

⁴ American Otological Society, 1886.

⁵ Read before the Boston Society of Medical Observation, March 7, 1882.

⁶ Archiv. f. Ohrenheilk., vol. xliii.

ures, my memory leads me to believe that in a large proportion of the cases of suppuration, under my observation, the disease was confined to the attic or superior portion of the tympanic cavity. Most of the writers on this subject have advised the removal of the drum membrane together with the diseased ossicles. As the membrane forms a natural protector of the tympanic cavity I am impressed with the importance of exposing as little as possible of the mucous membrane to the effect of cold or what by chance may find its way into the ear. The cicatricial tissue closing the opening has been shown to form in many instances a vibrating surface capable of transmitting its movements to the stapes. Where the incus remains, its long process, through contact with this tissue, increases the hearing power, and in a measure also protects the delicate mucous membrane beyond. In my limited experience with this operation, but somewhat wider observation of the work accomplished by others, I have failed to find any evil effects which could be attributed to the operation, whereas the results obtained, both as regards effecting a cure and improving the power of hearing, have been extremely favorable. I believe that in all these cases every effort had been previously made in the way of both vigorous and mild treatment. I wish, however, in no way to be understood as advocating operative interference even when rough bone is demonstrated until the usual treatment has been thoroughly tried.

I might say in regard to the instruments necessary for the operation, that a series of triangular-shaped knives, bent at various angles, seemed sufficient for most of the tissues necessary to be separated. A case of Schwartz's curettes enables the walls of the attic to be cleared of granulation-tissue, great care being necessary in case of caries not to enter too far, the anatomy of the parts to be kept clearly in mind all the time. The ear must be perfectly illuminated, during the operation. In addition, a small pair of ear forceps for removing the completely excised ossicles is especially to be recommended, as it is more easily directed by the hand and less likely to do harm by undue force. A small olive-tipped probe is very necessary in determining the location and extent of the disease. A small hook is also useful in finding any adhesions which may remain after the operation. They should all be separated before attempts are made to remove the ossicles. All antiseptic precautions were carefully observed. Cocaine has proved a valuable aid in clearing from bleeding the very small field of operation. For the steps in the operation there is little I can add to the description given by Dr. Kessel⁷ or by Dr. Sexton.⁸

The house records of the following three cases occurring at the infirmary during my service for Drs. Green and Blake briefly illustrate what has been said:

CASE I. Mrs. M. F., forty-two years old. Has had a chronic, purulent discharge from the right ear for forty years, during which time it has never wholly ceased, considerable tinnitus. No pain, advised to enter the house for operation. Examination of the patient showed a slight discharge from the ear. Large perforation of the membrana tympani. Head of malleus rough to the probe and adherent to the promontory.

September 10, 1891. Patient was etherized and the malleus freed from all its attachments, which were

very firm and dense around the head of the bone and handle, and then removed with forceps. The ear was thoroughly syringed with a corrosive sublimate solution (1 to 2,000), and tightly sealed with absorbent cotton and a collodion dressing applied. Examination of the malleus revealed caries of head and short process. Most of the manubrium had sloughed away.

September 14th. There had been no pain since the operation. Dressing removed for the first time. The ear was found absolutely free from all discharge. Evening temperature 99° for three nights, normal the rest of the time.

September 16th. Ear perfectly dry. Meatus kept closed with antiseptic cotton.

December 5th. At the end of nearly three months, middle ear found dry and the mucous membrane white in color. Hearing greatly improved for conversation. W = 7%. No tinnitus.

CASE II. Miss L. V., about fourteen years old. On November 11th she entered the out-patient department for the relief of an otitis media suppurativa of the left ear, which had lasted for several years. Malleus was carious and had a large polypus growing from the handle. Bone very loosely held in place and partly destroyed by necrosis. Under ether, the malleus and polypus were removed with the snare and a few granulations in the upper part of the middle ear cavity were curetted. The meatus was then closed with cotton after being syringed with a corrosive sublimate solution (1 to 3,000). Evening temperature 100°.

November 12th. Considerable foul-smelling discharge from the ear. The patient was unable to bear the removal of the granulations so they were touched once a day with perchloride of iron. Syringed with a 1 to 5,000 solution twice a day, and followed with instillations of resorcin and alcohol. Temperature 99°.

November 16th. Amount of discharge much less. Referred to out-patient department; since that time nothing has been seen of her.

CASE III. Miss L. C. B., thirteen years of age. Had been troubled with chronic purulent discharge from the left ear for ten years; at times annoyed with dizziness. Examination showed patient in poor general condition and anemic; large destruction of the posterior segment of the drum membrane; malleus firmly adherent to the promontory; and the probe revealed a small spot of necrosis on the anterior edge of the handle of the hammer. Granulations were found covering an area of diseased bone on the inner wall of the middle ear cavity posterior quadrant.

October 1st. The patient was etherized, and an operation of half an hour performed. Malleus removed after some considerable difficulty, due to thick bands of tissue around the head of the bone. The granulations on the inner wall were curetted. Collodion dressing applied.

October 2d. Rallied from the ether well. Complained of some headache and slight pain in the ear. Temperature 99.8°.

October 3d. Dressing removed, and middle ear found filled with foul pus. Syringed three times daily, and powdered with iodoform. Evening temperature 99.5°.

October 5th. Discharge less. Slight headache and no pain in the ear. Temperature normal.

October 12th. Amount of discharge is very small. Ear wiped dry, and powdered once in two days.

⁷ Archiv. f. Ohrenheilk., vol. xiii.

⁸ Transactions of the American Otolological Society, 1886.

October 17th. Ear perfectly dry in the superior portion. After omitting treatment for ten days, slight moisture only over spot of necrosis in lower portion of the tympanic cavity. No change in hearing.

January 2, 1892. Ear without discharge. No complaint of dizziness. Hearing the same as before the operation.

In Case III healing was delayed by the condition of the bone concealed by the granulations on the inner wall of the tympanic cavity, although cured as thoroughly as possible. All discharge disappeared from the attic in a few days after the operation. In contrast to this case is the one reported first, in which, in spite of the long continuance of the suppuration, the ear healed almost immediately after removal of the carious malleus. I think the two cases illustrate the two classes into which suppurative processes in the middle ear may be divided, considered from the point of time necessary for recovery after the operation. First, I would class as simple cases those in which necrotic bone is confined to one or more of the ossicles, the bony walls of the middle ear cavity being perfectly free from such a disease; second, as complicated, those cases in which some part of the bony wall, together with the ossicula, is diseased. The most speedy cure may be very naturally expected after operation in the first variety of cases, for the simple reason that everything interfering with recovery is removed. Experience has shown that the ears heal almost at once without subsequent treatment being necessary. In the second class of cases healing is necessarily delayed, depending largely upon the seat of the diseased bone in the tympanum.

Removal of the ossicles and the membrana tympani will not cure every case of chronic otorrhea; but I am certain that many may be cured and the rest relieved by operation. Of the cases mentioned in this paper (twenty-three in all), twelve were cured in three months or less time; one in six months; five cases were improved; three cases were not improved and two passed from observation. As every variety of local treatment in most of the cases had previously been faithfully tried, it seems to me that the results of the operation have been most satisfactory, and that from the cases reported we may draw the following valuable conclusions:

(1) The removal of the drum membrane and ossicles is attended with little annoyance to the patient, proof of which is sufficient to warrant the performance of the operation as the only means of cure in many cases.

(2) The operation often produces marked improvement of the hearing.

(3) Satisfactory results may be expected towards the relief of tinnitus and vertigo.

(4) The results of the operation seem to be permanent.

Although not the chief purpose of this paper, I am tempted at this point to speak of operations on non-suppurating ears. The possibility of hearing well without the membrana tympani, malleus and incus has been successfully demonstrated in a number of cases; and this suggests what operative procedure may be expected to do in some cases of deafness due to hypertrophic catarrh of the middle ear without fixation of the stapes. The distressing symptom of tinnitus has been relieved by the same operation. It has also been done with success in certain cases of disturbance of

equilibrium from pressure transmitted through the middle ear. There are a few cases recorded in which the hearing has been in good part restored by removal of the membrana tympani and one or more of the ossicula. The successful operations have, however, been as yet too few to enable us to establish a rule.

A CASE OF EMPYEMA WITH RECURRENCE AFTER APPARENT RECOVERY.¹

BY S. H. AYER, M.D.

EARLY in the morning of January 4, 1890, I was called to see Mrs. P., when I obtained the following record. The patient was twenty-five years old, married, and had a good family history. Had had scarlet fever when a child. About nine o'clock in the evening of December 31st she was seized with the grippe. The following day symptoms of miscarriage began to show themselves, she being six months pregnant. The patient finally miscarried at eleven o'clock in the evening. She was attended by a homeopathic physician. Patient remained comfortable until the morning of January 3d, at which time she was seized with extremely sharp cutting pains throughout left chest accompanied by much dyspnea. The pain continued throughout the day and night, and as the physician in charge gave nothing that seemed to afford any relief, the husband decided to change doctors, and I was accordingly summoned.

It was 4.30 A. M. when I arrived at the house. The patient was apparently suffering intensely, and was in a very much exhausted condition. Pulse 120, temperature 101.4°, respiration 40. A hurried physical examination of the chest showed flatness with bronchial respiration in lower half of left back. A quarter of a grain of morphine was given by the mouth, and a poultice of mustard and flaxseed applied to whole left side, back and front.

At 8.30 A. M. I returned, and found that the patient had been dozing since six o'clock. Morphine, one-eighth of a grain, had been given twice during my absence. Lochia scant, whiskey and digitalis were ordered. Pulse 128. At 5 P. M. the pulse remained the same, respiration 32. Patient was very drowsy, and pupils were somewhat contracted. There had been no pain to speak of during the day. Numerous fine moist rales were heard in the lower half of left axillary region.

January 5th. Pulse 112, temperature 100.8°, respiration 36. Pain in side was gone. Took nourishment well through the night. The cough and expectoration were very slight, the latter being thick and tenacious. The tongue was moist and had a thin whitish coat. Patient complained of pain and tenderness in hypogastric region, the knees being drawn up. At 5 P. M., pulse 126, temperature 102.4°, respiration 36. There was marked tenderness over the uterus and also in both iliac regions. Vaginal examination found the passage hot, or somewhat open, moving of uterus painful. Lochia somewhat scant and slightly offensive. Iodoform was applied to vaginal outlet and the pain was controlled by morphine.

January 6th. Pulse 124, temperature 101.8°, respiration 28. Patient feeling much better. Abdomen

¹ Read before the Boston Society of Medical Observation, March 7, 1892.

nal pain and tenderness very much less. At 5.45 p. m., pulse 126, temperature 102.4°, respiration 37.

January 7th. At 9 a. m., pulse 100, temperature 100.2°, respiration 36. Patient was apparently much improved. Whiskey was reduced. The abdomen, however, was still somewhat tender, and poultices were accordingly kept on.

January 8th. At 12 m., pulse 98, temperature 100.6°, respiration 40. Some diarrhea, right cheek quite flushed, abdomen still tender. A partial physical examination of chest revealed dulness, merging into flatness below a point located in third left interspace in axillary line. Respiration absent over this area. The heart sounds were heard loudest at a point directly below the sternum. The back was not examined.

January 9th. At 12 m., pulse 96, temperature 100.8°, respiration 30. The tongue was clean, and there was apparently no abdominal tenderness. In the third right intercostal space, about one inch from edge of sternum was heard a to-and-fro friction sound, synchronous with the heart beat. With the patient lying on her right side percussion showed flatness in left back up to spine of scapula, with moderate bronchophony but no vocal fremitus. Percussion over left infra-clavicular region was tympanic.

January 10th. At 12 m., pulse 96, temperature 99.2°, respiration, 34. From this time to January 16th condition of patient remained about the same, the respirations keeping up from 30 to 36, pulse from 96 to 108, and temperature 97.2° to 100°. Tincture of iodine was applied to chest and back on left side, and on January 17th the patient was removed to St. Elizabeth's Hospital. The physical examination at this time was as follows: Position of patient prone, percussion over left front was tympanic down to third interspace, at which point and below it in mammary line, was flatness and absence of respiratory murmur. Respiration was diminished above third space on left side. Percussion over whole of left back was flat. Respiratory murmur and vocal fremitus were absent. Apex beat of heart was heard loudest in median line of body just below ensiform cartilage. The patient was given liquid diet, and tincture of digitalis and citrate of potash were administered.

January 19th, Dr. George E. Thompson saw the case with me, in consultation, agreeing with me in the justifiability of aspirating. A hollow needle, one millimetre in diameter, was accordingly passed into the sixth interspace just back of the axillary line, and one ounce of laudable pus withdrawn. There was no shock and very little discomfort from the operation.

The following day Dr. Kingman saw the case with me. In order to allow the patient to escape, if possible, the making of a permanent opening into the chest, two trocars were introduced, the latter being one of the largest size. Poor success followed this procedure, only a few drops of pus working through into the aspirating bottle with the larger, and practically none with the smaller. There was considerable pain associated with the passing of these trocars, but, nevertheless, the patient was quite comfortable the next day. The temperature then began to rise slightly, reaching 102.4° on the evening of the 21st. The to-and-fro sound in the third right interspace remained.

January 24th. The examination of the urine being negative, save a moderate diminution of the chlorides, the patient was etherized and the following operation performed, Dr. Kingman assisting. A hollow needle

was first passed into the chest, through the sixth left interspace at a point directly behind the posterior axillary fold. Pus showing itself again through the needle, and, using the latter as a guide, a permanent opening was made into the chest. Fully two quarts of pus were evacuated, containing numerous large pus clots the size of one's thumb, thereby accounting for the poor results obtained on passing the trocars four days before. A double rubber drainage-tube three-sixteenths of an inch in diameter, was inserted, and the cavity washed out with a solution of chlorinated soda (1 to 20). A dressing of iodoform gauze, rubber tissue carbolized gauze and cotton batting was applied.

The following day percussion was tympanic over the whole left front, but the heart sounds had apparently not changed their locality. The after-treatment, though finally satisfactory, was not entirely smooth sailing. Several times the cavity was found not to be draining sufficiently, and on removing the tubes, large pus clots would be found drawn into same, completely obstructing the outflow of any fluid behind them. In spite of these drawbacks there was steady improvement. Respiration increased over the left chest, being heard on February 4th down to the nipple. Numerous friction rubs were also heard in left infra-clavicular region, as also in mammary and axillary regions. The apex beat was heard loudest just to left of sternum. The respiratory murmur was heard in left back down to a point one inch above the lower angle of the scapula. The chest was washed out daily with chlorinated soda solution, and the cavity measured from time to time.

The case proceeded well; the capacity of the cavity gradually diminished; the discharge lessened in amount, becoming on February 28th mostly of a serous character, at which time one tube was removed. I should have remarked that the solution of chlorinated soda had been followed by one of compound tincture of iodine (1 to 7) since February 18th. March 7th, the cavity held thirteen drachms. Six days later the second tube was removed, the cavity measuring three and three-quarters inches in depth. A soft rubber tube, four inches long was inserted, and drawn out about three-eighths of an inch daily, it being removed permanently March 21st. The sinus apparently healed nicely, and the patient left the hospital on April 1st, there being simply a small granulating surface the size of a silver three-cent piece, over the site of the external incision.

The patient's health remained excellent throughout the months of April, May and part of June. So good in fact, that in May she went to work at dressmaking for three weeks.

On the evening of June 28th, she came into my office with the statement that for the past six days she had not been feeling well. Malaise was really the only symptom I could obtain. The pulse was quickened, and the temperature was 102.4°. The tongue had a thick, whitish coat. There were absolutely no symptoms referable to the chest.

The following morning at eleven o'clock I saw the patient at her home. The temperature was 101.4°. There were no rose spots, no abdominal tenderness nor gurgling. The spleen could not be felt. A careful physical examination of the chest showed nothing further than the signs of an apparent recovery from empyema, there being, as I have said, no symptoms referable to the chest. Seeing the case every day

soon convinced me that I was not dealing with a case of typhoid fever. The tongue continued coated, and the fever was more or less present, being, however, much higher in the afternoon.

On July 10th and 12th, at noon, the temperature was normal, but at 4 p. m., on the latter date, it registered 100.8°. By leaving my thermometer the temperature was taken twice daily, showing a normal temperature in the morning, and from 101.8° to 102.4° in the afternoon.

July 18th, diarrhoea appeared, which I would here remark lasted without intermission until November 25th, the number, but not the character, of the dejections being controlled by morphine.

July 20th, vomiting began, taking place every night about 9.30 o'clock. So regularly did this make its appearance, that the possibility of there being a malarial element in the case was quite seriously considered, and quinine administered at 9 and 2 o'clock in the day without effect.

July 24th. As the vomiting did not appear to abate, and as the surroundings were such that the patient could not receive the proper care, she was sent to the Boston City Hospital.

When the patient went out of my care no chest symptoms had been discovered by me. I had not, however, listened to her chest for several days. On referring to the records of the City Hospital, through the kindness of the visiting physician, Dr. Folson, I found that copious fine crepitant rales were heard in the right back, with occasional friction rubs, this being, please notice, on the side opposite to the one on which was the empyema.

August 20, was a note, saying that there was "some cough and expectoration the past few days." The patient was up and about most of the time, and went out doors in pleasant weather. The evening temperature kept up, and on August 25th she was discharged relieved, the final note being, "Condition in lungs about the same. General condition no better. Diagnosis, phthisis."

On August 28th, I examined her at home, and found no signs of moisture in the lungs, with the exception of a few fine rales in the region of the right nipple, the old empyema signs remaining the same as before. Her general appearance, however, was bad; her expectoration greenish and thick; weight 100 pounds; pulse 120; in fine, she did look phthisical. So, thinking that there probably were some signs, which did not show themselves to my stethoscope, I prescribed creasote, whiskey and Fellows' Hypophosphites, and sent her to Melrose Highlands, where she had friends.

She returned to Boston on September 14th, but I did not see her until the 16th. She had not improved during her absence, and had developed a new symptom, namely, continual pain and soreness in left back below angle of scapula, and also in right axillary region. The pain was sufficiently severe to keep her awake nights, she being unable to get into a comfortable position. The cough had also increased, in fact, she said she coughed almost all the time, raising a rather thin, greenish fluid, a pint being raised in about two hours the previous night. Much dyspnoea on the slightest exertion. Pulse 128, temperature 101.6°.

It was at this point that I blame myself for not having discovered the true condition of things. My only excuse is, that considering the case from all sides, I

had finally decided the case to be one of rapid phthisis, notwithstanding the negativeness of the physical signs. My physical examination at this time, though probably biased by the diagnosis at which I had arrived, was somewhat interesting. It was as follows: marked dulness at right infra-clavicular region, with numerous medium, moist rales. Cracked-pot resonance over this area, but no signs of cavity on auscultation. No metallic tinkling. No rales nor adventitious sounds heard elsewhere. The same treatment was continued with the addition of a Beverly-Robinson inhaler, creasote being used. The pain in left back disappeared in a couple of days, expectoration diminished, and in a week she was feeling quite a little better, so much so, that she decided to return to Melrose, which she did September 24th. I should have stated that at this time there was marked clubbing of the finger-nails, and also night sweats and diarrhoea.

I heard from her occasionally through her husband. On October 1st, he left word at the house, I being away at the time, that a swelling had appeared in the left side in front just below the nipple. About two weeks later he told me personally the same thing. Her condition generally remained about the same. Toward the latter part of October she was seen by a Melrose physician, who pronounced the swelling to be a surface abscess, and ordered a poultice. The following day he lanced the abscess, there being a profuse discharge of pus. Coincident with the opening of this abscess the cough stopped, and the patient's appetite, which had been poor, began to improve. In a short time the discharge began to be extremely foul, and although the patient's condition was very much improved, at the same time she was suffering from edema of the ankles and legs, night sweats and dyspnoea.

Three weeks after the opening of the abscess, November 17th, the patient again entered the St. Elizabeth's Hospital, at which time the following conditions were found: patient much emaciated, edema of ankles, diarrhoea. Examination of right lung was negative with the exception of a few sibilant rales in mammary region. Respiration absent over whole left front and back, with the exception of much diminished respiration in infra-clavicular region. The skin over an area the size of a silver dollar in left sixth interspace in mammary line was bluish in color, there being an opening in the centre of same about one-third of an inch in diameter. The opening was discharging a stinking, watery, purulent fluid.

November 19th, at 5 p. m., temperature 102.2; pulse 120.

November 20th, at 11.30 A. M., there being no albumen in the urine, the patient being etherized, the following operation was performed, Drs. Kingman and Conant assisting. An incision about three inches long was made through the centre of the before-mentioned discoloration parallel to the ribs. Upon inserting the little finger it passed directly into a depression in the sixth interspace in mammary line. Artery forceps were first pushed through the opening followed by an uterine dilator, and about a quart of pus evacuated.

The cavity was then washed with a solution of corrosive sublimate (1 to 3,000). The tissue over the seventh rib was then dissected down to the seventh interspace and an inch of the seventh rib removed with bone forceps. The cavity, which was deeper than the index finger, was curetted with a dull curette

and washed out again with a solution of corrosive sublimate (1 to 10,000). Fully a half-teacupful of masses of lymph was washed out of the cavity. A double drainage-tube was inserted and the side dressed as before. The patient did uninterrupted well. Coincident with the operation the diarrhea stopped, it having been present continually since the preceding July. November 23d, the edema of the ankles also disappeared.

Measurement of the cavity from time to time showed a gradual diminution in the capacity of the same as follows: November 24th, five ounces; November 30th, three and one-half ounces; December 4th, three ounces; December 9th, two and one-half ounces; December 14th, two ounces.

On December 16th the probe passed in five inches, the cavity holding one and one-quarter ounces. The weight was 110 pounds.

On December 23d the discharge was quite purulent. The temperature, however, remained normal, and the patient was up and around the ward, doing considerable sewing.

On January 12th, although the patient's general condition remained excellent, nevertheless, the discharge was apparently increasing. A probe at this time passed in four inches.

On January 15th, having decided that further operative interference was necessary to insure the complete healing of the opening, the patient was accordingly etherized by Dr. Ross, and the old incision of November reopened, Dr. Conant assisting. About one inch of the fifth and sixth ribs were resected, the direction of the opening being outward and upward toward the axilla. Examination by the finger showed a cavity extending upward and backward toward median line of body about four inches in length. A double drainage-tube was again inserted, and the side dressed the same as before. The following day the patient was very uncomfortable, she being very restless and aching all over. The temperature registered 103.4°.

On January 18th she was quite herself again, as far as her feelings were concerned. A considerable amount of pus came away in the washings, but the capacity of the cavity steadily diminished at the rate of about a drachm a day, so that on January 29th the cavity held but two drachms, the character of the discharge being much more serous.

On February 2d, the tubes were removed altogether and the cavity filled with a mixture of iodiform and vaseline, twenty-four grains to the ounce.

On February 9th, nothing but the line of the incision remained unhealed, and on the following day she was discharged well.

Up to the present time the patient's health has been excellent, there being no symptoms whatever of any return of the disease.

SNAKES IN INDIA.—Sir Joseph Fayrer, in a lecture recently delivered at the Victoria Institute on the venomous snakes of India, reports that upwards of 20,000 human beings and some 3,000 cattle are annually killed by these reptiles in that country. The Government of India is offering rewards for their destruction, as was shown by a return that 578,415 snakes were caught and killed at a cost of 19,004 rupees in the year 1890.

Clinical Department.

PLACENTA PRÆVIA AND URÆMIA IN THE SAME PATIENT.¹

BY CHARLES W. TOWNSEND, M.D.

Mrs. C., thirty-two years of age, was first seen by me late in the evening of December 19, 1891. She had been married one year, during the first four months of which she had aborted twice. At the time of my visit she was six and a half months pregnant, and had begun to have pains and flowing at four that afternoon. I found she had lost considerable blood, several napkins and a small blanket being more or less soaked; but I also observed her edematous face and extremities, which were very pale and bloodless.

On questioning the nurse, it was discovered that the edema had appeared in the last two days, that a severe headache began that same morning, and that her vision became blurred, the sight in the left eye being very defective. Nothing abnormal had been observed about the appearance or quantity of the urine. The os uteri was rigid, admitting only one finger. The placenta could not be felt, although from the amount of hemorrhage which still continued, I believed that the placenta was partially detached from a low position. There was not enough urine in the bladder to flow out through a catheter, but the small amount that was caught in the end of the catheter was found to be of a smoky color and loaded with albumen. Labor-pains were present, but slight and irregular.

In the presence of the ante-partum hemorrhage, it was decided to dilate and deliver, the existence of uremia and threatened eclampsia making this course more urgent. Dr. T. F. Sherman kindly saw the case with me, and agreed with me in the diagnosis and treatment.

After full anesthesia with ether, manual dilatation was begun at midnight, completed in an hour and three-quarters, with Dr. Sherman's help. The placenta was found partially detached close to the edge of the os on the left side, and there was considerable hemorrhage at the completion of the dilatation. A dead six-and-a-half-months fetus, was easily turned and delivered.

The patient was given one-sixth of a grain of pilocarpine and drachm of brandy subcutaneously, and was surrounded with hot-water bottles and warmly covered. She began to sweat freely in twenty minutes, and came out of the ether well.

She was rational and comfortable that morning six hours later, and free from headache although the vision remained blurred. Her pulse was 120, temperature 100°. Ten hours from the catheterization before labor, the water, only four drachms in all, was again drawn, and found to be smoky, containing over one per cent. of albumen, and a sediment of much fresh blood, and numerous epithelial, blood, hyaline and fatty casts of large and small diameters.

She was again made to perspire freely with pilocarpine, and was given cream-of-tarter water to drink, in addition to milk diet. The bowels were moved freely, four watery dejections being obtained by the use of Epsom salts.

The kidneys from that time began to act, and in the next twenty-four hours she passed two and one-half quarts of urine, containing but a trace of albumen.

¹ Read before the Obstetrical Society of Boston, March 12, 1892.

Two days later the urine had increased to four quarts in the twenty-four hours, the edema had disappeared, she had had no more headaches, and her convalescence was fully established. The albumen gradually diminished, and in five weeks after confinement none was to be found in the urine.

My excuse for reporting this case is the fact that two such grave obstetrical emergencies as uremia and placenta previa were met with in the same patient. It is reasonable to suppose that the free hemorrhage from the placenta previa prevented the onset, in this case, of eclampsia.

PLACENTA PRÆVIA COMPLICATED WITH URÆMIA AND IMPENDING ECLAMPSIA.¹

BY CHARLES M. GREEN, M.D.

THE following case was seen in consultation with Drs. Martin and Chandler of Medford: to Dr. Chandler I am indebted for the notes of the case.

The patient was an American woman, thirty-nine years old, in the tenth lunar month of her first pregnancy. She was first seen by Dr. Chandler for Dr. Martin April 24, 1891, when he found her suffering slight pains and flowing quite freely. Examination revealed a placenta previa, and the os uteri undilated. A vaginal tampon was introduced, and morphia given, after which pain and hemorrhage ceased. It was learned at this time that the patient had always had more or less stomach trouble, and that for five or six months it had been worse. For a month she had had a good deal of headache, and frequent attacks of nausea and vomiting. The urine was found to be scanty, of low specific gravity, and containing one-half per cent. of albumen and numerous casts: there was moderate edema of the feet and legs.

Next day the tampon was removed and a douche given: there was no more hemorrhage; but nausea was constant and vomiting frequent. It was obvious to Dr. Chandler that immediate obstetric interference was urgently indicated; but circumstances prevented, and Basham's mixture was prescribed. No improvement followed, and on April 28th and 29th not more than ten ounces of urine were passed in twenty-four hours. Pilocarpine one-sixth of a grain, repeated in half an hour, did not start perspiration.

April 30th, flowing began again and was controlled as before with tampon and morphia. May 1st I saw the patient in consultation, and found complete placenta previa, but no present hemorrhage: the os was slightly dilated. This condition was in itself an indication for immediate delivery: the grave symptoms of uremia and impending eclampsia made active interference doubly urgent. Ether was given, the os uteri was dilated manually, and a living child was delivered by internal podalic version: the infant, though asphyxiated, premature and poorly developed at birth, has thus far survived.

Next day, there was no more vomiting, and the patient was passing more urine. The following day, the patient passed a good amount of urine, took plenty of nourishment and suffered no nausea. One month after delivery, the urine was found free from albumen and casts.

Placenta prævia is a rare complication of pregnancy and labor, occurring perhaps once in a thousand cases:

it occurs six times as often in multigravidae as in those pregnant for the first time.

Eclampsia occurs about twice as often as placenta prævia and is most frequently seen in primigravidae, especially in elderly primigravidae. The combination in the same patient of these two most serious complications of pregnancy is of sufficient rarity to make all such cases worthy of record.

TRICHINOSIS: REPORT OF CASES.

BY C. W. MACDONALD, M.D., BOSTON.

FOR the past twenty years there is no authentic account of cases of trichina poisoning in Boston. For a longer period there have been no fatal cases of it. Its comparative infrequency yet fatal tendencies, are, I think, sufficient inducements to note well and publicly the insidious nature of the dread visitor. With this objective view I propose to report my experience lately with a few cases in my neighborhood.

About the last of March a patient came to my office complaining of some purging with abdominal pains. Having no other serious symptoms, I concluded that the trouble was caused by some indigestible irritant and prescribed accordingly. Two days later I was called to his boarding-house to see the proprietor, who was in bed and seriously ill. His symptoms were somewhat similar to those of patient No. 1, but much more exaggerated, and, in addition, he had a temperature of 102° F., bulging of eyes, headache, and "pains all over his body."

Being assured of no unusual diet in the household, and, consequently ignorant of the true nature of the disease, I treated the matter symptomatically and expectantly, and left with typhoidal thoughts agitating my mind. Next day my second patient's sufferings were intensified; temperature 104.5°. Still I postponed my diagnosis, and gave ten grains of quinine every three or four hours and all the brandy the patient could take. Next morning my anxiety was considerably removed by finding my patient with a temperature of 102°, and his other symptoms very much ameliorated.

And now, with the invasion of other members and friends of the family, to the number of fifteen, came the solution of what thus far had proved a mystery. About ten days previously, the family larder had been reinforced by the addition of a partially smoked ham. A neighboring family was also similarly supplied, and sandwiches, of the raw pork from both hams, had been more or less freely partaken of. Every one who had eaten of them, was, in about forty-eight hours, similarly affected. Some more seriously than others, the degree of affliction not at all in proportion to the quantity eaten. One visitor at my patient's house, who had eaten two sandwiches, died in about ten days, despite the best medical attendance.

Now, to return to my patient No. 2, whom we left with a temperature of 102°, upon quinine and brandy. He made an uninterrupted recovery. His was the most severe and the most typical form of trichine infection of all my cases. At the present writing, though past the seventh week, the usual time of active trichine symptoms, all the affected are still troubled with some diarrhea and muscular pains, but they have resumed their respective avocations, and get on toler-

¹ Read before the Obstetrical Society of Boston, March 12, 1892.

ably well with liberal libations of brandy and occasional doses of quinine.

In connection with this report, I may add, that the microscopic examination of the infected pork revealed numerous and active swarms of trichinae.

Trichinosis, fortunately a rare disease, occupies but a small space in medical literature. Whilst the parasites are generating in the intestinal tract, some measure of treatment with the hope of either their elimination or annihilation is offered, but its efficiency, in either case, remains an open question. When the trichina reaches its coveted home in the muscular tissue within its encysted walls, it, thus far, bids defiance to any adversary that may pursue. That quinine and alcoholic stimulants in large quantities, should, apparently at least, arrest a serious case of trichinosis, in one instance, does not establish a principle, but the coincidence, to my mind, is too striking to be forgotten. Besides their stimulating effects, may they not have some specific properties?

In a recapitulation of the subject, the following facts may be gleaned:

- (1) Necessity of thorough cooking of pork before eating.
- (2) Necessity of a true history in disorders simulating typhoid fever or diarrhoeal troubles.
- (3) Speedy microscopic examinations of suspected pork.
- (4) Tonics and alcoholic stimulants.
- (5) Imprudence of a sudden or premature arrest of alvine evacuations.

Medical Progress.

REPORT ON THERAPEUTICS.

BY FRANCIS H. WILLIAMS, M.D.

TREATMENT OF CROUPOUS PNEUMONIA IN CHILDREN.¹

The generally accepted opinion as to the element of danger in pneumonia is the tendency to cardiac exhaustion or heart-failure. In order to guard against this danger, it is of the highest importance to understand how such a condition is brought about. An excellent paper by Dr. A. H. Smith called attention to the important part played by the engorged condition of the diseased lung in producing cardiac exhaustion. It was shown that the right heart and not the heart as a whole was the main source of exhaustion, and that it was far safer to watch the pulmonary second sound of the heart than the pulse, as a danger signal of this condition. In Dr. Dessen's paper, from which this is taken, we have an inquiry based upon this hint. Owing to the obstructed circulation in the engorged lung, the blood-vessels of which are in a state of permanent dilatation, the right heart becomes overcrowded. In the systemic circulation the arterioles are contracted. The left heart has therefore to work more powerfully which forces more blood into the venous circulation, but the right heart, owing to the obstruction in the lungs cannot readily empty itself before it is filled by the return flow from the veins. Dilatation of the right ventricle follows.

If such a condition is the probable interpretation of the tendency to heart-failure in croupous pneumonia, the treatment, so far as the circulation goes, should

attempt to relieve the right heart by increasing the capacity of the systemic system and lessen the rapidity of the heart's action.

Since croupous pneumonia, especially in children, tends to recovery, our efforts should be directed to assisting nature. As a means of dilating the superficial blood-vessels and producing diaphoresis simple remedies such as the spirits of mindererus, or the solution of acetate of ammonium, or sweet spirits of nitre are serviceable. Sponging the entire body with water at 116° F., or the warm bath at 95° F., is also recommended. This sponging and bath are given for the purpose of dilating the cutaneous vessels and inducing diaphoresis and should be so conducted as to accomplish these ends, and with them the use of friction to the skin may be advantageously employed. It has been observed that hot sponging reduces temperature better than the ordinary antipyretics. To give the venous circulation still more relief the blood from it may also be diverted to the liver, a reservoir capable of holding a large amount of this fluid. Furthermore the increase in the blood supply to the liver will stimulate its functions, among which is to be noted the destruction of poisonous products in the blood, and this is suggested as a point of much practical importance. To bring about this flow of blood to the liver small doses of calomel in triturates of one-tenth of a grain each are given every hour for six doses, on the first day and thereafter every three or four hours daily, according to its effect upon the bowels. The diuretic action of small doses of calomel should not be lost sight of as the kidneys are important organs for the elimination of fever products.

Aconite is mentioned as a remedy which may be used to reduce the heart's action. This is administered in half a drop or drop doses at the onset of the disease, and repeated hourly while the patient is awake, this not only slows the heart's action, but it assists in dilating the cutaneous vessels and promoting respiration.

Large doses of digitalis are mentioned, and condemned. Carbonate of ammonia seems to him useful only as prompt diffusible stimulant to the circulation as a whole at the period of crisis.

A warm poultice aids diaphoresis by means of warmth and moisture, but the employment of a warm wet binder serves the same purpose as the poultice, is neater and less disturbing to the patient. The above are some of the views outlined by Dessen while following out the lines of rational therapeutics. He believes that in order to treat croupous pneumonia in the best way one should keep the principle of continuous dilatation of the cutaneous blood-vessels always in mind. In this way relieving the right heart, reducing the temperature while producing diaphoresis. If there is a morbid poison it is thought that its elimination through the skin and kidneys may be promoted and its destruction in the liver aided.

THERAPEUTIC USE OF THE SALTS OF STRONTIUM.

As the salts of strontium have been found to be diuretic when given to dogs, it was expected that they would behave in the same manner in man. On testing them, however, Professor See found that diuresis could not be produced by their means even in cases in which it was easily set up in other ways. It was noticed, however, that in patients with Bright's disease, or heart affections, the digestive troubles, underwent

¹ Archives of Pediatrics, 1891, No. 93.

a very marked improvement. This led the author to try the effect of bromide of strontium in gastric affections.

Thirty-two patients, mostly suffering from acid dyspepsia, either with or without dilatation of the stomach, were thus treated, the minimum daily dose being thirty grains, and the maximum a drachm, taken between meals. All showed marked improvement, the diminution of gas formation was very noteworthy. In eight other cases of dyspepsia from reduced hydrochloric acid formation, the drug produced equally satisfactory results, completely controlling fermentative changes and the formation of lactic and acetic acids.

Dujardin-Beaumetz makes the following statements as to the clinical uses of the salts of strontium. The only salt of which he had had any experience was the lactate. This he had employed in a number of cases of Bright's disease, with albuminuria; under its influence he had the satisfaction of seeing the albumen diminish very considerably, in some cases being reduced to one-half of that previously excreted. He attributed this favorable action rather to the very beneficial action of the strontium salts on digestion than to their direct action on the kidneys. At the same time he pointed out that the greater or less quantity of albumen passed was of less importance in the prognosis of the disease than the proportion of toxines retained in the organism, which the renal filter either retains or allows to pass into the urine. He recommended that a milk and vegetable diet be employed in combination with the drug, which he gave in doses of one and a half drachms per diem.

THE USES OF STRONTIUM BROMIDE.

In experimental doses of salts of strontium bromide, in thirty-two cases of dyspepsia, he gave from thirty to forty-five grains a day, in three doses, with meals; and those cases in which there was excess of hydrochloric acid rapidly improved and developed much less gaseous products. In six other cases, where there was vomiting with deficiency of acid, there was complete cessation of the sickness. Strontium lactate did not produce any good effect, strontium bromide, as well as calcium bromide, was found of use by M. Sée in epilepsy; and this was confirmed by M. Férc, who found, in fact, that owing to its easy agreement with the stomach, it was sometimes advisable to give strontium bromide in preference to the potassium salt.²

NAPHTHALIN IN WHOOPING-COUGH.

Ivanoff, referring to Chavernais's paper, says he has treated all his cases of pertussis by naphthalin for several years past, the result being invariably excellent. It is absolutely necessary, however, that the patient should inhale the naphthalin fumes continuously day and night till recovery takes place. It is sufficient to fasten a small linen bag containing the drug on the child's neck, or to rub the substance into the patient's clothes. It is also advisable to sprinkle the powder freely all over the floor of the sick-room. The paroxysms of coughing very quickly subside, and soon disappear altogether. In very severe cases the author sometimes resorts to the internal use of bromide of sodium or potassium as an adjuvant.

(To be continued.)

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

J. C. MUNRO, M.D., SECRETARY.

REGULAR meeting, Monday, March 7, 1892. DR. S. G. WEBER in the chair.

DR. J. B. AYER read a paper on

THE THIRD YEAR OF THE INFLUENZA EPIDEMIC.³

DR. H. W. WILLIAMS: I had a personal experience of influenza last year; having an attack come on in the very sudden way described. I was at the hospital and did my morning work, seeing a large number of cases within a comparatively limited time; but I felt, contrary to my usual habit, tired after finishing my work, and it seemed to me afterwards that I said something a little irrelevant to one or two of the students who asked me some question relating to the cases. I managed to get home very well, but went immediately to bed and was unconscious for a week. Fortunately I had no severe pains in the head, but was absolutely unconscious. Then I had a little complication; a portion of one lung being affected with pneumonia at the lower part, and yet I had no suffering of consequence at any time during the duration of the disease. I took enormous quantities of milk, and almost from the beginning of the time when consciousness returned I was able to take solid food, eating my rations almost as if at the dinner table, but it was a number of weeks before I was able to do much work. I felt wretched in every way, but had nothing to complain of in the way of severe cardiac or other symptoms. For a considerable time I was less inclined to exertion, but was able to do nearly everything I wished to, intellectually, after I had recovered consciousness. On the whole I feel that I had a very fortunate experience; though a particularly unpleasant one to me accustomed as I have always been to very active work. I had a little return of influenza at the beginning of this winter, and for three or four days was in bed a part of the time, but I have had no other trouble from it. I think the doctor has given an admirable sketch of the course of the epidemic as I have had occasion to observe it.

DR. C. J. BLAKE: There have been more publications on the other side of the water than in this country upon disease of the ear in connection with the influenza epidemic. In all that has been written there is one point noted which illustrates the remark of Dr. Ayer in reference to the effect on the nervous system. A vasomotor inhibition showing itself by very considerable congestion in the middle ear, and in the cases of serous exudation a greater predominance of hemorrhagic effusion, not perhaps distinctly to the extent of being sanguinolent, but with a sufficient number of blood corpuscles to make the discharge very markedly yellow.

DR. J. STEDMAN: I was unfortunate in not being in early enough to hear the paper. I have been much interested in the epidemic this year. It seems to me that in many cases it is more likely to prove of long standing than the epidemic of two years ago, and in Ward 23 the tendency was to the pulmonary organs, especially pneumonia, although a large number of cases of bronchitis without pneumonia were observed.

² British Medical Journal, January 9, 1892; Practitioner, February 1892.

³ See page 513 of the Journal.

I noticed that the convalescence was tedious and the nervous system very much reduced, that strong men who were taken down had a good deal of nervous disturbance, headache, and great prostration. I found that keeping them strictly in bed, economizing their strength, feeding them well and in many cases the use of stimulants seemed to be the best plan to subdue the influenza attack. I noticed several cases similar to those Dr. Blake has spoken of, and in some the ear trouble was severe. I think bronchitis, pneumonia and ear troubles so far as I have observed, were more marked than in the other epidemics we have had.

DR. SPEAR: Dr. Blake would leave the impression, upon the medical practitioner, that during the influenza the ear is not very seriously affected, when on the contrary the ear is often very seriously inflamed, and the hemorrhagic conditions which he mentions are exceedingly common rather than otherwise. The vasoconstrictor irritation or lack of inhibition as he described it, is quite marked. It has been my privilege to see a large number of cases on account of my term of service at the Eye and Ear Infirmary giving me the winter months, and I can recall and contrast the two epidemics. In the first we had a very large number of acute inflammations and this year as well, and in nearly all of them we were surprised at the large amount of blood which formed in a coagulum as a sort of cast of the canal. The treatment did not differ very much from that of the acute inflammations which we ordinarily see. I had no difficulty whatever during the first month, that is through January, because the cases came early, but later during the second month the patients who had been treated by other gentlemen or who had neglected treatment or had been improperly treated by others, presented mastoid cases, that is to say, complications of acute inflammations such as mastoid inflammation and meningeal inflammations and the severer forms which always come from neglected acute inflammations of the ear. I should like to ask Dr. Ayer if he can tell me what the pathognomonic sign of an acute attack of influenza is. From my slight experience I think I have noticed that the first appearances present that condition which Dr. Blake alluded to, that is vasoconstrictor paralysis, and one finds a flushed face, high temperature, bounding pulse. The last article that I read, which has been copied by the public press, was an account by the Austrian specialist, Nothnagel, who described the disease as a neurotic one, that is to say, as a nervous disease. I think we may add that it is a disease of the sympathetic nervous system, which is that portion of the general nervous system which I sometimes explain as that which remains awake during sleep. There are two systems of nerves, cerebro-spinal and sympathetic; the sympathetic governs all the functions of the body not under control of the will and is held in abeyance by the cerebro-spinal system. In this disease the sympathetic system gets the upper hand, as it does in certain ear cases, and the result is that the weakest portion of the economy, be it throat, ear, lung, or abdominal organ, shows in its later pathological condition the effect of that want of inhibition, and we get, as the gentleman has described very carefully, the pharyngitis or laryngitis, the pneumonitis or enteritis, etc., and all these diseases capable of producing their various phenomena in proportion to the amount of disturbance and to the amount of treatment. I notice with pleasure that my observations agreed with those

of Nothnagel, who also claims that stimulation at the time when we have been taught that stimulants should not be given, is the proper thing.

DR. HODGES: I should like to mention a curious coincidence in regard to the influenza at Nahant. Three years ago, when it first came there, it affected at first the people living in the houses on the southwest side, on Boston Bay, and from there it spread slowly into the upper part of the village. This year there were a large number of people affected with the influenza there, and it came in the same way. So far as I have been able to inform myself, in that part of the town known as Short Beach Village, a community of seventy-five or a hundred people, none of the people have had influenza this year, while, three years ago they were more or less universally affected with the disease.

DR. MUNRO: There is a point about the temperature I have noticed in uncomplicated cases of influenza which I have not observed in other diseases. In the morning it is lowest, begins to rise about noon and reaches its height at six; but by nine or ten o'clock in the evening it has fallen considerably.

DR. J. B. AYER: I have no doubt that the sympathetic system is principally to blame, but I must confess that there is much which I do not understand. While last year it would seem that that would be a proper explanation, I do not understand why there should be so many catarrhal cases now.

DR. S. H. AYER reported

A CASE OF EMPYEMA, WITH RECURRENCE AFTER APPARENT RECOVERY.²

DR. INGALS: I think the patient, as well as the reporter, deserves a very high degree of credit for mutually sticking together through such a series of disasters and troubles. I think the report is admirably made, and I think the reader deserves great credit for his perseverance, his care and his skill.

DR. F. L. JACK read a paper on

OPERATIVE TREATMENT FOR THE RELIEF OF CHRONIC SUPPURATIVE AFFECTIONS OF THE MIDDLE EAR, WITH REPORT OF THREE CASES.³

DR. BLAKE: I have listened to Dr. Jack's paper with much interest, and would like to ask one question, that is as to his observation in regard to the effect on the chorda tympani in the removal of the malleus and incus.

DR. JACK: There is some loss of the sensation of taste on the side of the tongue corresponding to the ear operated upon. This is said to disappear in a few days.

DR. BLAKE: I think the removal of carious ossicles comes under the head of a simple, justifiable surgical procedure, and am quite in accord with the remark which the reader makes also with reference to preliminary treatment, having in view the cleansing of the suppurating cavity in the upper portion of the tympanum by the use of the middle ear syringe; the presence of horizontal reduplications of mucous membrane often presents a decided obstacle to the passage of the pus which may be formed above them, downward into the lower portion of the tympanic cavity and so outward, and it is sometimes found that the use of the middle ear syringe can be much favored by a thorough

² See page 547 of the Journal.

³ See page 545 of the Journal.

division of these folds from before backwards. Given careful and painstaking attempts to stop a suppurative process in the upper portion of the tympanic cavity without resort to operation and given caries of the malleus and incus, removal of these bones, as the writer has said, comes distinctly in the line of simple surgical procedure and as such is to be carried out with the precautions which he mentions.

In confirmation of Dr. Jack's remark as to persistence of the hearing in cases of loss or removal of the membrana tympani, malleus, incus and stapes, I may mention one case in which there has been destruction of the membrana tympani, sloughing away of the malleus, incus and greater part of the stapes, with a fair amount of hearing remaining under these conditions.

DR. J. O. GREEN: The paper is a very interesting one. I think the removal of carious bone is indicated and experience proves that it can be done perfectly well here. I am very glad to see the principles of general surgery being applied to these minute parts as they can and should undoubtedly be and the whole principle of the treatment of otorrhoea I would bring under general surgical treatment applied to the minute anatomy of the parts and with the adaptation of special instruments to get at those parts.

In regard to the occurrence of caries here, I think the later German observations show that the anvil is more inclined to caries than the hammer. I think recent observations in the *Archiv für Ohrenheilkunde* from Schwartz's clinic show that the incus is 40% oftener involved than the malleus, and therefore I think in the removal of these bones that it is better to include the removal of the incus with the hammer. If you remove the hammer the incus is of no possible use, and as the pathological investigations of the last few years have shown that the incus is more likely to be diseased than the hammer, therefore, I think we had better take out both when we take out either. I have had two cases this winter which are in confirmation of this. In one case there was no incus remaining. In the second case I brought away the merest little shell about twice the size of a large pin-head, so thin it crumbled in wiping it off the hook with which I brought it out. The hammer in this case was largely diseased, but still there was a large part of it remaining.

In regard to the rapidity with which caries occurs in these cases, I have had a case this winter which interested me because I was able to determine this point. I had a case of scarlatinal diphtheria, or, as it is sometimes called scarlet fever and diphtheria, with total loss of the drum membrane. I did not see the case until the drum membrane was destroyed. In syringing a week or two afterwards the incus and hammer came away. Both showed the beginning of caries which is an interesting fact showing how rapidly caries may attack these bones. It could not have been more than four weeks in this case.

In regard to removing the incus I cannot think that the forceps will succeed in the majority of cases. I have experimented some on the cadaver and have done the operation a number of times, and the only instrument I find to work satisfactorily is the little incus hook invented by Ludewig. The incus in the majority of cases lies so high up that I do not think it is possible to get at it satisfactorily with a pair of forceps. The bones are firmly attached, and this little hook can be passed far up into the cavity.

The question of hearing is an interesting one. You

find these cases of caries of the ossicles with very good hearing. You find the drum membrane entire except in the membrana flaccida with ossicles carious and the hearing very good indeed. I have had two of these cases where it was quite a question in my mind what to do, for if I took out the drum membrane I was sure to injure the hearing. In both of these cases I found it was necessary and was glad I did it. In one of the cases I did and in the other I did not remove the whole of the drum membrane. In the future I should take out almost the whole of the drum membrane I think. You often have with these cases caries of the walls of the tympanic cavity. In one of these cases I had but a small opening into the tympanic attic and the drum membrane healed before I got rid of caries of the attic wall. In the next case I took out nearly the whole of the drum membrane with greater success, so that in the future with my present knowledge I should take out almost the whole drum membrane in order to make sure I did not get too rapid healing. Having taken the hammer and incus a cicatricial membrane over the whole drum membrane would be as good as a cicatrix up in the little angle where you take out only a small piece and if you have caries of the walls you have a large opening that will keep open a long time and you are able to treat that caries until it has got well.

In regard to prognosis we must be careful not to make it too favorable, for in quite a proportion of cases we do find caries of the walls of the attic which will keep up the otorrhoea afterwards. Although I believe in the operation thoroughly, and although I think its future will be more useful than now, yet we must bear that in mind and be guarded in the prognosis. You are not sure when you begin on the case that you are not going to find caries of the tympanic walls.

In regard to relapses I think we must be a little careful also about promises, because in a certain proportion of these cases, according to the modern theory which is probably the correct one, there are in the irregularities of the bone, spots in which the microbes lie at rest for a considerable time when they will, from some cause we do not understand, again resume their growth and activity, and set up a fresh attack of inflammation. In spite of these possibilities, in the majorities of cases I am satisfied the operation is an extremely useful one, and occasionally saves life.

DR. BLAKE: The incus often slips upward out of the way and is in such position as to be difficult to get hold of. I have generally used for the removal of both the malleus and incus a snare with stout wire. After removal of the malleus and incus or where disarticulation of the incus from the stapes has been effected I have in several instances added to the operation a step found useful in cases of non-suppurative inflammation of the middle ear, namely, division of the tendon of the stapedius with reference to further freeing the stapes.

DR. SPEAR: I have been pleased by listening to Dr. Jack's paper though he has mixed his cases so that unless they are disentangled the impression will be given that all cases of loose ossicula would come under the head of removal of the ossicles. He reports three cases of removal of the ossicles in cases of chronic suppuration of the middle ear for the cure of the chronic suppuration. The second case is one of simple exfoliation of the malleus which he fails to

trace to a conclusion and which I happen to know about as the result of the case is still very much in doubt. I have had the case under treatment for the last two months. The patient still has a large amount of granulations in the canal, a profuse discharge of pus, and has no hearing. It was a clear case of exfoliation of the malleus.

I have here the *American Journal of Otology*, in which there is a review of Wolf:

"Exfoliation of The Necrosed Bones of The Ear." Os-car Wolf: *Archives of Otology*, September, 1881.

The author of this paper finds that the cause of exfoliation of these bones in most cases is due to the so-called exudative necrosis in scariatinum diphtheria. The exudation is propagated from the pharynx through the tubes.

This diphtheritic process is not the only cause, for in twenty-eight cases analyzed by Wolf we find, scariatinum, eighteen; seroflu, two; typhus, two; measles, one; parotitis, one; diphtheritis, one; acute tuberculous, one; while in four there could be discovered no constitutional affection.

Exfoliation of the small bones rarely occurs without some constitutional disease. The incus alone was exfoliated six times in twenty-eight cases, while the malleus alone in two cases. The malleus is nourished not only by the vessels of the tympanum through the tympanic artery, but also from the external meatus."

I think the reading of this will emphasize what I have remarked that it is not an uncommon thing to find exfoliation of the ossicula. It is, however, very unusual for a carious bone to continue in the ear and the healing process go on, so that Dr. Jack and the other gentlemen who have done this operation are certainly correct.

DR. JACK: There is certainly no doubt that one or more of the ossicles are at times exfoliated in cases of long existing otorrhoea, especially in children. Usually, however, by the time this occurs caries of other parts of the ear is well on its way. Consider for a moment what desperate chances are taken all the time a long standing suppurating middle ear continues discharging. We have a septic cavity surrounded by bone which is in close relation to very important parts; any portion of which is very liable to become carious at any time, and there is no telling whether the process will stop short of serious mastoid trouble or abscess of the brain. Again there is possibility of absorption of septic matter to say nothing of the gradual loss of hearing. In fact carious bone in the middle ear can do no end of mischief. If the diseased portion can be safely removed why not remove it? Is it not quite as important to get rid of as possibly any diseased bone in the body?

I think the hook spoken of by Dr. Green would be useful in bringing the incus down into view in cases where the long process could not be reached with forceps. The bone is, I believe, generally so loosely held in its place as to offer little resistance to its removal.

DR. SPEAR: I do not wish to be understood as not advocating the operation. I agree that the carious malleus or incus, or both, should be removed under all circumstances in which the purulent process has been going on some time, but the report of the second case shows that Dr. Jack took hold of the polypus with the snare, and the malleus, which was loosely attached came out with it, while the contrast between the two cases is very marked. He leaves no record of improvement in hearing and I know there has been none,

and not only that, but the polypus and the granulations returned and still remain in spite of the operation. I think it would have been a much stronger paper had that second case been left out.

DR. JACK: We are told to report apparent failures as well as successes. Inasmuch as the patient neglected to continue under observation after the operation, the case shows nothing for or against the operation. Still I feel sure the ear was in a better condition to effect a cure after, than before, the operation.

THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

MEETING, March 12, 1892.

DR. E. H. BRADFORD reported, by invitation,

A CASE OF HYSTERECTOMY IN A CHILD,

of which the following is an abstract. The patient was a child who had enjoyed excellent health, until within the last six months.

A tumor was discovered in the lower portion of the abdomen, and this grew rapidly in the three months previous to the time when the child entered the hospital. There were no digestive disturbances or symptoms of pain or fatigue. But as there had been a rapid increase in the size of the tumor, an operation was thought advisable. On palpation, a large mass could be felt in the lower portion of the abdomen, a short distance — an inch and a half — below the umbilicus, and filling the lower portion of the abdominal cavity. The tumor was movable and irregular in shape. It appeared to be attached, in the middle line, to the lower part of the pelvis. An abdominal incision was made, and a firm, resistant tumor was found, occupying the middle line of the body, and without adhesions to the intestine or to the abdominal wall, except at the base. In order to remove the tumor, it was found necessary to free the attachments of both broad ligaments and to enlarge the incision above the umbilicus and to take the mass of the tumor out of the abdominal cavity. The tumor was friable, and some bleeding occurred from the unavoidable tearing of the external surface. This was controlled by the application of a rubber-tube around the base of the tumor. Hysterectomy pins were inserted at the base, and the *ecruseur* applied. The tumor was pressed upward by pressure in the vagina as well as by pulling it upward by means of hooks, and in this way it was possible to place the wire of the *ecruseur* around the neck of the uterus below the mass of growth. The tumor was then cut off above the point of insertion of the needles, and the stump seared by the Paquelin cautery. The abdominal incision was sewed up, with the stump outside of the abdominal cavity. The patient suffered from some shock. The pulse was rapid and remained rapid for nearly a week. There was no elevation of temperature beyond the two days following the operation. The case progressed rapidly and uninterruptedly to recovery. The slough came away after a fortnight, and the wound healed entirely at the end of two months. The patient was discharged from the hospital six months after entrance. There is no evidence of recurrence at present.

On microscopic examination, the tumor was found to be a growth of the ovary, which had invaded and surrounded the substance of the uterus so completely as to form one mass, it being impossible to distinguish

without microscopical examination where the abnormal tissue ended and the normal uterine tissue began. On careful examination, it was found that the whole of the growth had been removed, and that the base consisted of normal uterine tissue. The rapid cellular development had prevented any cystic formation in the growth, so that the tumor was entirely solid. It is too early to form an opinion as to probability of recurrence.

DR. F. H. DAVENPORT referred to the precocious development of the mammae and of the pubic hairs sometimes seen in these cases of pathological processes in the genital apparatus of girls.

DR. E. H. BRADFORD said that he had expected to find a sarcoma in this case, that being the commonest form of rapidly growing tumor in children. As to the frequency of disease of the ovaries in children, Spencer Wells has recorded only three ovariotomies in children out of a thousand cases.

DR. C. M. GREEN reported

A CASE OF PLACENTA PRÆVIA COMPLICATED WITH UREMIA AND IMPENDING ECLAMPSIA.¹

DR. C. W. TOWNSEND reported

PLACENTA PRÆVIA AND UREMIA IN THE SAME PATIENT.²

DR. A. WORCESTER asked, in view of the embarrassment of the kidneys, why not use chloroform and avoid the irritation from ether.

DR. C. M. GREEN replied that, notwithstanding the theoretical objection to ether in these cases, he had always used it, and had never seen any apparent ill results.

DR. A. WORCESTER said that at the Johns Hopkins Hospital it was considered almost criminal to give ether to a patient having any embarrassment of the kidneys.

DR. G. HAVEN had seen a case of eclampsia where chloroform was used and where the patient was very blue apparently owing to the chloroform.

DR. A. WORCESTER had gone from ether to chloroform simply from theoretical reasons and from published reports, but he had had good results with both of these anaesthetics.

DR. W. L. RICHARDSON had always used ether and with good results. As regards hemorrhage after delivery in cases of eclampsia, he had often noticed that this was more than in non-eclamptic cases, even where ether had been used to the same extent. He believed that it was a fortunate provision and one that tended to stop the eclampsia.

DRS. GREEN, C. E. STEDMAN and SINCLAIR believed that the post-partum hemorrhage was greater in these cases.

DRS. J. G. BLAKE and TOWNSEND thought that there was naturally no more tendency to hemorrhage after delivery in eclampsia than after ordinary delivery where the same amount of ether was used, but that we were less ready to check it at the start believing in its salutary effect on the convulsions.

DR. MINOT said that about nineteen years ago he was called to a woman, twenty-four years old, who had labor-pains for several hours. For some days she had complained of a sense of fullness in the head, but without headache, had epistaxis once in the night, and noticed that her ankles were swollen. At 4 a.m.,

spontaneous rupture of the membranes took place. The os was then hardly dilated, but soft. The presentation was normal. The pains continued through the day, the os slowly dilating. Towards evening the pulse began to rise, and at 7 p.m., was at 120. The os being at that time sufficiently dilated the forceps were applied, and delivery was easily effected. The child, male, was, and is still, living. About a pint of blood was discharged at the birth. The urine, by catheter was very "smoky." The pulse continued rapid, but there was no other unfavorable symptom until 9 p.m., when a convulsion, with frothing at the mouth, took place, lasting fifteen minutes. Ether was given by inhalation, and after an hour of heavy sleep consciousness returned. At midnight another convolution occurred. A pint of blood was then taken from the arm, and a quarter of a grain of sulphate of morphia was injected under the skin. Consciousness again returned, but at 3 a.m., of the next day, there was a third and last convolution, less violent and shorter than the others. The patient did well, although for some hours she was in a confused state of mind. Twenty-four hours after delivery twelve ounces of urine, the secretion of twenty-one hours, were drawn by catheter. It was less dark than before, and was moderately albuminous, and it contained a few transparent casts, with an abundance of rhombic uric acid crystals. The patient was freely purged by jalap and cream of tartar, followed by castor oil, and the urine became normal in a few days.

The plethoric condition of the patient, the epistaxis, and the sensation of pressure in the head seemed to indicate blood-letting in the case, and while it could not, of course, be assumed that life was saved by this procedure, it is certain that no harm followed it.

DR. R. L. HODGDON said that he always used chloroform in eclampsia, but he had never dared to do a prolonged operation without the use of ether.

DR. B. E. COTTING referred to several cases of eclampsia where he obtained favorable results by bleeding.

DR. J. G. BLAKE could recall no case out of a very large number where bad results ensued on the use of ether. In a woman now living he had given some twenty years ago ether more or less continuously for thirty hours for post-partum convulsions.

DR. W. L. RICHARDSON said that the mortality from eclampsia has very markedly diminished since we have early emptied the uterus. Twenty years ago the mortality was stated to be 83 per cent.

DR. C. M. GREEN said that Lusk in his edition of six years ago, puts the mortality from eclampsia at 23 per cent., but in careful hands it is undoubtedly much less. He can recall but very few fatal cases at the hospital. Nevertheless, some cases will die even with the best care, and even if they are delivered at once. A great deal depends on the care subsequent to delivery. He remembers one case where the patient was nearly drowned in her saliva, the pilocarpine having no effect on the skin.

DR. E. J. FOSTER referred to two cases of labor where there was prolonged etherization and much post-partum hemorrhage.

DR. W. L. RICHARDSON, DR. A. WORCESTER, and DR. A. D. SINCLAIR had not the slightest doubt but that ether favored post-partum hemorrhage.

DR. C. M. GREEN said that ether in any amount predisposed to post-partum hemorrhage, although he would

¹ See page 551 of the Journal.

² See page 550 of the Journal.

never hesitate to give plenty of it for operative purposes. The improper use of ether and the one which especially favored hemorrhage was the use of it in large quantities in the first stage. Another frequent cause of post-partum hemorrhage was, he believed, the expression of the placenta in too much of a hurry, before the uterus had time to retract. He would set no time-limit for the third stage, but would not attempt to express the placenta until the uterus had firmly contracted several times, and a proper amount of retraction had taken place. Immediate Credé without reference to the state of the uterus was a frequent cause of post-partum hemorrhage.

DR. W. L. RICHARDSON said that he had always taught that there was a third stage of labor. It was therefore absurd to try to expel the placenta until the uterus had begun to contract, or to use Credé's method except when the uterus was hard. He recalled one case of placenta praevia at the hospital where after the delivery of a living child by version he had thoughtlessly put in his hand and peeled off the placenta before the uterus had begun to contract. A severe hemorrhage took place at once from the open sinuses in the lower uterine segment.

DR. A. WORCESTER said that he had had much fewer cases of post-partum hemorrhage since he had adopted this principle in the management of the third stage.

DR. S. L. ABBOT referred to a case in the days when ether was first used in confinement, where two pounds of ether were given during a labor of 56 hours. The child was finally delivered with forceps after waiting, as was the practice then, perhaps 24 hours longer than we should wait now. It was still born as might be expected.

DR. RICHARDSON said that ether given in this way would indefinitely prolong and stop labor.

DR. HODGDON said that 10 years ago he had given ether in the first stage so that it indefinitely prolonged the labor, but he had not used it so since then.

DR. A. WORCESTER said that he considered ether much inferior to chloroform in quickly relieving the pains of labor, although for obstetric operations he uses ether.

He has for some time used with great success a mixture of bromide of ethyl 1 part, chloroform 3 parts, alcohol 4 parts. Three or four drops are put on a handkerchief and very speedily give relief from pain, although they do not stop the labor, and the patient does not lose consciousness but knows what is going on and is able to obey orders.

The advantages over chloroform are that this mixture is quicker and safer. It is safer because the bromide of ethyl tends to produce hyperemia of the brain which neutralizes the ischaemia produced by chloroform.

DR. C. W. TOWNSEND reported briefly

THREE CASES OF OBSTETRICAL INTEREST

which he had seen in the out-patient department of the Lying-in Hospital during the week.

The first case was one of twins, where the first child presented by the feet, sitting cross-legged as it were, in such a way as to prevent delivery. There had been no progress for some time. The pulling down of the leg that was caught gave immediate relief to the mother and was followed by the speedy delivery of a living child. After the delivery of this child the mother's

abdomen measured 52 inches in circumference, she being extremely obese. On rupturing the second sac the second child presented O. D. P. extended. Finding that it was impossible to flex the head manually, and that the position was rapidly becoming a brow, ether was given and Dr. Townsend on introducing his hand found that both hands of the child were folded below the chin, in such a way as to prevent flexion. On pushing these out of the way, the head was easily flexed, rotated manually to O. D. A., forceps applied at the brim and living child, number two, at once delivered. The children weighed six and one-half and seven and one-half pounds respectively.

The second case was of interest from the fact that the patient then in labor with her seventh child, gave the history of instrumental delivery each time. She had then been in the second stage for three hours. The child presented at the superior strait O. L. A., good flexion. The pelvis was slightly contracted in all its dimensions, the true conjugate measuring three and three-fourths inches. Delivery was easily accomplished with the Vienna forceps.

Case number three was of interest in showing the use of encouragement and the evils of discouragement. The externe having just had charge of the case of contracted pelvis, jumped to the conclusion that case number three also suffered from the same trouble, as her labor was a long one owing to poor pains, and had expressed the opinion that instruments would be necessary. After a period of several hours of no progress, Dr. Townsend succeeded in bringing about delivery within ten minutes of his arrival at the case, simply by encouragement. This has been well called by Dr. Richardson, the use of mental forceps.

ADDENDUM.

At the reading of the records of the Society at the next meeting, DR. B. E. COTTING said that he could not let the matter of the use of chloroform as advocated by Dr. Worcester go without protest. Chloroform has caused death and that too, whether diluted or not. The series of letters published in the *Boston Medical and Surgical Journal* some fifteen or twenty years ago, under the name of "Inominatus," were all by the same person, all protesting against the use of chloroform, and he was glad to see that the English medical journals had of late years come around to the same way of thinking. The same one who had protested then, would still protest now.

DR. S. L. ABBOT said that as far as he could learn from Dr. Brunton's therapeutics, bromide of ethyl recommended to be used with chloroform, so far from counteracting any of its effects was an extremely powerful drug and would only increase the effects of chloroform.

THE VALUE OF PRISON LIFE.—Under the heading "Back from Prison," an advertiser in a German daily paper states that she has just been liberated from prison where she had served a term for libel of a certain reputable physician. She further states that while in prison she had an opportunity, which the extent of her practice precluded before, of going over in her mind the histories of her many thousand cures, and from the material thus obtained she has been able to formulate a method by which she can positively cure consumption and rickets.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JUNE 2, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

TREATMENT OF ACUTE RHEUMATISM IN THE PARIS HOSPITALS.

DR. MARCEL BAUDOUIN has made the tour of the hospitals of Paris to ascertain the methods in vogue for the treatment of acute rheumatism, and has published the results of his inquiry in *La Semaine Médicale*.

Naturally, the medicine the most in favor is still the salicylate of sodium, which is everywhere the remedy first thought of, and generally in some manner prescribed. According to Dujardin-Beaumetz, it is the only specific medicine, of which, to obtain the full effects, the doses employed should be proportioned to the intensity of the rheumatism. He would prescribe fifteen grains every three hours, day and night, to very acute and febrile cases, and the treatment should be continued several days after the cessation of the pain and fever. There are but two contra-indications to the employment of this medicament, renal impermeability and pregnancy: for patients who may be laboring under the one or the other of these conditions, he would substitute exalgine, phenacetin, or antipyrine.

Talamon, of Bichat Hospital, thinks that there is no contra-indication to the employment of the salicylate, not even albuminuria. It is very important, says Talamon, to give large doses and to push them. Small doses, thirty to forty grains a day, amount absolutely to nothing. Begin with fifteen grains every two hours till you have given six doses; this is enough for the first day. The next day, eight such doses may be given; and this treatment must be kept up four, five, or six days, according to the tenacity and intensity of the malady. Ordinarily, by the fourth day, the fever has fallen, the pains and the articular swellings have ceased. Then the tapering-off method is begun, only four of the fifteen-grain doses being given each day for four or five days, then two doses a day for five or six days, the patient being kept in bed all this time. Relapses call again for the full doses. When the stomach

tolerates the medicine badly, it may be given with Vichy water, the patient swallowing the medicine in capsules (cachets), and washing it down with a small glass of Vichy. For neuropathic patients, he would occasionally combine the dose of the salicylate with twenty grains of bromide of potassium.

"All the therapeutics of rheumatism," says Professor Chauffard, "is summed up in two medicines, sodium salicylate and antipyrine." For several years past, he has resorted in preference to antipyrine, giving to adult patients from sixty to one hundred and twenty grains a day. The latter is a maximum dose rarely attained. The effect of the medicine in producing analgesia and fever-fall is immediate, and in most cases the swelling of the joints begins soon to abate. The antipyrine is ordinarily well borne, and produces none of the painful head-symptoms which sometimes follow the salicylate when given in full doses. If the sweating is too profuse, M. Chauffard prescribes concurrently with the antipyrine, several granules of atropine.

There is but one advantage which the salicylate has over antipyrine: it is an agent of elimination which favors diuresis and the removal of waste-proteids. It is, then, a good plan to associate with antipyrine as a corrective the usage of *milk diet* and *diuretic ptisans*.

Professor Straus prescribes salicylate of soda, but he gives it only twice in the twenty-four hours in the dose of forty-five to sixty grains; the first dose may be administered late in the afternoon and the second two or three hours afterwards. A convenient vehicle is peppermint water. He thinks that the effect of the medicament is much more energetic if it be administered in this way, than if the daily quantity (six to eight grammes) were divided into numerous small doses to be given every two or three hours during the twenty-four. The medicine is continued as long as the fever and swellings last; then it is given in diminished doses (the quantity being lessened by about fifteen grains a day) for five or six days. When the salicylate provokes profuse and inconvenient sweats, M. Straus gives an atropine tablet ($\frac{1}{10}$ to $\frac{1}{5}$ grain) in the evening.

M. Straus has no doubt that acute rheumatism is an infectious disease, caused by "an animated agent," but all attempts, thus far, by himself and others, to discover any specific micro-organism have failed. Everything points to the conclusion that it is not a streptococcus nor a staphylococcus, nor the pneumococcus; the efficacy of salicylate of soda is too manifest in typical rheumatism, and its action is too insignificant, if not nil, in affections due to the latter microbes to justify any supposition that they have any causal agency in rheumatism, though often found connected with the complications of acute rheumatism and in the pseudo-rheumatisms.

Professor Bouchard associates salicylate of soda (seventy-five grains in the twenty-four hours) with sodium bicarbonate (one hundred and fifty grains a day).

M. Barth, while prescribing salicylate of soda in

fairly large doses from the beginning of the sickness till convalescence is well established, insists upon complete rest in bed (at least three weeks) notwithstanding disappearance of the joint-swelling and fever, as an essential condition to good recovery. Where the salicylate is contra-indicated (from pregnancy, cardiopathy, Bright's disease, arterial atheroma), or badly tolerated, M. Barth has recourse to quinine and antipyrine combined (five grains of quinine with ten of antipyrine, three times a day.) At the same time he applies to the affected joints a series of blisters and gives diuretics, tonics, and sometimes vapor baths.

M. Barié, besides treatment by the salicylate of soda which is given in three daily doses of thirty grains *just before meals*, prescribes absolute rest and the application of soothing liniments to the joints which are kept constantly wrapped in wadding. The diet should be principally milk; he does not absolutely prohibit alcoholic stimulants. Is fond of ordering Vichy and other alkaline waters, and if the joint swellings tend to persist, he resorts to revulsives, as iodine paint and cantharidal collodion. In some cases, he finds benefit from rather large doses of phenacetin and exalgine.

M. Comby used to give quinine in acute rheumatism — fifteen to thirty grains a day. Now he trusts to salicylate of soda fifteen grains every two hours in severe cases. Where the latter medicine is not well tolerated, he resorts to quinine, in full doses. As accessory medicines, he prescribes purgatives and diuretics.

In acute rheumatism in children; M. Simon and M. Sevestre trust exclusively to salicylate of soda, giving from thirty to forty-five grains a day to children under six years of age. It is better to give the medicine in three or four large doses (eight to twelve grains) than in numerous small doses during the day. Diet to be almost exclusively milk. The joints are wrapped in wadding and covered with oiled silk.

M. Ollivier has tried antipyrine repeatedly, and not obtained satisfactory results, he has long discontinued the use of colchicum.

"In acute rheumatism, *à frigore*, the salicylate of soda still gives the best results; the daily quantity being from thirty to ninety grains, according to the age of the child."

FIRST ACTIONS OF WOUNDED SOLDIERS.

In an article on this subject, in the *Popular Science Monthly*, Mr. G. L. Kilmer relates some of his own observations during our civil war, and cites others reported on good authority. The sensation of a soldier when he is first wounded is often out of all proportion to the severity of the wound. His first action when he finds himself wounded is also largely dependent upon what he is doing at the time. It follows, therefore, that the first actions of severely wounded soldiers are very different from each other; but the effect seen on the stage where a man staggers, clasps the wounded spot and then falls is very rarely or never seen in battle. A slight wound is often felt more at the time than a fatal one. A spent ball may make the victim

feel as though an arsenal had struck him, whereas the wound which is finally fatal may be either not noticed or may be considered a slight prick. In a general way, when felt at all, bullets through muscle usually produce a burning sensation; when bones are broken, stinging accompanies the burning; when bones are hit but not broken, there is a numbing sensation in the whole region involved in the shock, followed very soon by severe and sometimes intense pain; when muscles and tendons are involved, there is a tugging sensation sometimes very slight; and shell wounds produce feelings similar to those from bullets. Cannon balls, as a rule, leave nothing behind to exhibit feelings. When a man feels that he has been hit, he often has a mixed sensation, as if not quite certain whether he wants to cry or swear. If a soldier is in a state of intense nervous excitement, he may apparently be entirely unconscious of a quickly fatal wound and may continue his way as if nothing had happened until he suddenly drops dead. Well authenticated cases are mentioned in which, after wounds through the heart and even after complete decapitation, the body has remained in the saddle with the arm stretched out as it was before the wound was received, for some seconds before falling. From his experiences upon the battlefield, the author formulates a rule that a man who is hit above the hips comes down. After a wound through an important organ, men, unless much excited at the time, generally sink at once, or reel and tumble with very little self-control. The wound and the fall create a temporary panic, but as long as consciousness remains, they strive to help themselves. A wounded man's first thought is of the rear of the column, not from fear, but because he expects surgical aid from that direction. As long as he can move, he goes towards the place of help; when no longer able to move, he makes himself as comfortable as possible and waits.

ELECTRIC LIGHTING IN ITS RELATION TO PUBLIC HEALTH.

A COMMITTEE of the Society of Public Medicine of France recently communicated a report¹ upon the subject of electric lighting (January 27, 1892), in which the above question is treated with reference to the general effect upon health, and as to its effect on eyesight. The conclusions are as follows:

(1) Under ordinary conditions of use, the electric light does not injure the eyesight.

(2) Electric light is superior to all methods of lighting known at the present time, since it has little or no effect upon the composition of the air and generates but little heat. Its employment may, therefore, be generally recommended for occupied apartments.

(3) The danger of fire arising from the use of electricity can be avoided by a careful arrangement. Some of the accidents are due to the contact of conductors of electric currents. The number of such accidents

¹ *Revue d' Hygiène*, February, 1892.

has diminished, in proportion as the use of electricity has increased, which proves that the accidents which were attributed to it in earlier periods were due to ignorance of the conditions of proper management. Attention should be called to the establishments or plants in which mixed light is used (electricity and gas), and to currents of high tension.

(4) There should be no special danger attributable to electricity in the establishment of central stations. The danger amounts to absolutely nothing if hydraulic motors are employed. If steam is used, then the danger is the same as that which attends any other industry in which coal-furnaces are employed for generating power, and all regulations intended for the protection of the public health and safety which are required for such furnaces or boilers suffice equally well for central electric stations.

MEDICAL NOTES.

A PRACTICAL USE OF BACTERIA. — It is reported that a few weeks ago a plague of mice threatened to destroy the whole harvest of Thessaly, in Greece. The Greek Government asked Professor Löffler, of Greiswald, to assist it, which he effectually did by inoculating some of the mice, and turning them loose, thus causing a fatal epidemic among them.

CHRISTIAN SCIENCE. — A case has recently been tried in Southern California which has attracted a good deal of attention. A young man suffering from an accumulation of pus in the frontal sinus, which had perforated into the orbit, was attended by a professor of Christian Science, who treated him by the usual expectant methods of that school. After five days the patient died of meningitis, the pus having also perforated into the cranial cavity. In the prosecution which followed, a few statements made by the defendant are interesting. She testified that Christian Science treated strychnine poisoning, the bite of a rattlesnake, smallpox, cholera and fevers in the same way. She admitted that surgeons were necessary in cases of broken bones, but that in the case at issue, surgery was not admitted, and that the pus which had accumulated would, by her system, be allowed to remain in the body. The jury, after remaining out all night, finally returned a verdict of not guilty. It was generally believed that this result was reached because the defendant was a woman, and that many women had appeared in court and did all that they could to elicit sympathy.

THE SOCIETY OF THE RED CROSS. — The fifth international conference of this society was held in Rome during the last week in April. Most of the nations of the earth were represented, and many distinguished men were sent as delegates. The Geneva treaty, from which the society may be said to have begun its existence, was signed in 1864 by France, Belgium, Italy, Sweden, Portugal, Switzerland, Holland, Spain, Denmark, and several German States. The United States was admitted in 1882. Conferences have been held at varying intervals, this being

the fifth. The King of Italy has given ten thousand francs for investigations as to the best method by which each soldier on going into battle may be provided with materials for immediate use if wounded. Medals will also be prepared as prizes in an international exhibition of materials and apparatus for use on the battlefield. This exhibition will be held in connection with the next international medical congress. Among the subjects discussed were: the practical use of floating hospitals; the protection of the red cross emblem from unauthorized use, as for proprietary medicine advertisements, and the like; free transportation of supplies, and popular instruction in red cross methods.

THE STOMACH AND THE CORSET. — In a recent essay, published in Paris under this title, Dr. Chapotot, among other disadvantages of tight lacing, describes its effect upon the stomach, especially in connection with the gurgling sounds in the epigastric region often noticed in young women. These noises he attributes to a vertical bilobulation of the stomach. The air, during inspiration with any fluid present, is pushed from the upper to the lower lobe and during expiration is forced back again by the pressure of the abdominal muscles. In passing by the constriction, this air and liquid produce the characteristic gurgling sounds. If the constriction is removed the sounds are no longer heard.

NEW ENGLAND.

THE AMERICAN SURGICAL ASSOCIATION is now in session in Boston. On Tuesday morning the President's Address was delivered by Dr. Phineas S. Conner, in the Natural History Building. Several interesting papers were read and discussed, a detailed account of which will be given in our columns next week. Between thirty and forty members from other cities are present.

The following officers and members were elected at the Executive Session: President, Dr. N. Senn, of Chicago; Vice-Presidents, Dr. W. W. Keen, Philadelphia, Dr. Chas. B. Porter, Boston; Secretary, Dr. J. R. Weist, Richmond, Ind.; Treasurer, Dr. John B. Roberts, Philadelphia; Recorder, Dr. J. Ewing Mears, Philadelphia; Members of Council, Dr. Roswell Park, of Buffalo, and Dr. R. F. Weir, New York; Member of the Executive Committee of the Congress of American Physicians and Surgeons, Dr. R. McLane Tiffany, Baltimore — alternate, Dr. James McCann, Pittsburgh.

It was decided to hold the next meeting in Buffalo, in May, 1893; and Dr. Roswell Park was elected Chairman of the Committee of Arrangements.

The following were elected to membership: Dr. John B. Deaver, Philadelphia; Dr. Frederick H. Gerrish, Portland, Me.; Dr. Wm. S. Halsted, Baltimore, Md.; and Dr. H. R. Wharton, Philadelphia.

CENTENNIAL CELEBRATION OF THE CONNECTICUT MEDICAL SOCIETY. — The Connecticut Medical Society was organized in New Haven, on May 25, 1792. The centennial celebration was held in the same city

last week, and was very largely attended. Several interesting papers were read, describing the condition of medicine, in New England, prior to, and subsequent to 1792. The following officers were elected: President, C. B. Newton, M.D.; Vice-President, Francis D. Edgerton, M.D.; Secretary, N. E. Wordin, M.D.; Treasurer, W. W. Knight, M.D.

NEW YORK.

THE MORTALITY REPORT FOR THE WEEK ending May 21st, shows a gratifying improvement in the health of the city. The number of deaths was 854, which is 26 below the average of the corresponding weeks for the past five years, and represents an annual death-rate of 24.48. There was no death from typhus fever, and only one from small-pox reported. Measles, scarlet fever and diphtheria, however, still continue very prevalent.

RELIEF FOR THE OVERCROWDED ASYLUMS. — The sale to the city of a portion of Ward's Island, hitherto owned by the State, having been authorized by law, the Board of Emigration Commissioners, who formerly had charge of it, have transferred it to the municipal authorities: and the work of relieving the overcrowded city asylums for the insane has already commenced, by the occupation of the buildings that have been used by the Emigration Bureau, some six or seven hundred patients from the institutions on Hart's and Blackwell's Islands having been removed to them.

THE MANHATTAN HOSPITAL. — The handsome and well-appointed new buildings of the Manhattan Hospital and Dispensary was opened for inspection on May 26th, when a reception was given by the Board of Managers and the Ladies' Association of the Hospital. This institution is doing an excellent work in the upper part of the city, the district covered by it extending from 86th Street to Spuyten Duyvil and from Sixth Avenue to the Hudson River. It has been closed for two months on account of the improvements being made.

Miscellany.

SUBCUTANEOUS BLOOD INJECTION AND TRANSFUSION.

VON ZIEMSSEN,¹ in a paper before the Congress for Internal Medicine in Leipsic, describes his method of injecting blood subcutaneously as a substitute for transfusion. Blood is taken from a vein through a hollow needle into a sterilized syringe and immediately injected into the subcutaneous tissue of the thigh or back. It is then massaged actively until no tumor is felt. In this way it is prevented from coagulating, at least until it has become thoroughly diffused in the subcutaneous tissue. By this method he has injected as much as 400 cubic centimetres at one time. The process is painful so that it is generally necessary to narcotize the patient. The region remains sensitive for some time but shows no signs of inflammation.

¹ Münchener med. Woch., May 10th.

For transfusion he employs the following method, and has never produced any disagreeable results with it. A hollow needle is introduced into the vein of the person from whom the blood is to be taken and another one into the vein of the patient. Three syringes each holding 25 cubic centimetres are thoroughly cleaned and warmed, blood is then drawn into the syringe which is immediately detached and connected with the needle in the patient's vein and emptied before coagulation can begin. While the first syringe is being emptied, the second is being filled. The first after being emptied is washed in sterilized water while the third is being filled with blood. When the third is full, the first has been washed and is ready to be used again. In this way an almost constant stream of blood passes from one person to the other. The needles are put into the vein directly without any previous incision of the skin.

THE BACILLUS OF ECLAMPSIA.

GERDES,² in the pathological department of the University at Halle, has found a bacillus in the liver, lungs, kidneys and blood of a severe case of eclampsia. Cultures of this bacillus when inoculated in rats and mice cause shallow respiration, coma, subnormal temperature, and in the mice, convulsions. It is very virulent, causing death in a short time. In guinea-pigs intravenous injections caused convulsions, intraperitoneal did not. The bacilli were found often in the form of bacillary emboli, the starting point of which was probably a focus in the placenta.

INTESTINAL EVACUATION IN OPERATIONS FOR OBSTRUCTION.

MR. GREG SMITH,³ in a paper read before the Royal Medical and Chirurgical Society, advocates operative evacuation and drainage of intestinal contents in cases of obstruction of the bowels where distension is a marked feature. Mere over-distension of the intestinal walls is a potent factor in the production of obstruction: physical and physiological causes combine to render an over-distended gut incapable of passing onwards its contents. Therefore operative treatment of intestinal obstruction is not completed until this continuing cause is removed. According to the nature of the case, the author believes that the measures adopted should be one of the following: (1) Simple evacuation of contents with immediate return of the gut; (2) evacuation with drainage for several hours or days, and subsequent closure and return of the gut; (3) evacuation with drainage that may be permanent. In operations, while the stomach is distended with fluid, anesthesia should never be used. Either the stomach should be artificially emptied, or the operation should be performed with the help of a local anesthetic. Anesthesia should be continued only for so long as is necessary to make the parietal incision and place the sutures. These measures are intended to supplement and complete the ordinary surgical methods for relief of the strangulation, and in no sense to replace these.

¹ Deutsche med. Woch., May 12th.

² British Medical Journal, March 12, 1892.

A UTERUS IN A SCROTUM.

A CURIOUS case of hermaphroditism was recently reported by M. Beckel to the Académie de Medicine.¹ A man, twenty years of age, has had since birth an inguinal hernia, to relieve which an operation for radical cure was undertaken. The hernial sac was found empty, but in its posterior wall there was found, covered by peritoneum, a triangular body, which was supposed to be an intestinal diverticulum. Further examination, however, showed that the inguinal canal was empty, and that the organ in question had no connection, whatever, with the digestive tube. Compression of the abdomen above the ring resulted in the extrusion through the external inguinal ring of an ovoid pearly body resembling the testicle. Lying parallel and above this body, and united to it, was a fringed cystic organ, which could not be anything else but the Fallopian tube. All these structures were carefully isolated by dissection and extirpated. Cicatrization was complete at the end of ten days. Examination of the extirpated mass revealed (1) a bicornate uterus, the mucous membrane of which was lined by ciliated epithelium; (2) a Fallopian tube and a testicle provided with an epididymis and a vas deferens; (3) a broad ligament enclosing these organs. This is the only known example of female sexual organs being contained in the scrotum of a man. The patient's appearance and habits were entirely those of a male.

by the sphincter. The external plegget soon becomes felted together into a pad, retained by the fibres caught by the sphincter. Where the piles are chiefly internal, the hamamelis may be applied in the dose of half-a-drachm to a drachm, either diluted with water or undiluted, by injecting it within the anus by means of a glycerine syringe. Itching and eczema may be relieved by eau de cologne.

Correspondence.

ANOTHER MUSICAL ANUS.

UNIVERSITY OF MICHIGAN,
ANN ARBOR, May 29, 1892.

MR. EDITOR:—Your correspondent, K., refers to Dante's mention of a case of musical anus. I cannot compare the references now, but Montaigne, in one of his many essays interesting to medical men ("On the Force of Imagination"), gives the following:

"St. Augustin (*de Civit. Dei.* xiv, 24, and the Comment. of Vives, *in loco*), speaks of having seen a man who could command his back trumpet to sound as often as he pleased, and Vives, supports this statement with another example, in his time, of one who could do this in tune."

The above seems to be of sufficient interest—pathological as well as literary—to be put on record.

Yours truly,

D.

THERAPEUTIC NOTES.

CALOMEL FOR HEMORRHOIDS.—James² has for some years treated hemorrhoids by applying calomel to them with the finger alone, especially when inflammatory action was obvious in the hemorrhoidal mass, characterized by mucous discharge and hemorrhage. All these symptoms were speedily relieved.

METHYL-BLUE IN TUBERCULAR AFFECTIONS.—Althen³ has used methyl-blue for pulmonary and laryngeal tuberculosis with very good results. It may also be used for the local treatment of tubercular ulcers. Internally twenty-two grains were given daily. Strangely if it occurs may be relieved with flaxseed tea. Occasionally gastric symptoms appear, in which case it is necessary to suspend the treatment and to begin again with small doses gradually increased.

THE TREATMENT OF PILES WITH HAMAMELIS.—In a paper on the treatment of piles and allied afflictions read before the Medical Society of London, Dr. Lauder Brunton⁴ recommends, especially brisk horse exercise. Another useful exercise is to touch the toes with the fingers, keeping the knees straight, several times every morning. Of the utmost importance is a regular action of the bowels. If the piles tend to come down much, it is better for the patient to get into the way of emptying the bowels every night before going to bed. It is always well for the patient to wash the anus immediately after a motion, with a soft sponge. A small plegget of prepared wool dipped in hamamelis should be introduced within the anus, and another introduced so far that a few fibres of it at least are caught

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 21, 1892, TO MAY 27, 1892.

CAPTAIN HENRY S. TURILL, assistant surgeon, U. S. A., granted leave of absence for three months.

CAPTAIN AUG. A. DELOFFRE, assistant surgeon, U. S. A., the leave of absence on surgeon's certificate of disability granted in S. O. 93, A. G. O., April 29th, is extended one month on surgeon's certificate of disability.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 28, 1892.

T. J. TURNER, medical director, retired, granted one year's leave of absence with permission to leave the United States.

H. N. T. HARRIS, assistant surgeon, promoted to passed assistant surgeon.

GEORGE B. WILSON, assistant surgeon, promoted to passed assistant surgeon.

MARY F. GATES, assistant surgeon, ordered to Naval Hospital, Portsmouth, N. H.

J. F. UHL, passed assistant surgeon, detached from Naval Hospital, Portsmouth, N. H., and to the U. S. S. "Chicago."

J. C. BYRNES, passed assistant surgeon, detached from the U. S. S. "Chicago" and granted three months' leave of absence.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING MAY 21, 1892.

MURRAY, P. D., surgeon. Granted leave of absence for fifteen days. May 14, 1892.

HAMILTON, J. B., surgeon. Granted leave of absence for eleven days. May 20, 1892.

GAASSAWAY, J. M., surgeon. Granted leave of absence for ten days. May 10, 1892.

GODFREY, JOHN, surgeon. When relieved as medical inspector of immigrants, to resume command of station at New York. May 11, 1892.

IRWIN, FAIRFAX, surgeon. To proceed to New Bedford, Mass., on special duty. May 17, 1892.

CARTER, H. R., surgeon. To proceed to Gallipolis, Ohio, on special duty. May 18, 1892.

WHEELER, W. A., surgeon. Detailed as medical inspector of immigrants, port of New York. May 11, 1892.

BANKS, C. E., passed assistant surgeon. To assume command of Service at Portland, Me. May 11, 1892.

DEVAN, S. C., passed assistant surgeon. To assume command of Service at Norfolk, Va. May 11, 1892.

PERRY, T. B., passed assistant surgeon. To assume charge of Cape Charles Quarantine Station. May 14, 1892.

WOODWARD, R. M., passed assistant surgeon. Granted leave of absence for five days. May 16, 1892.

VAUGHAN, G. T., passed assistant surgeon. Detailed as recorder of Board for the physical examination of candidates, Revenue Marine Service. May 9, 1892.

WERTEBAKER, C. F., assistant surgeon. Granted leave of absence for seven days. May 10, 1892.

HOUGHTON, E. R., assistant surgeon. To assume command of Service at Vineyard Haven, Mass. May 11, 1892.

MAINE MEDICAL ASSOCIATION.

The fortieth annual meeting will be held in Common Council Chamber, City Building, Portland, Me., Wednesday, Thursday and Friday, June 8th, 9th and 10th. The Annual Oration by A. H. Burbank, M.D., on Thursday evening, after which there will be a reception and banquet, given by the physicians of Portland.

EDWIN M. FULLER, M.D., President.
C. E. WILLIAMS, M.D., Auburn, Secretary.

RECENT DEATHS.

THOMAS G. RICHARDSON, M.D., died in New Orleans, May 26th, aged sixty-five. During the war he was medical director of the staff of General Bragg. In 1868 he went to New Orleans as Professor of Anatomy in the University of Louisiana. He was president of the American Medical Association in 1879.

AUGUST WILHELM VON HOFMANN, M.D., Professor of Chemistry in Berlin, died May 5th, aged seventy-four years. In 1848 he was called from Bonn to London where he was connected with the School of Chemistry until 1862, at which time he was called to Berlin. His most important work was in connection with the chemistry of the coal-tar derivatives and his discovery of the aniline colors.

BOOKS AND PAMPHLETS RECEIVED.

Catalogue of the Harvard Medical School Association, 1892.

Thirty-first Annual Report of the Cincinnati Hospital for the Year 1891.

The Fifty-third Annual Report of the Boston Lunatic Hospital for the Year 1891.

The Annual Report of the Health of the Imperial Navy for the 23d year of Meiji (1890).

Thirty-fourth Annual Report of the Washingtonian Home for the Year ending April 25, 1892.

The Science and Art of Midwifery. By William Thompson Lusk, A.M., M.D. New edition, revised and enlarged. New York: D. Appleton & Co.

A Baby's Requirements. By Elizabeth Robinson Scovil, Superintendent of Newport Hospital, Newport, R. I. Philadelphia: Curtis Publishing Company. 1892.

Eleventh Annual Report of the State Board of Health of Illinois for the Year 1888, with an Appendix containing the Official Register of Physicians and Midwives, 1892.

Clinical Lecture: Tenotomy by Open Incision for Talipes Equinus; Torticollis from Rheumatoidal Arthritis; Subcutaneous Tenotomy of Sternio-Cleido-Mastoid for Torticollis. By H. Augustus Wilson, M.D., Philadelphia. Reprint. 1892.

Addressees.**THE MEDICAL PROFESSION AND THE COMMONWEALTH.¹**

BY FRANK WINTHROP DRAPER, M.D.

In the discharge of the distinguished duty which places me in your presence at this time, I ask your indulgent attention to a study of the relations which, as physicians, we hold toward the Commonwealth.

Our obligations to the State derive added significance from the circumstances attending the incorporation of the Society of which we are the Fellows. It was at the time when the national government was in revolutionary instability and our own Commonwealth was in its infancy, that a few medical men, chiefly resident in Boston, saw the desirability of an association that should bring qualified practitioners into closer relations for their own benefit and for the good of the public. Their purpose was to make a "body politic and corporate" which should establish "a just discrimination" between educated practitioners and ignorant pretenders in medicine, a purpose that had in view the welfare of the community in its broadest sense. They therefore asked the General Court to give permanent expression to this object by granting the name of the Commonwealth to the new guild, and by bestowing corporate privileges that should correspond therewith. That request was granted and we are the *Massachusetts* Medical Society, broader than medical sectarianism, abhorring exclusiveness, loyal ever to the State's highest interests, proud of the charter, which, bearing the historic names of John Hancock and Sam Adams in attestation of its validity, the State bestowed upon us in 1781, the first document of the kind granted under the constitution. The Commonwealth thus became our *alma mater*. Besides giving her name to our newly created body, she endowed us with valuable rights; and she bestowed other encouraging assistance and recognition. If she did not actually rock the infant "body corporate" in the "cradle of liberty," she added a flavor of legality and dignity to our first proceedings by loaning the "county court-house in Boston," as the place of meeting for Dr. Holyoke and his thirty fellow-founders, and placing us under new obligations of gratitude later by permitting meetings of the Society in the State-house and in other public buildings belonging to the State.

Such was the beneficent and disinterested aim of our fathers in founding this association; such the gracious and helpful attitude of the Commonwealth in aiding that foundation. It is becoming in us, the heirs and beneficiaries of the endowment thus established, to ask how the aim of its creators has been fulfilled during all the years of the century now drawing to its close; to what degree the prosperity of the State has been advanced by the Fellows of this organization; and what are our present duties to the public in the discharge of the trust which our organic charter imposes. The little company of physicians which assembled in the county court-room near Scollay Square, in November, 1781, has by normal growth become a multitude so large that it requires an entire block of buildings to supply the needs of its anniversary meetings, outrunning all less adequate accommodations. Keeping pace with the progress which has made our Commonwealth

a leader in all things that promote the highest civilization, our organization holds, and has long held the highest rank as the representative of the best type of scientific and practical medicine.

Massachusetts, in founding its constitutional government in 1780, established three co-ordinate, yet independent, departments; and ordained that the legislative, the executive and the judicial functions should be forever distinct. This three-fold distribution of organic powers and duties in the State invites consideration of our relations, as physicians, to each of the fundamental departments, and leads us to ask what has been accomplished, and what remains to be done in directions wherein the Commonwealth and the medical profession are mutually concerned.

I. To what extent, then, in the first place, has the State, through its General Court, as its legislative department, enacted laws that are of particular interest to the members of our profession as a class? An inspection of the public statutes will be rewarded with the discovery of the fact that when we compare the legal privileges and obligations which to-day apply to Massachusetts physicians, the obligations far exceed the privileges. The State exacts more than it gives. When we have mentioned exemption from jury and militia duty, some preferment of the claims of physicians against insolvent estates, the rarely used permission to dissect dead bodies, and the happily infrequent opportunity of attending a judicial hanging, we have included all the essential benefits which the Commonwealth bestows on medical practitioners. It is not a long list of special indulgences, or a very valuable one.

The critical student of the public statutes who searches for any evidence therein that the Commonwealth through its legislature has ever set up any standard of education or skill on the part of medical men, will find little in existing laws to reward him for his inquiry. There is no attempt in the statutes to classify or to define "physicians," to declare by legislative act who may practise medicine and who shall not. Massachusetts has ever been hospitable to all sorts and conditions of men, and she welcomes with a reckless graciousness any who choose to pass her open door. She knows no sects, no schools, no differences among physicians; all doctors are alike to her, and, according to the assembled wisdom of her law-givers, they can safely be left to take care of themselves according to the principles of the common law.

This attitude of Massachusetts, allowing unrestricted freedom in the practice of physic, has exposed the State to much criticism. It has given rise to the impression that her present policy of non-interference with medicine has always prevailed, and that she is now simply carrying forward a traditional rule of conduct in obstinate indifference to the lessons of experience learned in other and younger communities. This inference is incorrect. Long before any of the modern devices for statutory regulation of medical practice were announced, long before many of the Commonwealths which are now taunting us had been staked out in the primeval wildernesses of the West and Northwest, Massachusetts saw the need of controlling the pretensions and active arrogance of charlatancy within her borders and the clear duty of bestowing her recognition upon reliable men and women.

We need not look beyond the words of our own charter of incorporation to find full evidence that long

¹ The Annual Discourse delivered before the Massachusetts Medical Society, June 8, 1882.

ago the State discriminated sharply between those who merited confidence and those who deserved to be restrained. The whole document, from its preamble to its conclusion, is filled with the flavor of this wholesome feeling. But that which applies itself chiefly to our purpose in this regard is the remarkable sentence which, like a strong back-bone, is built solidly into the very middle of the charter :

"And whereas it is clearly of importance, that a just discrimination should be made between such as are duly educated and properly qualified for the duties of their profession, and those who may ignorantly and wickedly administer Medicine, whereby the health and lives of many valuable individuals may be endangered, or perhaps lost to the community:

"Be it therefore enacted by the authority aforesaid, That the president and fellows of said society, or other such of their officers or fellows as they shall appoint, shall have full power and authority to examine all candidates for the practice of physic and surgery, who shall offer themselves for examination, respecting their skill in their profession."

This placed a premium on proper qualifications and proved fitness. It established a standard and made our society the keeper of that standard, and if with the recently accepted Bill of Rights in popular remembrance, it did not forbid the practice of medicine by those who neglected or failed to become licentiate under this charter, it nevertheless gave the community, what it had not had before, a chance to have its medical practitioners classified according to their worth and learning. It was a most responsible function to place upon this young organization, but the trust was adequately fulfilled then and is to-day being fulfilled; and the men and women who possess the letters testimonial of the censors of the Massachusetts Medical Society attesting their demonstrated and approved knowledge and fitness need no further passport to the full confidence of the people and no better certificate to distinguish them from those who "ignorantly and wickedly administer medicine."

But broad as our charter was, in its permissive provisions, it was not in the least useful as prohibitive legislation. We might admit all duly qualified practitioners to our ranks, we had no control over the disqualification pretender who cared little for the privileges which the Massachusetts Medical Society offered. This weak negative side in the then current statutes came at length to be seen, and in 1818 a law was passed which was designed to remedy this defect. It is of interest to us that the State continued to turn to this Society to aid in the fulfilment of its purpose. The statute provided that every person practising physic or surgery in Massachusetts, without a medical degree from some college or university, or without being licensed by some medical society, or college of physicians, or by three Fellows of the Massachusetts Medical Society to be designated in each county by the Councillors, should not have "the benefit of law for the recovery of any debt, or fees, accruing for his professional services"; and every licensed practitioner was required to deposit a copy of his license with the clerk of the town where he resided. Just a year later, the general court modified its predecessor's work and enacted that no person entering the practice of physic or surgery after a specified date should be entitled to the benefit of law for the recovery of any debt or fee for his professional services unless, previously to ren-

dering those services, he had been licensed by the regularly appointed censors of the Massachusetts Medical Society or had been graduated a Doctor of Medicine in Harvard University.

This law, it will be observed, distinctly recognized the principle of the regulation of medical practice, and this was the only good purpose which it served. It had two ludicrously weak features; it did not provide any punishment for failure or neglect to procure the required license, and while it presumably made the way of the irregular practitioner a difficult one in the matter of collecting his fees, it left him perfectly free to do what no reputable physician ever does, it left him free to take his pay in advance. Nevertheless, the law was so satisfactory and acceptable in its working, that it was re-affirmed in all its main features in the Revised Statutes of 1836, seventeen years later, this Society being still designated by name as the authority to manage the machinery of examination and licensing; but there was this important modification — the courts were no longer closed to unlicensed physicians. This anomalous statute (*vox et preterea nihil*) remained in force without amendment until 1859, when it dropped out of sight in the general revision of the laws made by the legislature of that year. Since its disappearance from the statute book there has been nothing unlriendly in "ignorantly and wickedly administering medicine" to the people of Massachusetts in violation of any statute; the principles of the common law are the only safeguard.

Meanwhile, during this period of thirty years, a wave of legislative virtue has swept over the land with reference to the regulation of medical practice. One State after another has passed restrictive laws of greater or less stringency but with the single aim of discouraging quackery. How effective these laws have been in accomplishing their purpose, or how zealously they are executed, in the various communities, we are not now concerned in determining; the suggestive fact is that Massachusetts stands almost alone in her attitude of toleration. Of one result of this state of affairs we are all clearly aware. The action of neighboring States, near and more distant, in requiring irregular practitioners to move on and to stand not upon the order of their going, has brought to our too hospitable territory a horde of medical pretenders who have not been slow in discovering the advantages of an asylum here. It is safe to state that never in the history of the Commonwealth has such a wide variety been offered to her people in the matter of choosing a medical counsellor in time of sickness, and that never has the class of charlatans been so numerous or so haughty.

And what a motley company they are, these disreputable parasites upon the medical profession! They offer to the student of anthropology a great diversity of types, ranging all the way from the long-haired male Indian doctor to the short-haired female Christian scientist; creatures with "natural" and supernatural powers, extraordinary owners of superior intellects who find no difficulty in the problem of curing the incurable; bio-chemists, nature-pathists, mesmerists, vivipaths, psychopaths, botanic healers, magnetic healers, — a great procession of social pests with labels designed to captivate the unwary and the credulous.

But these people who boldly affect superiority by announcing themselves openly as irregular practitioners, and by assuming an eccentric or distinctive title

in proof of it, are not the worst representatives of their class. The charlatans who are most harmful are those who deliberately and fraudulently take on the simple designation of "physician," and so far as any outward sign is concerned are not to be distinguished by the public from the best and noblest members of our profession.

Then, there is another form of fraud which manifests itself in the shape of "medical institutes." These are evidently business enterprises simply, and the management being in the hands of several persons, who are always announced as distinguished, successful and trustworthy exponents of medical science, the victims of disease read the obvious lesson that in a multitude of such counsellors there must be safety.

But, however, we may classify and differentiate these people, they all have certain characteristics in common; there is nothing beneficent in their motives or actions; they are to the last degree mercenary; they are busy obtaining money under false pretences; they add nothing to the common stock of knowledge; they defile the columns of the daily press and of the religious weekly journals with disgustingly suggestive notices of their pretensions and insinuating invitations to walk into their parlors. Through their advertisements, they make open solicitations to the victims of lustful practices to add crime to imprudence, and they cover with the thinnest disguise their public and defiant announcements that they will commit unlawful acts and will take all risks of detection and exposure. They deface all accessible surfaces with their bold and lying promises, and offend good morals by their too open allusions to unmentionable subjects. Like juggling fiends, they take advantage of every form of human misery to raise hope where hope is vain, and they wickedly and cruelly draw the last possible dollar from their credulous victims, who get small comfort from the fact that payment has been made in advance for the wretched disappointment of unfulfilled agreements. If in such a case death comes to the relief of these double sufferers, the ignorance of the only physician recognized by the statutes in such a relationship is attested by the manner in which the required certificate of the cause of the death is executed, sometimes unintelligibly, sometimes fraudulently, covering a crime under the name of an innocent disease, and always raising a doubt and question of the value of such data for the purpose of vital statistics.

Can it be possible that Massachusetts, which has long defended its claim to the possession of superior wisdom in the care of all matters pertaining to public health and public morality, is willing to tolerate this state of affairs indefinitely? Is not her indifference reprehensible? And have not we, as physicians, remained far too quiescent under these growing evils? Have we not evaded a duty while we maintained a neutrality? Ought we not now to speak out boldly and persistently until some effective measure has been adopted to control and suppress the fungous growth of quackery? It is to legislation, supported by an enlightened public sentiment, and rendered fruitful by an energetic enforcement, that we must look for the real remedy, legislation that shall be practical without being cumbersome or needlessly burdensome. This is not the occasion for outlining the details of such legislation; whether the statute should supply a method of registration administered by some already established board, like the State Board of Health; or

should require examination and license through the agency of a purely medical board; or should be framed upon the model of the English law which forbids the false and fraudulent use of any name, title or description, implying that its user is a physician or surgeon, when he has not been educated or licensed as such, — all these matters may safely be left to legislative wisdom. But the main point is that the Commonwealth should afford its citizens some guarantee that the persons who are permitted to practise medicine are trustworthy by virtue of education. Above all, let it be understood and insisted upon that this guarantee, with its attendant conditions and penalties, is not a matter into which sectarian medicine enters in any degree. Let there be an avoidance of all differences relating to schools of practice. Let not the smoldering embers of medical contention be drawn out of the ashes and fanned into life for the gratification of controversialists. Let it be remembered that this is not a question of therapeutics or of medical ethics, but a question of medical education, with the fundamental purpose of excluding from medical practice those who are unfit for it through ignorance or wickedness.

But, some will say, how does this matter concern the Massachusetts Medical Society, as a society? Why need this organization trouble itself to take any part in securing legislation against quackery? Are we not in the possession of an indefeasible charter, with ample protection of our rights and privileges as physicians? Does not the public recognize in this association a body of medical men and women offering ample evidence of the trustworthiness and intelligent skill that are desired? If any educated physician in Massachusetts wishes to acquire the benefits of this recognition, by entering this fellowship, is not the way easy and the method simple? Why need we, an old and honored body of regular physicians, fret about quackery? Do not the charlatans give us new and profitable business by their blunders? Why should we meddle with the inherent right of every individual to choose his adviser in case of injury or sickness? Will not the prudent man make seasonable inquiry and select the best; and cannot we wisely leave this decision without dictation, sure that in the long run the fittest will survive? Why need we ask to have new burdens and restrictions placed upon us?

From the point of view of expediency and propriety, as they apply to this Society, this course of reasoning is clearly correct. This organization will do well to maintain its independent attitude. It has no wish for a renewal of the legislation which formerly made it the sole censor of medical practice in this State. It is content to attend to its own affairs. It has no ambition to pose as a monopolist in medicine. It sets an example in medical tone, and in its traditions and present aim, cordially favors the highest attainable development in medical education and medical practice, but it has seen the mischief and disappointment which have attended attempts made, in its name, to influence and procure medical legislation. But this view does not absolve us, its individual members, from grave responsibility regarding questions of public welfare. We are citizens of the Commonwealth as well as physicians; and, as citizens, jealous of the good name of Massachusetts, ashamed of her false position in the matter now under discussion, we have the right and the duty to protest that some remedy should be applied to eradicate the evils which I have tried to describe. We

ought to do all in our power to secure some practical process of sifting which shall afford to the people an assurance that the State is unwilling to trust the lives and health of her inhabitants to charlatans and adventurers. We ought to insist, and insist again, that it is not for ourselves, or to promote our own interests, that we wish the State to interfere, but that it is in behalf of the thousands in her population who, through lack of knowledge or discrimination, become the victims of chicanery and fraud. We ought to demand that protection for the classes of people that do not and cannot protect themselves. If professedly intelligent and cultured persons choose to demonstrate their wisdom in a peculiar fashion, by amusing themselves with the mind-cure, and Christian science, and hypnotism, and other genteel fads, it should be with the distinct condition that it is without the State's approval of their folly. The strong desire shown by a certain class of individuals in this community to imitate and emulate their prototypes in ancient Athens in eagerness "to hear and to tell some new thing" needs checking when human life is in the balance as the material upon which the novelty is to be tried as a experiment.

Is it not extraordinary that Massachusetts has always been so ready to legislate in an endless variety of other directions affecting the life and well-being of her population, and is reluctant to interfere with uneducated and unfit practitioners of medicine? The general court has provided for the inspection of nearly everything that enters into domestic administration, and has ordained proper penalties for frauds and adulterations; we have ample protection in the matter of milk and vinegar, chocolate and nails, gas and leather, confections and drugs; but none against the charlatans. Massachusetts licenses her auctioneers and her peddlers, her pilots and publicans, her pawn-brokers and her warehouse-men, her dentists and her druggists; she places even clergymen and lawyers under regulations, but no difference exists in her esteem between the educated physician and the fraudulent healer which an adjacent State has spewed out upon our soil. We have statutes for the protection of lobsters and smelts, rabbits and partridges; but for sick people, the State offers no defence against quackery.

Let not medical men say that it is useless to seek a remedy from the legislature, that charlatanism has become too firmly rooted here to be eradicated by any means, however drastic. Repeatedly it has been demonstrated that measures of reform have been successfully accomplished with the aid of our profession in shaping and guiding legislation. Take a single illustration, the evolution of the methods prescribed for the commitment and treatment of the insane. As late as 1827, an act was passed by the Massachusetts Legislature which included every excited lunatic with "rogues, vagabonds, common beggars, and other idle, disorderly and lewd persons," and provided for his incarceration in a jail or house of correction until he was "restored to his right mind." This barbarity continued until the State, in 1832, heeding the representations of physicians, established the first lunatic hospital at Worcester. For many years after this, the process of commitment continued to be a purely legal one, without any required medical examination. But the protests of physicians again prevailed. In 1844, the legislature passed an act which recognized, for the first time, that insanity was a disease, whose diagnosis re-

quired medical knowledge, rather than legal acuteness. In 1862, it was enacted that for the commitment of an insane person to a lunatic hospital, "the evidence and certificate of at least two respectable physicians" should be required as a preliminary to establish the fact of insanity. Some modifications have been made in the amount and character of the medical evidence in these cases, but the recognition of the true nature of insanity and of the propriety of placing its humane treatment in the hands of physicians, rather than in those of the keepers of jails, was due to the labors of such men as Bell, Wyman, Ray and Jarvis. This result shows the effects which medical men may accomplish at the State-house if only their efforts are rightly directed and persistently exercised. Other examples of this force might be cited. The statutes relating to the public health, to the registration of vital statistics, to compulsory vaccination, to the use of subjects for anatomical study, to the investigation of deaths by violence, are all memorials of the intelligent zeal of medical men in shaping and obtaining wise legislation. What physicians have accomplished in the past is an augury and proof of what they may now accomplish in the attainment of statutory regulation of medical practice. And not in this direction alone. There are other matters wherein wholesome laws are needed. I have only to suggest the desirability of legislation for the more effectual prevention of the spread of contagious diseases, including syphilis; for less barbarous methods in the punishment of convicted murderers; for better dwellings for the poor; for medical inspection of schools; for the compulsory establishment of a local health-board in every town; for reform in the methods of using medical experts. In these, and other similar directions, the educated physicians of Massachusetts have it in their power to bring about salutary changes. It is a power that is not sufficiently appreciated by us, its possessors. It is a power which may find its correct exercise in various ways; in the open and candid expression of opinion as we meet our acquaintances and clients; or in properly formulated memorials to the general court; or in attendance and spoken testimony at hearings before legislative committees; or even in service in the law-making body itself. It is to the credit of our Society that its members have shown their willingness to interrupt their professional labors and to respond to the call of their neighbors to represent them in the legislature. It is an honorable service, and nearly every session has found, included in its rolls, the names of reputable physicians, members of this Society, who have given intelligent and faithful attention to legislative problems, the satisfactory solution of which has been largely due to their wise counsel and to the experienced judgment derived from their medical training.

(To be continued.)

A DISCONTENTED DOCTOR.—The *Berliner Tagblatt* recently contained the following: "I have read with envy and some indignation that the corn porters of Berlin, who are now earning from ten to twelve shillings a day want to strike for higher pay. Would that instead of being a Berlin doctor I had been a corn porter!" The communication was sent to the paper by a young doctor of three years' experience in the profession.

THE PRESIDENT'S ADDRESS BEFORE THE
AMERICAN SURGICAL ASSOCIATION.¹

BY F. S. CONNER, M.D., CINCINNATI, O.

FELLOWS OF THE AMERICAN SURGICAL ASSOCIATION:—After a series of meetings at the national capital, it is fitting that our first journeying should bring us to a city with which is associated so much that is good and great in the history of our country, political, literary, scientific and professional. Here, as a part of the university, that, like Salernum of old is *mater et caput* of the schools, was established the second medical school in the Western Hemisphere, where for more than a century, scientific medicine has been well and thoroughly taught. The Massachusetts General and the City Hospitals have been the theatres of much work that has strongly affected the practice of our art the world over, and one of them will ever be remembered as the place in which "the problem of surgical anesthesia was definitively solved." Their surgeons, learned, skillful, progressive and inventive, by labors and teachings have honored themselves and the profession of which they have been such distinguished members. Not in America only, but everywhere, the profession has held and now holds in high esteem the Medicine and Surgery of Boston.

The active life of the Surgical Association, that begun with the meeting in Philadelphia, embraces a ten-year period than which no other in professional history has been more strongly characterized by extent and accuracy of investigation, by scientific judicious experimentation, by the discovery of important facts, by improvements in the technique of old operations and by the introduction and general adoption of new procedures. In the study of the causes of disease many master minds have been at work, and more positive knowledge has been gained than in all time before, so that in the bacteriological laboratories, a new pathology has been worked out, in large measure revolutionary of both opinion and practice. Speculation and theory have given place to experimentation and fact, and the disease-producing influence of airs, of earths, of waters have been found to lie in organisms that have been seized upon, separated, classified and tested.

We can scarcely realize that it was only in 1882 that the startling announcement was made that tuberculosis was consequent upon the presence and action of a definite micro-organism, that could be isolated, cultivated and inoculated; and that so short a time ago, the doubters were many, more indeed than the believers. In this single decade just passed, the fact has become universally acknowledged, the sceptics are now but professional curiosities; a new literature has been written; even a new language created in which strumous (except as a synonym of tuberculous) has no more place than phlogiston.

The long-known chronic affections of bone, of joints, of glands, of skin, have been shown to be in great measure the result of the presence and action of a bacillus, that everywhere and under all circumstances moves in one and the same way and that a destructive one, though antagonized at every step by healthy tissue (not seldom successfully) and subject more or less completely to the power of our Art, directed to the procuring of the destruction or encapsulation of the germ, the removal of the infected tissues or the

taking away of the affected part. We can understand now why rest is of so much importance, why excision or erosion may be followed as it so often is, by non-recurrence; why on the other hand, in spite of, or even because of operative interference, parts near or remote become secondarily infected.

The most important work, as it seems to me, that has been done in connection with surgical tuberculosis, is that which has had for its object, the finding out and properly applying a therapeutic agent which will destroy the organism and secure its expulsion from the body, or secure such condensation of non-infected tissue about it as shall form a wall around and by encapsulation render it harmless. Far better will it be to administer generally or locally a remedy that will remove the bacillus or make it innocuous than to do the most brilliant operation followed by the most rapid healing and recovery in large measure of functional integrity. The end is far from having been reached, but a long step in advance has been made, and the reviewer of the work of another ten years, may find the result secured and a non-operative, truly curative treatment in use. It is certainly to be hoped, though, that scientific medicine will not again have to pass through such an experience as that of a couple of years ago, the history of which will always be of much interest to the students of psychology and of mental epidemics.

Of the three wound complications which from the earliest times have been the bane of surgery, septic infection, erysipelas and tetanus, the cause of only the first had been determined a decade ago; that of each is now known, and known because of the application to the tissues and fluids of those affected by them of the same methods of bacteriological investigation that had revealed the existence and life history of the pyogenic cocci. In erysipelas have been satisfied the three requirements of proof of bacterial origin, isolation, cultivation and inoculation into the human subject with resulting development of the original disease. Not a few of the long time perplexing questions connected with tetanus have found answer in the discovered identity of its causative organism with the earth bacillus and in the anaerobic nature of it. In every case that has come under my observation, so far as I can now recall, except those associated with toy-pistol wounds, I am able to trace either direct contact with the naked ground, or probable almost unavoidable contamination of the wound with dust and dirt. In the toy-pistol wounds of the hands there is that exclusion of air and retention of fluid that are most favorable to the growth and activity of secretion of an organism that flourishes in the absence of oxygen, an organism that at the time of injury or later was located doubtless upon the dirty hand. Knowledge of the habits of the bacillus is sufficient of itself to indicate the treatment to be pursued, that tetanus may not supervene, to wit, thorough opening up and free drainage of the wound. Further, not only has the causative organism been found, but also it has been shown that there may be developed from it an antitodal chemical agent, the injection of which can produce immunity or act remedially upon a tetanic patient.

It is in the treatment of the diseases and injuries of the viscera and their envelopes that the greatest advances in our art have been made in these later years. Numerous and carefully conducted experiments upon animals and operative procedures upon man, new, bold

¹ Boston, Mass., Tuesday, May 31, 1892.

and highly successful, have again and again been reported, and in the work that has been done, our own Fellows have had no minor part.

The abdominal cavity that for so long a time was an almost sacred territory not to be invaded except under peculiar circumstances and for the relief of a very few morbid conditions, has, because of the secured protection against sepsis, become one of the more common fields of operations, done on account of wounds, of tumors, of obstructions and of infective inflammation. Such operations, not seldom, have been, it may be believed, ill-advised, ill-timed, unnecessary and harmful, entered upon by inexperienced men, whose eagerness to cut has found explanation in the fact that in simple abdominal section few operative difficulties are usually met with and no dangerous hemorrhage is to be expected, the arresting of which might test the knowledge and skill of the operator.

Penetrating and perforating wounds of the hollow and solid viscera are no longer treated solely by opium and ice with a resulting fatality truly appalling, but by section of the wall, suture of the wounds, ligation of the bleeding vessels and antiseptic plugging, if necessary, of openings in the solid organs. The mortality-rate is still unfortunately very high; how high cannot be definitely stated, since the number of reported cases is yet limited and includes without doubt an undue proportion of successful results. Not a few of the deaths, it cannot be doubted, have been due to the delay, the incompleteness and the imperfection of the operation, but many must be credited to the damage primarily done. Made by bullets of other than the smallest calibre, the pistol wound of the stomach, of the intestines, of the mesentery or of the liver, is likely to prove mortal from shock or hemorrhage, even though treated properly and skilfully, and is almost absolutely certain to do so if fecal extravasation has occurred and septic inflammation has set in. It cannot be questioned but that wounds made by very small balls may be, and have been recovered from without operative interference, and there is good reason for believing that in the absence of symptoms of active hemorrhage such wounds will do as well or better without as with laparotomy; an operation, however improved its technique, is still an addition to the risk of the case. It is as unwise as it is untrue to declare that there are no dangers attaching to incision of the abdominal walls and exploration of the intestinal tract. But when it is a bullet of large size that has entered the cavity, the safety of the patient almost certainly lies, if anywhere, in speedy, thorough operation. It is hard to understand such statistics as those of Reclus, in which it would appear that while without operation only thirty-five per cent. died, with operation, the mortality-rate was from seventy-three per cent. to eighty-six per cent. That in three out of four, or six out of seven patients thus wounded, the result was a fatal one may be believed, but that it should be so in only one out of four expectantly treated, is to say the least, very remarkable. Not the smallest of difficulties often associated with these wounds, is the determination of the occurrence of penetration, which at times can only be through opening up and following down of the parietal wound. Inflation of the bowel with hydrogen gas, the earlier experiments with which were so brilliant and so captivating, will not always give the desired information and may be positively detrimental to the best interests of the patient, as it

certainly has been in certain cases already put on record.

The septic inflammations about the head of the colon, originating so generally in the appendix (which some would regard as an "intestinal tonsil," but which may well be looked upon as a useless survival of a once important organ) have in the period under consideration been brought within the province of the surgeon, not as before at a late day when the resulting abscess has fortunately come well forward toward the surface, but at an early stage when by evacuation of the fluid with or without removal of the appendix, relief may be afforded and the patient be protected against the lethal effects of perforative peritonitis or perinephritic suppuration. The cases of acute disturbance in the region of the cæcum due to an overloaded bowel or to the catarrhal inflammation, will find relief in the future as in the past in the therapeutic measures of the physician; but suppurative gangrene producing appendicitis, it has been proven, and that chiefly by the experience of our American surgeons, can with safety be treated only by the knife. Whether or not it is advisable to remove, during a quiescent stage, the appendix that has been the seat of repeated attacks of inflammation, is a question as yet unsettled.

A very cursory examination of the professional literature, home and foreign, for the past decade, would convince any one that an immense amount of work, experimental and operative, has been done in the determination of the proper and most advisable methods of treatment in cases of obstruction, acute and chronic, malignant and non-malignant, located in any part of the tract from the cardiac extremity of the stomach to the lower end of the rectum. Strictures have been dilated, affected areas removed, anastomosis secured, "cut-offs" established, new openings formed, with the result in favorable cases of effecting cure or affording relief. The technique of the older operations has been much improved, modifications have been introduced, and not a few altogether new procedures have been devised, tested and widely accepted.

Pyloric stenosis, for which ten years ago pylorotomy was all that the surgeon could offer, may now, if of non-malignant character, be relieved by digital division through the open stomach, by curetting, by a pyloro-plastic operation, or by gastro-enterostomy; and if due to malignant disease, by the latter operation, in every way to be preferred to excision of the cancerous mass, being speedier and easier of execution and having a mortality-rate but one-half or perhaps only one-fourth as great. In its performance, as in similar operations upon lower portions of the intestine much use has been made of the approximation plates, as of decalcified bones, of leather or of potato, and of cat-gut rings and mats; but at the present time there is certainly a strong and growing feeling that their employment is not only not necessary but rather an injury than a benefit to the patient. It may be well questioned, if after all, viewing the subject in its widest aspect, operations for cancer of the stomach have really been or can be of much service. They certainly have often afforded much temporary relief and are to be resorted to when suffering is great and starvation is imminent; but on the other hand, the prolongation of life when the operation is recovered from is, with only now and then an exception, but slight, excision has almost never protected from recurrence, the abnormal anastomoses are very likely to speedily

become seriously contracted with resulting loss of the benefit primarily secured and the necessitating disease must go on increasing though it may be more slowly than before. In not a few of the reported cases, the condition of the patients at the time of operation was fairly good, the suffering was slight and the general strength but little impaired, yet as the direct result of the surgical interference life was cut short. If we balance these cases against those in which a few weeks or months were gained by excision or anastomosis, it is very questionable if we can find in the result of operation any material addition to the sum total of life.

Malignant disease located in the rectum too low to be removed through an anterior abdominal incision and too high to be thoroughly extirpated through a perineal one, may be reached from behind, after resection of the coccyx, with or without, as necessity may require, that of the lower portion of the sacrum. This new operation, neither specially difficult nor dangerous, may be done in place of a colotomy, lumbar or inguinal, the latter being to-day more generally preferred. The same objection to such radical treatment as compared with palliative, namely, increase of risk without compensating probability of cure, holds good here as at the pylorus, although in less degree.

In no other part of intestinal surgery has more been done in thought, in experiment and practice than in that dealing with excisions of the bowel in continuity, rendered necessary on account of wounds, growths or gangrene. As the technique of the operations has been improved, the time of performance has been lessened, the risk to life diminished and the range of applicability increased. It is still undetermined whether end-to-end or lateral anastomosis is to be preferred, of how much value bone plates or rings, or other like aids really are, to the patient, at least, how far omental grafts may be required, or how much additional security they afford.

The solid organs have again and again been brought under surgical treatment on account of wounds, of growths and of tubercular, parasitic and suppurative diseases. The kidney, spleen and even the pancreas have been removed entire, the liver in part. The gall-bladder has been opened and its contents removed (stones, bile, pus) and later sutured and left in place or stitched to the abdominal wall or cut away altogether. Pancreatic cysts have been at times extirpated, at times drained. These operations have yearly been more frequently performed for more varied causes, by steadily improving methods and with a marked diminution in the resulting fatality.

Special notice cannot be taken of the new and improved operations upon the uterus and its appendages which have had for their object the relief of the distressing and grave conditions, and as their result, preservation of life and restoration to health in large and steadily increasing proportion of the cases treated.

Of the work done upon the bladder much might well be said; but only a passing reference to the high esteem in which, so justly, the suprapubic section is now held; to the greatly improved and more successful treatment of tumors and to the established position that in the period under consideration, litholapaxy has taken as the most generally applicable method of dealing with stone, even in young children, for the relief of whom ten years ago, lithotomy was everywhere regarded as the only operation to be ordinarily thought of.

Though there have been many operations of very considerable extent upon the thoracic wall to secure closure of an empyemic cavity and for the extirpation of tumors, in intra-thoracic surgery but little has been done and that almost entirely in the evacuation of lung abscesses and the removal of hydatid cysts the result in the latter class of cases has been remarkably successful. Pneumonotomy for tubercular abscess, according to the report made to the French Congress of Tuberculosis last year, had relieved in about fifty per cent. of the cases and cured in about one-fourth as many, but the number of patients thus far treated has been so small that the figures are of little importance in the consideration of the advisability or otherwise of active interference. It certainly stands to reason that the opening up and draining of the pulmonary tubercular abscess will not be likely to afford other than temporary relief, such pus collection being commonly not solitary, but one of a number in an extensively diseased organ. In the removal of deeply located foreign bodies and tumors other than those connected with the wall, almost nothing has been attempted, and there are difficulties, anatomical and physiological in the way of such operations, which, if in any given case not insuperable, will probably always tend to make prudent surgeons cautious about entering upon one of them.

Pneumonotomy, experimentally shown to be readily done and attended with no great amount of danger, will doubtless in the future have a place in the treatment of lung injuries, in which already it has been a few times employed, according to one report, in fifteen cases with a death-rate of less than fifteen per cent. That it will ever be an accepted method of treatment for tuberculous lung may well be questioned.

It is in the surgery of the head and spine that the greatest advances have been made, the largest number of new procedures introduced, the most brilliant operations done; and in these regions more than anywhere else the surgery of to day is a new surgery, much of it the growth of even fewer years than those included in the lifetime of the Association. More and more constantly are all depressed fractures of the skull being treated actively, and basal fractures, antiseptically. Stronger and stronger is becoming the conviction of surgeons that fractures of the spine associated with evidence of pressure upon or injury of the cord, should not be left to nature, if the general and local symptoms indicate lesions that can be removed or relieved by elevation or extraction of vertebral fragments, or the lessening of intra-dural tension through opening of the sheath.

It has been proven to be wise to treat bullet wounds of the brain like other punctured wounds of the organ, by exploring, cleaning and draining the track; and occasionally it has been found possible to extract the ball through the wound of entrance or a counter-opening in the skull. The future must determine how far it is wise to go in the way of effecting removal of the bullet, and this must largely depend upon previously ascertained extent of liability to the supervention of epilepsy and mental disturbances, weeks, months or years after the lodgement of a ball which, at the time of injury, did comparatively little damage, or damage, at least, that was spontaneously recovered from.

Trephining for epilepsy following injury of the skull is no new operation, but of late such treatment has been quite largely employed, not only in cases where

there has been an old fracture or contusion, but in those in which by application of the now well-established rules of cerebral localization it has been possible to determine the place of a meningeal thickening or of a limited chronic encephalitis or a new growth, solid or cystic, acting as an exciting cause of motor disturbance. Electrical stimulation of the exposed cortex has been made to indicate with exactness a diseased area, the removal of which has been followed by relief, temporary or permanent, of the spasm symptoms. The attained perfection of operative procedures has reduced the mortality-rate to a very low figure and even the after-presence of a gap in the skull has been prevented by re-implantation of the removed bone. Unfortunately in very many cases of recovery from operation, in a few weeks or months or it may be years, the convulsive seizures will come on again. An established "epileptic habit" is independent of the original lesion, and after a certain time, which is a very uncertain one, the patient can no longer be assured that the cause removed, the effect will cease. But for all this, the morbid condition is so disabling, the relief afforded may be so great, the risk run is comparatively so small, that after proper and properly continued, yet unavailing medicinal treatment, an epileptic in whom the seat of the disease can be fairly well located should become the subject of operative interference.

Trephining has also been done because of the existence of long-standing severe headache; and in cases in which the thorough application of the therapeutic test has proved that the cephalgia does not depend upon a cause that can be reached and removed by drugs, the operation may certainly with propriety be recommended.

Considerable sections of the skull have been taken away to permit of the expansion of the microcephalic brain, but though improvement in mental condition in certain cases has followed such linear craniotomy, at the present time the operation seems to be of very questionable utility. Before it is to be accepted as an advisable method of treating feeble-minded children, further investigation must be made into the causes of arrested cerebral development and how far it is productive of, and how far consequent upon, premature ossification of the cranium.

Insanity of traumatic origin has in a very large proportion of the few cases surgically treated, been much improved or cured, because, we may believe, of relief of "intra-cranial fluid pressure"; and even general paretic have been thought to have been benefited by trephining.

A few years ago, who would have dreamed of opening up the lateral sinus and removing from it a pyogenic thrombus? Yet it has now been done several times, and with success.

In not a few cases intra-cranial abscesses have been definitely located and operatively relieved.

But the most brilliant chapter in this history of brain-surgery in recent times, is that relating to tumors. There is set forth in it not only what has been done, remarkable as it is, but also the unity of medicine and the interdependence of its various departments. It is because of the work of the anatominist, the physiologist, the pathologist, the neurologist, that it has been rendered possible to locate with close approximation to exactness the position of the neoplasm and its character; without knowledge of which the skill of the surgeon and the most careful operative

technique would be of little or no avail. Even the experimental therapist has played a part because of his demonstrations of the influence of morphia upon the intra-cranial circulation. Though in but a small percentage of cases of tumor, has it been or perhaps can it be practicable to effect removal, because of location or pathological character, yet when it is so, the gain is enormous, even though the relief afforded be but temporary, as in dealing with certain growths it must be.

Much less operative work has been done upon the spine than upon the head. It has had for its object the evacuation of abscesses, the relief of paralysis and the removal of tumors pressing upon the cord, and has been in a high degree satisfactory and full of promise.

As never before, the congenital malformations, meningomyelocele, encephalocele and spina bifida have been subjected to surgical treatment, and that with an increasing success, as improvements have been made in the methods of execution. Renewed attempts have been made to permanently get rid of intra-ventricular effusions by tapping and drainage, but the results have not been what might be desired, and that, whether the old route to the ventricle has been followed, or the new lateral one.

In the special departments, as in general surgery, these last ten years have been busy ones, and each may justly claim that there has been advance made in the recognition of disease and improvement in its treatment. But consideration of the work done in them does not concern us here.

Any retrospect, be it never so hurried, of the work of the decade, furnishes good warrant for pride in what has been, and high hopes of what is to be. The world over, educated minds and trained hands are busy with the problems of cause, of course, of termination, and seeking out surer, safer, and speedier means of relief, therapeutic and operative. Week by week, and month by month, what is accomplished becomes tree and common property; everything is proven, and the good held fast. What will be the outcome of all this thinking and experimenting, and operating and writing, even in the near future, who would dare to predict? American surgeons have had not a little to do with the work in the past; Fellows of our own Association, some of whom have fallen asleep, have been closely identified with the discovery, the early adoption and the thorough testing of not a few methods of treatment; and we may expect with confidence that it will be with us hereafter as it has been, and yet more so.

As an organized body, certain duties rest upon the Association. Representing the surgery of a country of wide extent and of very varied climate and soil, of a people of many racial origins, there should be conducted by it a series of collective investigations, which, for example, might show the prevalence, and as far as possible, the more remote determining causes of certain surgical diseases, chief among which is cancer; or the influence of the local conditions, as of altitude, of average temperature, and of moisture upon the healing of wounds; or of the relative resisting-power to the action of morbid organisms of the descendants of immigrants from different nations, still more of members of the several color races; four of which are to be met with within our boundary lines in numbers large enough to be of value in an investigation of this sort. From our meetings, year by year, should go out

to the world, reports, as it were, of the surgical state of the nation, and, as far as can be ascertained, the reasons therefore as found in place, in race, in occupation and in social position.

In the *personnel* of the Association, the years that have gone by have brought much change. It could not but be so. Thirty-three of the Fellows have passed away, leaving to us a memory of worth, of learning and of skill. Since our last meeting Agnew, and Campbell, and Johnston, and Kinloch, and Peck have rested from their labors. Each, honorable and honored; in his own place and in his own way, aided humanity and advanced medicine, and each will long be held by us in kind remembrance.

ABSTRACT OF THE PRESIDENT'S ADDRESS BEFORE THE ASSOCIATION OF AMERICAN PHYSICIANS.¹

BY HENRY M. LYMAN, M.D., CHICAGO, ILL.

REFERENCE was made to the absence of the Secretary, Dr. Hun, who "obedient to the higher impulses of his being, has taken unto himself a wife, and departed for the happy hunting grounds of European seclusion."

Since the last meeting, death has removed two of the members of the Association, Dr. Francis Donaldson died in Baltimore, Md., after a period of declining health, which was suddenly terminated by heart failure on the morning of December 9, 1891. He had reached the age of sixty-eight years. The story of his life covers everything of interest pertaining to medicine in his native city during the past half-century. He was a graduate of the University of Maryland; afterwards studied in Paris. From 1863 to 1866, he was Professor of *Materia Medica* in the Maryland College of Pharmacy, and later Professor of Physiology and Hygiene, and Clinical Professor of Diseases of the Throat and Chest in the University of Maryland. He was a frequent contributor to medical periodicals and an accomplished teacher. He was one of the consulting staff of the Johns Hopkins Hospital. He was one of the finest types of the energetic, accomplished and thoughtful men who adorned the last generation of American physicians.

Dr. Henry Ingersoll Bowditch died in the city of Boston, January 14, 1892, in the eighty-fourth year of his age. He was a son of the celebrated mathematician, Nathaniel Bowditch. As a schoolboy and student, he was remarkable for all the best characteristics, physical, mental and moral of a New England youth of his day. He graduated from Harvard in 1828, entered the medical school in Boston, and received the degree of M.D., in 1832. He spent nearly two years under the instruction of the famous French teachers, Andral, Chomel and Louis. From these eminent pioneers of modern medical science, he acquired the rudiments of that power of acute observation and accurate inference that was so conspicuous a feature of his after-life. From the year 1838 until the close of his active career, he was intimately connected with the Massachusetts General Hospital, the Boston City Hospital, the Carney and New England Hospitals in the city of his residence. He was one of the earliest and most prominent advocates of sanitary science and pub-

lic sanitation; and after the creation in Massachusetts of the first State Board of Health ever known in this country, he devoted ten of the best years of his life to the arduous labors of its presidency. As a man, as a citizen, as a physician, no purer, brighter, nobler spirit has ever adorned the medical profession.

The past year has not been particularly fruitful in brilliant discoveries within the field of medicine. Medical progress can advance only as the allied sciences pave the way by discoveries that can be utilized for the explanation of physiological and pathological phenomena, thus rendering possible new investigations in therapeutics. For these reasons, it is highly important that we should carefully follow the course of research in all departments of scientific investigation.

During the past year, a number of beliefs that were previously held upon hypothetical grounds have been subjected to the final test of experimental evidence, thus enlarging the field in which the uniform operation of the laws of physics and chemistry has been demonstrated.

Brief reference was made to the fascinating researches in the realm of astronomy which have been so recently accomplished by the aid of photography and the spectroscope. To us the principal interest lies in a demonstration thus afforded of the unity of type and method in all the cosmic movements of matter, enabling us to read in the language of the stars the past history and the future course not only of our own solar system but of the planet upon which we dwell.

Experiments in electricity by Professor Hertz, of Karlsruhe, have continued to bear fruit during the past year. It may be now assumed as experimentally demonstrated that electricity, as well as light and heat, are what they have been long supposed to be, modes of motion in an all-pervasive ether. By this demonstration we are brought one step nearer towards the complete definition of the antithesis between mind and matter.

Among the biologists during the past year, research has been particularly occupied with the investigation of the elementary composition and attributes of protoplasm. In connection with the questions that bear upon the subject of heredity, many interesting observations have been published: the investigations of Strasburger, Fleming, Guignard and Fol have thrown new light upon the phenomena of fecundation and reproduction, giving reason to hope that in no very distant future the problems of heredity may receive a satisfactory solution.

Another important question regarding the ultimate organization of protoplasm itself is gradually approaching its solution. Two rival hypotheses at present occupy the field: Altman, Straus and Vogt are of the opinion that a cell-protoplasm is to be considered as an aggregation of co-ordinated elementary organisms that bear to the animal or vegetable cell a relation not unlike that of independent microbes. The bearings of such speculations upon the facts of infection and of fecundation is quite obvious. On the other hand, Butschli maintains that it is entirely unnecessary to assume the existence of any special co-ordinating force, and is of the opinion that all the phenomena which are exhibited by protoplasm may be produced by the operation of ordinary chemical and physical forces.

The past year has been distinguished by the completion of a new edition of Eichhorst's great work on "Internal Medicine," and by the appearance of the

¹ Washington, D. C., Tuesday, May 24, 1892.

first two volumes of the French "Traité de Médecine." In our own country Osler has laid upon us all a debt of gratitude for his admirable volume on the "Practice of Medicine."

These epoch-making achievements indicate the complete recuperation of the French school of medicine from the stunning shock of the Franco-Prussian War. The consecutive volumes of Eichhorst remind one of the German infantry, ponderous, thoroughly trained and invincible, but war-worn and weather-stained to the last degree. Turning from those serried ranks to the French side of the line, we find all the pomp and circumstance of war, all the glitter of gold, the splendor of apparel, the *élan* and *esprit* that have always characterized the French nation. Judging from the already published volumes the new "Traité de Médecine" will be, when completed, the most valuable contribution to the literature of internal medicine that has yet been produced. The world, certainly, cannot yet dispense with the services of the French any more than it can do without the Germans.

RECENT ADDED FACILITIES FOR THE EXAMINATION OF THE EYE.

BY HASKET DERBY, M.D.

- I. THE OPHTHALMOMETER OF JAVAL-SCHIÖTZ. — II. THE PHOTOMETER OF STEVENS. — III. THE ARC-LIGHT ADAPTED FOR THE OPHTHALMOSCOPE.

I. THE OPHTHALMOMETER OF JAVAL-SCHIÖTZ.

IT needs not the memory of a veteran in the practice of ophthalmic surgery to recall the time when patients who supposed they might need the aid of glasses were advised in the text-books to consult some reliable optician. And even after the publication of the classic articles of Donders on refraction and the selection of spectacles, the boxes of trial lenses for years contained no cylindrical glasses. After the latter had been finally introduced, at no very remote epoch, the present writer can remember trying to convince M. Nachet of the desirability of having a double row of cylindrical, just as of spherical, lenses; and insisting on having his own box constructed with this addition, much to the surprise of the optician. Von Graefe wrote his first article on muscular asthenopia in 1862. At the present time there is no case exhibiting asthenopic symptoms in which the thought of abnormal astigmatism, as well as of a want of proper balance in the motor apparatus of the eyes does not occur to us. And a daily increasing number of cases come from the general practitioner to be examined for the possible existence of these defects.

A thorough functional examination of the eyes has therefore become a long and laborious process. It is not sufficient to ascertain the amount of vision, and, if it seems imperfect, to bring it up to the normal standard by the employment of the ordinary spherical lenses. Small degrees of astigmatism must be carefully looked for, and in cases where frequent headaches occur, or the continuous use of the eyes on near objects is attended with difficulty, their complete neutralization is to be undertaken. Muscular insufficiencies are also to be considered, those not only of the internal recti, formerly thought to be the most frequent, but also of

the externi, as well as of the superior and inferior straight muscles. The ophthalmoscope must of course play its part and thoroughly search the interior of the eye. With the means of examination formerly at our command, such a complete investigation of a single case might well extend over several visits, be fatiguing both to patient and surgeon, and involve the use of atropine or homatropine to paralyze the accommodation, thus involving a tedious delay and disabling the individual for a length of time that many an active worker could ill afford.

Fortunately for the public, as well as the profession, science has placed at our command the means of materially shortening these examinations, while the accuracy of the results obtained are in nowise diminished. With the improved Ophthalmometer of Javal-Schiötz, for the investigation of astigmatism, the Photometer of Stevens for gauging the strength and condition of the muscular apparatus, and the Arc-light, made comparatively portable and adapted for use in the ophthalmoscopic closet, the comfort and time of patient and surgeon are no longer unduly encroached upon. Within the limits of a single and comparatively brief visit a thorough examination of the functions can be made, the state of the refraction being sufficiently ascertained without the use of atropine, the muscular equilibrium or want of equilibrium estimated, and a view obtained of the interior of the eye that, for clearness of detail and purity of tint, was rarely approached in the days when our only means of illumination was the flame afforded by oil or gas. It is to briefly call attention to these three improvements in our means of examination that the present article is written.

Of all devices hitherto furnished for the purpose of ascertaining the existence of abnormal astigmatism, none compare with the ophthalmometer of Javal-Schiötz, and I refer particularly to the model of 1889, with the Edison incandescent lamp attachment. This apparatus, as is well known, consists of a metal disc 640 millimetres in diameter, fenestrated in each lower quadrant for the passage of the hand. On it are painted in black and white concentric circles, and its periphery is marked off at intervals of 15 degrees, the figures being reversed that their reflection on the cornea may be more readily made out. The disc is mounted on a tripod, sliding in brass grooves along an horizontal stand, to the opposite extremity of which is attached at right angles an upright frame for the face of the patient, consisting of a sliding chin and fixed forehead rest, the latter having a lamp connected with either corner. Through the centre of the disc passes a small telescope, itself fixed in the centre of a movable curved bar or arc, and by rotating the tube this bar moves over the anterior face of the disc. A long pointer, attached at right angles to the centre of this arc, and a shorter one at each extremity indicate its position. On the arc slide two small parallelograms (or "mires" as they are termed), one with straight, the other with notched edges, each traversed by a straight line drawn across its centre, the two lines forming but a single one when the mires are in apposition. In the body of the telescope is placed a Nicol's prism, which doubles the reflections of the mires on the cornea of the patient. At the back of the tripod supporting disc and telescope is a large screw, the turning of which tilts the apparatus forward or backward and thus changes the inclination of the telescope.

The electric lights are 16 candle power each and

are furnished with reflectors which aid in the illumination of the disc and mires.

The patient's head being placed in position and the eye that is not under examination covered, the observer takes his place at the eye-piece of the telescope, directs it toward the cornea by lateral movements with the hand and vertical with the screw, brings thus the cornea into the field, and alternately pushes forward or withdraws the tripod until a clear image of the disc is obtained on the corneal surface. Disregarding the lateral images of the mires the central ones are brought into contact by passing the hand through the opening in the disc and sliding one mire along the arc. If now one of the cross lines is on a different level from the other the tube of the telescope is grasped and revolved slightly until the lines are continuous, the angle being noted on the small reflected image. The arc is now swept over 90 degrees until the small pointer is in the position that the long one previously occupied. Should the one mire appear to have moved to some extent over the face of the other, and to show white against it, there is astigmatism, each notch that has so impinged giving an astigmatism of one dioptre, while the position of the meridian is shown by the pointers. If the mires in the second position should separate there is astigmatism "against the rule," the extent of the separation indicating its amount.

The advantages of this method of examining for astigmatism are evident. A comparatively short time is occupied. The testing is wholly objective, the judgment of the patient not being appealed to. All he has to do is to keep still and to look in one direction. In ordinary cases, no mydriatic need be used. This last advantage can scarcely be overestimated. For the average individual dreads the artificial dilatation of the pupil. If homatropine be used for this purpose he must sit for hours, applying it at short intervals, and subsequently submit to a partial deprivation of useful vision for a day or more. If atropine be the agent chosen, the time needed for its application is less, but the effect remains for a week or more. A subsequent affection of the eye is often attributed by the ignorant to the use of the drug. It is with difficulty that we persuade many to undergo a second similar examination. It is a well-known fact that the fear of the process deters not a few from submitting to the test. It may be objected that, although the ophthalmometer gives us the astigmatism, we cannot yet ascertain the total hypermetropia without paralyzing the accommodation. Admitting this fact, I would ask why it is so necessary to inquire into the amount of this error of refraction that may be latent. We have already seen that we can find out the astigmatism, the manifest hypermetropia is easily corrected, and it rarely happens that more is desirable. I cannot but agree with Roos as to the frequent occurrence of a hypermetropia that needs no correction, it being a normal condition of the eye, and coincide with him in the belief that there is a very large proportion of cases of asthenopia cured by the simple neutralization of the astigmatism.

I do not wish to be understood as claiming that the ophthalmometer is a perfect instrument and never disappoints the observer. It does not give us the astigmatism of the lens, a factor, however, that it is not ordinarily necessary to regard. It gives the gross amount of the astigmatism but not its kind, this must be subsequently ascertained. Its accuracy on the other hand is often remarkable. It may be likened to a

guide who tells us which one of several roads we are to take, and accompanies us a portion of the way. The aid it affords may not be always perfect, but it is most valuable, while the economy in time is great. This latter consideration is especially felt when the needs of a large clinic are taken into account. At the Eye Infirmary in this city we find it difficult to realize how we got through our work before we possessed an ophthalmometer.

II. THE PHOROMETER OF STEVENS.

That muscular asthenopia exists, that its situation and amount may by proper investigation be ascertained, and that it may be relieved by either prismatic glasses, or by partial or entire tenotomy of the antagonist muscle, would seem to admit of neither doubt nor denial. And yet on this point controversy has long been active. There are those who would relieve many cases of ordinary headache, chorea, and epilepsy by one or repeated operations on the recti muscles. Led by some success in this direction the enthusiasm concerning this method of treatment has gone to yet greater lengths. It is within the personal knowledge of the writer that an internal rectus has been divided for chronic constipation, while in another instance a rheumatic affection of one shoulder was treated by the partial tenotomy of the superior rectus muscle of the corresponding eye.

As may well be supposed a reaction in the opposite direction has taken place. Melancholy results of misdirected zeal for ocular tenotomy, the artificial insufficiencies and persistent diplopia that have resulted from a faulty diagnosis or want of care in the choice of proper cases, have induced many to deny the usefulness of aiding or attacking the motor apparatus of the eye. The medical pendulum ever swings from side to side and is rarely arrested midway.

While we cannot all agree with Dr. George T. Stevens in the extent to which he has pushed his theories, we must respect the sincerity of his convictions. And I think it should be agreed that he has not only devised the most delicate and perfect instruments for operations on the ocular muscles, instruments by the side of which those we have previously possessed appear rude and clumsy, but that he has given us in the phorometer an apparatus for the ready estimation of muscular insufficiencies that ensures accuracy, saves time and trouble, and bears the same relation to this field of investigation that the ophthalmometer does to astigmatism.

An upright column, the length of which may be varied, is inserted in a firm and loaded base, and has hinged to its upper extremity an arm that may be extended at right angles, and, by means of a screw be readily brought into horizontal position, the accuracy of which is at once shown by a spirit level attached to its extremity. On the extended arm is placed a rectangular slide with a broad base, enabling it to stand upright. In this slide are two square apertures, so situated that the patient looks through each with a single eye. Into each aperture is fitted a revolving disc in which is placed a prism of five degrees, the discs having toothed edges and being so connected with each other by a smaller disc that the motion of one is transmitted to the other. By raising a small lever attached to the right-hand disc into a vertical position the prisms are brought base to base. A patient whose head is six or eight inches away sees two images of

a candle at the other end of the room. According as these images are on the same or different levels the relative strength or weakness of the superior and inferior ocular muscles is ascertained; when the level is different a slight movement of the lever to the right or left makes the images even, and the strength of the prism that would be required in order to effect the same result is read off on an arc traversed by a little pointer attached to the centre of the right-hand prism. To test now the lateral muscles the lever is swept round into a horizontal position, thus bringing the base of the right prism up, that of the left down. The double images are now superposed. If out of line, the lever is raised or lowered till they come into line, and the excursion over a graduated arc of the pointer attached to the prism on the left shows the strength of the prism required to neutralize the weakness of the lateral muscles, as well as the position of the muscles requiring aid.

Those who have frequently had occasion to test for muscular insufficiency will appreciate the advantage of this ingenious apparatus. The patient's head is comparatively free, he wears no heavy frame, and need not be tested with a succession of single prisms, losing during the change to a new one the memory of the effect produced by its predecessor. Time, trouble and fatigue are alike spared. It is especially in hospital practice, where a large number of patients, often of limited intelligence, have to be examined in a given time, that the advantages of the phorometer, as of the ophthalmometer, are most gratefully appreciated.

III. THE ARC-LIGHT ADAPTED FOR THE OPHTHALMOSCOPE.

It is remarkable how little stress is laid by authors on the kind of light that is to be used for purposes of ophthalmoscopic examination. "The flame of a well-burning lamp" is all that is ordinarily specified. And I presume that the most of the profession regard the Argand burner as offering the best form of the flame, and gas, under ordinary circumstances, as the best source of illumination. Sunlight is spoken of as having been occasionally employed, but its use is often impossible and generally impracticable. He who has once been able to command a room darkened by shutters, with a round aperture in one of them, and who waiting for a suitable day has reflected from his mirror into the eye of the patient the light furnished by the surface of a white cloud, has seen the fundus illuminated with a clearness and purity of color he had never before witnessed, and has ever after longed to be able to dispense with the yellow glare of the ordinary gas flame, even though passing through a chimney of blue glass.

During the past winter I have been experimenting with the electric light. The incandescent lamp, to which I first directed my attention, was soon found to be impracticable. The outlines of the glowing loop of carbon were reflected on the interior of the eye, giving only linear illumination and leaving the territory between and around their borders in comparative darkness. Increasing the amount of candle power and shielding the flame by means of a frosted globe lessened, but by no means obviated the evil. I then secured a small arc-light, which has proved most satisfactory. As private houses with us are rarely furnished with other than the incandescent circuit, it became necessary to utilize this. The lamp constructed

uses five ampères of current and produces 500 candle power, when burning an arc of forty-five volts. A special carbon is used to give the proper quality and color of light. A resistance coil, placed in circuit with the lamp and connected with it by a flexible cord, takes up the balance of the voltage. The lamp is held on a metal base which carries an upright on which is mounted the apparatus for adjusting the carbons and feeding them toward each other. This upright is provided with a shield, at one end of which is a slide in which ground-glass may be inserted for the purpose of toning the light.

The lamp may be connected with any incandescent circuit, it and its resistance being placed in the branch with a five-ampère switch. The branch on which it is placed should have a carrying power of six ampères. The lamp I am at present using occupies a space of about six by nine inches. Its conductor being flexible it can be readily moved about the table. The aperture in the shield is an inch and a half in diameter. Through this shines a brilliant and steady light that readily adapts itself to the needs of the observer. He can employ it for oblique illumination, use it with the mirror alone for testing the transparency of the media or for retinoscopy, or apply it to the examination of the fundus in either the direct or inverted image.

Despite the character of this light, I find no unpleasant effect complained of by the patient. No complaint of dazzling has been made, and no greater inconvenience caused than would have been the case with the Argand gas-burner. I have no hesitation in stating that I find the light the best I have ever used. The color of the fundus approaches more nearly to that obtained under exceptionally favorable circumstances by day. The definition is greatly improved, being clearer than that obtained with any other form of artificial illumination. Repeated comparisons instituted between the Goddard gas-burner I have had in use for more than twenty years and the arc-light show the superiority of the latter. This has proved to be particularly the case in certain forms of slight macular disorganization I have lately had the opportunity of examining. The careful and repeated scrutiny required when gas was used yielded to the certainty afforded by a single glance aided by the electric lamp. Slight haziness of the vitreous, as well as floating bodies and membranes in this portion of the eye, assume unusual distinctness.

I cannot but think that when the arc-light has been perfected for this purpose it will supersede all lamps now in use. The reason for giving no drawings or additional details of the lamp I am at present using is, that we are now endeavoring to effect improvements in its construction. It is a distinct advance on its predecessor, and specifications for a third are now being worked out. I trust to have a good working lamp to exhibit at the meeting of the American Ophthalmological Society next July, and to be then able to refer those who may desire to obtain it, to the manufacturer.

THE GRADY HOSPITAL IN ATLANTA.—This hospital which was erected as a memorial to Henry W. Grady, was opened in Atlanta, Georgia, last week. The city appropriated \$15,000, the rest was raised by private subscription.

Clinical Department.**CASE OF OVARIOTOMY.¹**

BY GEORGE W. DAVIS, M.D., OF HOLYOKE.

MRS. C., widow, aged sixty-seven, has been in feeble health for many years, still able to be about and attend to her light house-work; has a chronic cough which has been quite constant for many years, worse at night rendering sleep in the dorsal position impossible. Examination failed to discover any organic disease of the lungs or other vital organs.

During the early part of the last winter she was troubled with vesical irritation and pressure about the bladder, which was in a measure relieved by medicines and drinks usually used for such symptoms. About January 1, 1892, she noticed that the lower portion of her abdomen was somewhat full, but did not consider it unnatural.

March 10, 1892, she was examined by Dr. Ellis M. Davis, who discovered an abdominal tumor, and asked me to see the case the next day. I then found a tumor in hypogastric region, well marked, slightly to right of median line, reaching two-thirds of the distance from symphysis to umbilicus, movable, of a semi-solid feel, and fluctuation doubtful. Vaginal examination revealed the pelvic brim filled with what felt to the examining finger as a solid mass with the cervix-uteri behind it and very intimately connected with it. A uterine probe entered one inch and a half. I could not at this examination become satisfied as to whether the solid mass was a uterine growth or an ovarian tumor wedged into the pelvic brim in front of the uterus.

At an examination one week later, the bowels having been thoroughly cleaned out by cathartic medicines, it was found that the tumor had escaped from the pelvis and occupied more space in the abdominal cavity, reaching nearly to the umbilicus. There was a cyst sufficient to give fluctuation in the flank and render the diagnosis confusing; fluctuation in the tumor was doubtful. A digital examination at this time proved that the mass together with the uterus had ascended into a more elevated and roomy position and the cervix was more nearly in its usual place. The uterine sound entered one inch and a half, and the uterus seemed to be more movable upon the sound than would be possible were the tumor uterine. I was also able at this time to get slight motion of the solid mass while the cervix uteri seemed to be stationary. Diagnosis was ovarian cyst, possibly uterine fibro-cyst. From this time on to date of operation, April 8th, the tumor increased in size, very rapidly extending two fingers breadth above the umbilicus and becoming very prominent in front.

Because of the patient's age, chronic cough, and general feebleness, chloroform was selected as the anesthetic. Its administration was entrusted to Dr. J. C. Hubbard. One ounce of brandy was given a few minutes before. During the operation, which lasted forty minutes, the doctor found it necessary to inject brandy hypodermically the pulse having ceased to be perceptible; vomiting and straining was marked, necessitating some delay in operating as the intestines were at times forced through the wound so as to render proper manipulation for the moment impossible.

The patient was operated upon in her own home, Drs. E. M. Davis and G. L. Taylor assisting. A bedroom leading off from the patient's sleeping apartment was cleared of all furniture, including carpet and curtains, thoroughly cleaned and aired and wiped with antiseptic solution as was all the furniture needed at the operation. A new tin wash-boiler was secured for boiling the water to be used in the operation and new earthen pitchers for the various solutions. Everything possible was done to make the patient and surroundings aseptic; and I doubt not with better success than is often the case in well-regulated hospitals.

The patient having been prepared and chloroformed, was placed upon a table in a good light, well covered with blankets, over which were placed such pieces of oiled cloth as would protect her from the liability of getting wet, with a hot-water bag at her feet; the seat of operation was surrounded with towels wet in warm sublimate solution. An incision three inches long, midway between umbilicus and symphysis through the linea alba to the peritoneum, was made, the peritoneum was picked up with dissecting forceps and nicked with scalpel, then slit upon the finger as a director to the same length as the integumentary incision. The cyst now came into view, and presented an unusually dark color, making a marked contrast with its present pearly-white appearance. This was caused by the dark brownish-green color of the cyst fluid. It very closely resembled a cyst filled with blood. The sack contained the so-called colloid fluid, portions of it being quite quick. After searching for attachments with the fingers, the hand being introduced for the purpose, the cyst was punctured with Tait's trocar, but its blunt point tore a hole too large to be easily managed with the trocar in position, and to prevent the fluid from flowing into the abdominal cavity, the trocar was laid aside, the edge of the sack quickly seized with Nelaton's cyst-forceps and drawn through the incision, allowing its contents to escape outside, it, at the same time, filled the opening in the abdominal wall, preventing protrusion of the intestines. The largest cyst having been nearly emptied, the opening in its wall was clamped with a large T-shaped cyst-forceps to still further lessen the liability of the cyst fluid entering the abdominal cavity. The cyst was now found to be multilocular, there still remaining another cyst which seemed independent of the first; it was as large as could be delivered through the abdominal wound without rupture. It was slowly lifted out of the abdominal cavity together with the solid portion of the tumor. The pedicle was very short and three inches broad, but not thick. It was so short as to make ligation difficult. It was ligated with silk ligature and tied with the Staffordshire knot and severed with scissors. There was very little hemorrhage. The toilet of peritoneum was done. A large flat sponge, moist with weak, warm, sublimate solution, was introduced so as to prevent the intestines from injury during the closure of the abdominal wound. Catgut sutures were used for this purpose. The wound was dressed with borated cotton, on which was smeared the following ointment: iodoform, one-half drachm; boracic acid, one drachm; sub-nitrate of bismuth, two drachms; vaseline, one ounce. Before tightening and tying the sutures, a glass drainage-tube was introduced and so placed behind the uterus as to drain that portion of the pelvis into which the pedicle had dropped. The omentum was carefully brought

¹ Read before the Annual Meeting of the Massachusetts Medical Society (Hampden District) April 20, 1892.

down in front and around the tube. The tube used seems to be a modification of Well's glass drainage-tube, the lower end being slightly curved and closed, but many perforations are found in its lower extremity. These perforations are larger than those in Well's tube, and I think they are too large as the tissues found their way into them, necessitating the use of some force in the removal of the tube. This gave the patient some pain, and must have disturbed the quietude of the parts surrounding its lower extremity in the immediate vicinity of the pedicle. The tube was removed thirty hours after the operation, and had been turned partly around and withdrawn to the extent of one inch at a previous cleaning. The manner of dressing the drainage-tube is important, and in this case the method adopted by Price was used. The tube having been placed in the lower angle of the wound with the flange which is three-fourths of an inch from the outer end resting upon the skin. The dressings were applied to the wound and carried a little distance below it towards the symphysis but leaving the end of the tube projecting through them. The five-tailed flannel binder was then applied; the tube still projecting through it. A piece of rubber dam about fourteen inches square was slipped over the end of tube and spread out upon the binder. Borated absorbent cotton with iodoform sprinkled upon it was used to cover the tube and absorb the discharge. The corners of the dam were turned up over the pile of cotton and pinned in such a way as to exclude the air; enclosing the cotton as it were in a rubber bag. Then to aid in keeping this bag of cotton in position another light binder was carried around the patient and over the bag of cotton. This might have been carried only from side to side of patient and secured to the flannel binder with safety-pins. The operation was now finished and the patient was quickly conveyed to her bed which had been supplied with hot blankets and heaters. She vomited several times, had hiccup and appeared severely shocked. Pulse was very slow, only about fifty beats per minute. She was kept very quiet with head low and she slowly reacted as the chloroform narcosis passed off.

The discharge through the drainage-tube was very moderate for the first six hours, after which it was never enough to fill the tube and color the cotton. The tube was however emptied several times of a little colored serum, but at the time of its removal the little serum found in it was clear. After the tube was removed a stitch was inserted and the dressing which had been slightly soiled from oozing by the side of the tube was removed and a new one secured in position by strapping. The binder was continued as before. The wound was in good condition.

The highest temperature recorded during the first week after operation was 99.4, while the pulse remained constantly at or below 70. The bowels were moved the fourth day with an enema; but, as its effect was slight, Rochelle salts were given which produced free catharsis; since which time the bowels have been sufficiently moved by an occasional injection of soap and water.

She has had no cough. The stitches were removed the eighth day. Patient was somewhat nervous that day and the evening temperature rose to 100.5° with a pulse of 76. She was allowed to swallow absolutely nothing for the first twenty-four hours after operation, and only tablespoonful doses of gruel, milk and beef

tea for the next two or three days; since which time the dietary has been gradually increased, and at present she takes ordinary food. There has been no tympanites and the abdomen has been perfectly flat since the operation. We have every reason to expect a perfect recovery. The patient sat up upon the sixteenth day and upon each succeeding day thereafter, and now, May 9th, is entirely well.

Medical Progress.

REPORT ON THERAPEUTICS.

BY FRANCIS H. WILLIAMS, M.D.

(Continued from No. 22, page 553.)

ALKALIES IN UNIVERSAL PRURITUS.

LANGE has found that sodium bicarbonate and lithium carbonate, combined with carbolic acid compresses, have a very prompt effect in relieving universal pruritus. He refers to an extreme case in which the condition was improved in a few days, with marked relief in six weeks, and in three months hypnotics were unnecessary.

BENZINE IN PEDICULOSIS.³

Nedzwiecki strongly recommends ordinary commercial benzine as the most effective, cleanly, and convenient application for destroying pediculi capitis or pubis. The affected parts should be freely bathed with the fluid for three or four minutes. Both pediculi and nits are killed almost instantaneously. As a rule a single application is sufficient, even in severe cases.

The smell of benzine is said to disappear very quickly. The remedy can be safely applied, even in the presence of an eczematous rash, since it causes only trifling pain, which soon passes off. The treatment must always be carried out in the daytime, as the substance is extremely inflammable.

THE TOXIC EFFECTS OF CHLORATE OF POTASSIUM.⁴

Dr. G. A. Fackler reports in the *Cincinnati Lancet-Clinic*, the case of a boy, fifteen years old, who had taken one hundred and fifty grains of chlorate of potassium in a period of six hours. The most striking feature was a slight bluish discoloration of the skin, especially marked about the lips, nose, ears and extremities. There was a slightly jaundiced appearance of the conjunctiva, abdominal walls not distended but painful on pressure, liver decidedly enlarged. During the examination the patient began to vomit, excruciating pain in the lumbar region followed and the patient lay moaning, retching, vomiting, and, with the peculiarly discolored skin, presented a rather harrowing picture. The urine was voided with marked strangury and sparingly, and upon examination was of a peculiarly yellowish-red color and found to contain albumen.

Sulphate of magnesia was administered and four hours subsequently the patient had profuse alvine discharges, slight dyspepsia was present, and there were a number of yellowish-brown maculae upon the side of the abdomen, the back, and anterior portion of the neck: acetate of potassium with tincture of strophantus was ordered. The symptoms gradually improved, and within five days had entirely disappeared, with the exception of slight pain in the epigastrium.

³ British Medical Journal, January 2, 1892.

⁴ Archives of Pediatrics, No. 33, 1891.

The best therapy for the future is to banish the remedy from our list of medicines, although it must be granted that in cases of throat affections and cystitis occasionally good results are witnessed, still, these results are wanting in a disproportionately larger number of cases. On the other hand, we have at our disposal a large number of substances which in their therapeutic value are not inferior to chlorate of potassium and do not possess much toxic properties. It is especially advisable never to employ it as a medicine for children.

Poisoning by Gelsemium Sempervirens.⁵

Dr. Jepson was called upon to treat a woman, aged forty, who was suffering from neuralgia in both temples. He gave her tincture of gelsemium in ten-minim doses every two or three hours; and as no relief had been obtained after one day, he ordered double doses in a quinine mixture. She took three or four doses during the night. Next morning at eight o'clock she seemed better, but an hour later she was found in a very peculiar state. Though perfectly conscious, she had lost power over her tongue: could not protrude it, could not articulate, could only swallow with very great difficulty. Her pupils were widely dilated, and she could not see clearly. She could not write, but nodded in reply in questions. A hypodermic injection of strychnine (grain $\frac{1}{2}$) was given with excellent results. Ten minutes after it there was a return of power in the tongue and hands, and an improvement in the vision. After a second injection there was still further improvement; she took food and stimulants; and all paroxysms disappeared. She had some return of the neuralgia and was very weak for a few days, but eventually quite recovered and enjoyed better health than for some time previously.

PENTAL, A NEW ANESTHETIC.⁶

Pental is a clear, colorless, thin, neutral, unirritating, fluid, with a peculiar sweetish odor and taste. It is more inflammable than chloroform. It has been found to have a distinct anesthetic action without unpleasant after-effects. The narcosis is not as profound as with chloroform, but it is sufficiently deep for the smaller and also larger surgical operations. Patients come readily under its influence in about four minutes and its use is seldom accompanied by the unpleasant features of anesthesia by means of chloroform. Out of 120 administrations of the drug there were serious though not fatal symptoms in one case. The drug was administered in an inhaler a few drops at a time, and every precaution used with chloroform was taken, narcosis was continued from forty seconds to eight and one-half minutes. It seems possible that this anesthetic may find a place in practice, but a proper estimate of its value can only be made after it has been used in a larger number of cases.

CHLORALAMIDE.⁷

Professor H. C. Wood and Dr. David Cerna have studied the physiological action of chloralamide and the results of their experiments indicate that the action of this drug upon the heart is so slight that it bids fair to be valuable as a hypnotic in cases of feeble heart; while its stimulating influence upon the respiration would seem to fit it for employment in cases of nervous

exhaustion. The exact clinical value of a hypnotic can, however, only be determined by clinical study. After the use of it to a moderate extent, in various forms of insomnia, Dr. Wood considers it to be slower and less certain in its action than chloral. Rarely have unpleasant after-effects been noted, but he has seen in some cases distinct headache. It has been recommended by Hagen and Hüffer as of especial value in cardiac asthma.

LAVAGE.⁸

In the *Révue de Thérapeutique Medico-Chirurgicale* for 1891, No. 18, p. 498, we find the method of Dr. Lienievitch, who proposes to relieve the vomiting which follows the administration of chloroform, by lavage. He believes that not only the chloroform, but also the irritation of the peritoneum produced by the antiseptics, is accountable for this symptom. He employs the tube of Faucher and washes out the stomach with warm water in which one-half to one per cent. of bicarbonate of soda has been dissolved, until the water returns clear. The abdominal walls are compressed (after an operation of laparotomy has been performed) during the washing. The results are excellent, in that, if necessary, water sufficient for the needs of the patient can be left in the stomach. The general condition improves, because there is freedom from nausea, gaseous accumulations, vertigo, and epigastric distress.

LACTOSE AND GLUCOSE AS DIURETICS.

B. Vespa has made a number of experiments as to the diuretic effect of lactose and glucose in various diseases. In the ascites of hepatic cirrhosis the diuretic effect was almost *nil*, and in acute and chronic nephritis it was hardly appreciable. In pleurisy with effusion, on the other hand, and in cardiac disease with disturbed compensatory action, the diuretic effect of lactose and glucose was most marked. As neither of these substances has any bad effect upon the heart or the nervous system they can be given at all times and in combination with any other remedy. They are well borne and do not cause nausea or other disagreeable effects.

Reports of Societies.

ASSOCIATION OF AMERICAN PHYSICIANS.

The Seventh Annual Meeting was held in the Army Medical Museum, Washington, D. C., May 24, 25, and 26, 1892.

FIRST DAY.—TUESDAY.

DR. V. C. VAUGHAN, of Ann Arbor, Mich., read a paper on

A BACTERIOLOGICAL STUDY OF DRINKING-WATER.

Since the opening of the Hygienic Laboratory of Michigan University, October 1, 1888, more than one hundred and fifty samples of drinking-water have been examined at the request of health officers. These examinations have been both chemical and bacteriological, and the latter has developed some facts which may be of interest.

There are kept on hand at the laboratory a number of sterilized bottles, with glass stoppers, and of two

and one-half litres capacity. These bottles are sterilized by steam, then set in wooden crates so arranged that the handle of the crate holds the stopper in place and makes it impossible to open the bottle without removing the handle, which is fastened by means of four screws. The use of sealing wax about the stopper is forbidden, and in cases where the over-zealous collector has resorted to this method "to make things more secure," the samples have been discarded and fresh bottles have been sent, with the request that the sealing be omitted. In some instances a piece of sub-limate gauze has been placed over the stopper and fastened about the neck of the bottle. This admits of the collector placing his seal upon the outside of the gauze. A health officer writes or telegraphs that he wishes one or more samples examined, and the desired number of bottles is sent. He is instructed to fill these and to return them immediately. In the great majority of cases the bacteriological examination is commenced at the laboratory within thirty-six hours after the samples have been collected. In some instances, the collector has been instructed to obtain new bottles and to sterilize them, but as a rule this has not worked satisfactorily, and many samples having been discarded on learning the method of sterilization employed, the above-described method is now insisted upon.

As soon as the sample reaches the laboratory, gelatine plates are made, and at the same time the chemical analysis is begun. The number of germs in given quantity of water (one drop or one cubic centimetre) is determined by counting the colonies which appear on the plates after twenty-four, forty-eight and seventy-two hours. It has been found that this number is very variable, and that it bears no constant relation to the amount of organic matter in the water as determined by chemical analysis. Moreover, the results obtained have led to the conclusion that the question of the fitness or unfitness of the supply as a drinking-water, cannot be answered by the number of germs. Some waters which contain hundreds of germs in each drop have been used by communities without causing sickness, while typhoid fever has, beyond any reasonable doubt, been traced to the use of water containing less than a score of germs in each drop. However, a record of the number of germs is kept in all instances; then each germ is isolated and grown on the various nutritive media. In fact, the life history of each germ is carefully observed and the observations recorded. The manner in which the germ grows on gelatine plates, in gelatine tubes, on agar, on potato, etc., is noted. The form and size of the germs, its reactions with staining re-agents, etc., are also studied and recorded. The effect of each germ upon guinea-pigs, mice, rats and rabbits, has also been studied. Especial attention has been given to those characteristics by which it has been proposed to distinguish the typhoid germ from other bacteria found in water.

Some of the conclusions which have been reached in this study are as follows:

(1) Many of the germs found in drinking-water will not grow at the temperature of the human body. These germs, therefore, are not capable of inducing disease. It matters not how rich a given sample of water may be in these germs, if it contains no others, it cannot be said that the water is a source of typhoid fever. The freedom of communities, using such water, from typhoid fever, seems to justify this con-

clusion. Such a water may not be, and certainly often is not, a desirable drinking-water. It may be turbid with suspended matter, unpleasant to the taste, and give off a disgusting odor, but there is no evidence that it can cause disease. Several interesting examples of this kind have come under observation. One of these may be mentioned. A certain city of about ten thousand inhabitants took, for a while, its public water-supply from a shallow lake, the bottom of which was covered with decomposing organic matter of vegetable origin. This water was turbid, unpleasant to the taste, and gave off unpleasant odors, but none of the bacteria in it grew at 38° C. On the other hand, many of the inhabitants of the city took their drinking-water from shallow wells, the water of which was clear, sparkling and palatable. The well-water, however, contained germs which grew abundantly at 38° C. The use of the lake-water in preference to that supplied by the wells, was recommended early in the spring of 1891. Some followed the advice, others did not. During the late summer and early fall of 1891, there were more than two hundred cases of typhoid fever in the city, and at a public meeting held by the State Board of Health in this place, about the last of October, every physician in the city agreed to the statement that there had not been a case of typhoid fever among those who used the lake-water exclusively. This positive testimony of the physicians was also confirmed by the other citizens.

(2) Of the germs which grow at 38° C or at higher temperatures, some are fatal to animals when injected subcutaneously, while others are not. This renders a division of these into toxicogenic and non-toxicogenic germs possible.

(3) There is no proof that these non-toxicogenic germs can multiply in the animal body. Indeed, all the evidence which has been gathered so far goes to show that they not only fail to multiply in the bodies of the rat, mouse, guinea-pig and rabbit, but some die when injected under the skin or into the abdomen. However, this does not furnish positive evidence that they would not multiply in the body of man. For these reasons, waters containing these germs have not been positively condemned, though it has been advised in some cases that their use should be discontinued.

(4) Some of the toxicogenic germs found in drinking-water produce the same symptoms and the same post-mortem appearances in the above-mentioned animals as are observed after the employment of Eberth's germ. Moreover, their pathogenic (toxicogenic) properties as tested upon these animals, are fully equal to those of Eberth's germ. They will not only live, but will multiply in the animal body. Waters containing these germs have in all cases been condemned.

(5) More than one germ obtained from drinking-water forms an invisible growth on potato.

(6) Several germs found in drinking-water will grow on the media prepared by Parietti, Uffellmann and others, as means of recognition of the Eberth germ. About thirty of the germs found in these samples of drinking-water have been studied sufficiently to admit of their identification. Several of these differ from any which have been reported by other investigators.

DR. G. M. STERNBERG asked whether these toxicogenic germs resemble the typhoid bacillus in morphology and whether they belong to the same class or group.

DR. V. C. VAUGHAN: The germs are bacilli and all

motile. One, the bacillus venenosus, is shorter and thicker than the Eberth germ that I got from the Hygienic Institute at Berlin. Another the bacillus venenosus brevis is still shorter; about twice as long as broad. There is one that liquefies gelatin only after four to six weeks. After it has been grown at a high temperature for a while it ceases to liquefy gelatin.

DR. G. M. STERNBERG: It is interesting that this germ liquefies at one time and at another time does not. It is only one case out of a good number that have been noticed by bacteriologists. Some of the phosphorescent bacteria behave in this manner. I got out a bacillus in Cuba which was a liquefying bacillus for a time, and after a time it failed to liquefy. We cannot, therefore, use the liquefaction of gelatin as an absolute characteristic to enable us to differentiate these bacteria. The definite characters which were first given to the typhoid bacillus will not stand. As to the invisible growth upon potato, we have all given that up as being distinctive. We encounter great difficulty in differentiating these lower organisms; and Dr. Vaughan has found, as many others have found, that it is hard to decide whether he has simply different varieties or well-defined species. There can be no doubt that we have species amongst these germs as well defined as in the higher plants.

DR. W. H. WELCH: The distinction which Dr. Vaughan makes between the terms "pathogenic" and "toxicogenic" is not what I anticipated it would be. I supposed that he would designate as a toxicogenic germ one that causes death by intoxication without multiplication of the germs inside the body. The distinction which he makes is doubtful and is difficult to carry out practically. Toxicogenic and pathogenic germs, according to Dr. Vaughan, are both capable of multiplication within the body, but the pathogenic ones cause lesions and symptoms that are definite and recognizable, and the toxicogenic ones cause symptoms and lesions that are vague and undefined. It seems to me this distinction is indefinite and of little value. I agree with Dr. Vaughan as regards the difficulty in the recognition of the Eberth bacillus.

Dr. Vaughan's statement that a number of bacteria, as obtained originally from water, appeared to be very unlike the typhoid bacillus, and that the same bacteria when obtained from the animal after inoculation grew like the typhoid bacillus, is, if confirmed, an interesting and remarkable observation. There is, however, a possibility of fallacy there which he has probably had in mind. A great many of these bacilli produce intestinal changes, and under these circumstances the bacillus coli communis is very likely to enter the organism. In this case one can readily obtain from the spleen and other organs the bacillus coli communis which may be mistaken for the micro-organism injected. It is perfectly true that one may obtain from the spleen of typhoid fever patients a number of different bacilli; and, as a rule, one can obtain in cases of typhoid fever, not perhaps so often from the spleen as from the kidney and lung, the bacillus coli communis. There is no doubt in my mind that a number of those who have written about the characters of the typhoid bacillus have been working with the bacillus coli communis, and not with Eberth's bacillus.

Unless one adopts the view of Dr. Vaughan, which is at present hardly likely to obtain general acceptance, that typhoid fever is not due to any one specific germ, but to a variety of more or less related germs, it is

difficult to see what the bearing of these experiments is upon the etiology of typhoid fever. I am not prepared to go the length of thinking that all these germs can be changed over into germs that may produce the same results as the typhoid bacillus and still less that they may under certain conditions acquire all of the morphological and cultural properties of the Eberth bacillus.

DR. V. C. VAUGHAN: If I could have had a number of spleens from the persons who had been drinking of each of these waters, it would have helped me very much. This is what I want to get in the next set of waters that I examine. When this is done, I think all will be able to decide positively, whether typhoid fever is due to one specific germ or whether there are varieties of the typhoid germ.

I meant the term "toxicogenic" to be indefinite. I cannot say that one of these germs will cause typhoid fever, because I have not tried it on man, and the disease that we get in the lower animals is not typhoid fever. I do not want to say that these germs are capable of producing any disease, and still I want to distinguish them from germs which do not grow at 38°, and which are capable of producing poisons outside but not inside of the body. It seems to me that to save the word "pathogenic" from meaning nothing, it would be better to use the word "toxicogenic."

With reference to the proof tests with the coli communis, I have studied this germ right along with the coli communis and Eberth's bacillus, and have made proof tests, and am satisfied that none of these germs are the coli communis, and that none of the germs that I have gotten from the spleen are the coli communis.

Certainly the great epidemics of typhoid in the cities generally start from the pollution of the drinking-water with typhoid stools; but I also believe that typhoid fever may originate without a pre-existing case of typhoid fever. I have seen cases of typhoid fever scattered amongst the farming population, amongst men, women and children who have not been off of their farms for weeks, and it would take a good deal to convince me that there was a common source of infection in these cases. I believe there are different germs, or different varieties of the same germ, that may cause typhoid fever, and that they are widely distributed.

DR. G. WILKINS, of Montreal, presented a paper on THE TREATMENT OF TYPHOID FEVER BY COLD BATHS.

The total number of cases upon which this paper is founded is 39, with two deaths. Of this number, seventeen were under the care of my colleague, Dr. Stewart, who is quite as warm an advocate of the baths as I am. During the first six months in which I made use of the cold baths, I adopted Liebermeister's method. Since then I have adhered to Brand's method, with slight modifications.

I seldom keep the patient in the bath longer than ten or twelve minutes, and place him there only when the temperature in the mouth reaches 102.6°. Whilst in the bath-tub, cold water compresses are placed on the head or the water poured over, and at the same time another assistant applies friction to the surface of the body. Sometimes, whilst in the bath, or just before it, half an ounce to one ounce of whiskey is given either in milk or water. The temperature of bath in 31 cases was 68° to 70°. In the remaining cases,

temperature 80° reduced to 68°. Greatest number of baths in any one case, 35; smallest number, two; average reduction of temperature, 2.8°, duration of fever, averaged thirty days; the date of entering into hospital, or commencing treatment, being on an average the tenth day.

I have not yet adopted the routine of treating every case of typhoid by cold baths. I treat mild cases on the expectant plan.

In regard to haemorrhage in this method of treatment, Hare states that in the large number of cases (1,173) in which he used the cold bath, whilst the actual mortality from haemorrhage was somewhat less than those treated on the expectant plan, the occurrence of haemorrhage was as frequent, though not more so.

It is a popular belief amongst the laity that the cold bath will tend to produce mischief in the respiratory apparatus, that is, the patient will "take cold"; as most of us know, quite the reverse in the case.

The advantages of the cold bath over other methods of treatment are: Immediate reduction of temperature from two to four degrees; resting quietly after it, or sleep; increased tonicity of the heart and slowing of pulse; fewer cases of lung complication, and, if present, marked amelioration of their symptoms.

The contra-indications are: Haemorrhage; peritonitis, and also determined opposition of patient.

Dr. OSLER: I will give briefly our experience with this method of treatment at the Johns Hopkins Hospital. From the opening of the hospital in May, 1889, until July 1, 1890, we treated the cases symptomatically. There were thirty-two cases with seven deaths. This was an unusually high mortality, which is accounted for in large part by the very serious nature of the cases. From July 1, 1890, to February 1, 1892, there were 107 cases treated rigidly by the Brand method. The temperature of the bath was 70°; the patients were bathed every third hour when the temperature rose above 102.5°. There were only eight deaths. One of these cases was not treated as he came in a moribund condition. The death-rate is practically that which has been obtained by the Brand method in all of the general hospitals in which it has been employed,—about seven per cent. In the garrison hospitals the percentage is two to three per cent. Cold baths do not always reduce the temperature, and there are cases treated under the most favorable circumstances which pursue a course almost uninfluenced by the baths. It is interesting to note historically that Nathan Smith, in his article on the treatment of typhus fever, written in 1823 or 1824, advocated, in a very interesting way, the treatment of the fevers by cold, and practised it as early as the summer of 1798, very shortly after its introduction by Currie.

Dr. KINNICUTT: This method of treatment has been adopted in the wards of St. Luke's Hospital for the past few years with exceedingly favorable results. My clinical experience corresponds closely with that of Dr. Osler and the author of the paper. I have frequently had cases of catarrhal pneumonia associated with the typhoid process that have done exceptionally well under the cold bath treatment. The greatest number of baths I have ever given in a single case is 175. The case was of exceptional gravity. The patient is now doing full duty as nurse in the hospital.

Dr. WM. PEPPER: I would like to say a word about

the labors of Hiram Corson, of Pennsylvania, in this direction. At the age of ninety years he is still practising in what is now a thickly settled region, but which was for many years but sparsely populated. He has advocated and practised the cold water treatment of the infectious diseases for the past sixty years, in opposition to all kinds of criticism. I want also to say a word of tribute to the value of the work of our colleague, Dr. Wilson, to whom, more than to any other man in America, is due the credit of calling attention to the cold water treatment of typhoid.

The difficulties of using the bath in private practice are vanishing. One of the leading druggists of Philadelphia, Mr. Frank Morgan, keeps a movable bathtub, made of fibre, available for the use of physicians at any hour of the day or night. These tubs are very light, can be had of any size, and can be moved through the door of any house. A hose thirty or forty feet in length will permit of its being emptied into some suitable place. It is in private practice that we will probably get the most complete satisfactory statistics.

I wish to testify to my own progressive conversion to belief in this treatment, and the desirability of its use in the vast majority of cases of typhoid as a routine treatment. I would like to emphasize the importance of friction during the bath. I feel that in this Brand has laid stress upon a point of first importance. We ought not to forget, also, the value of the cold pack.

Dr. I. E. ATKINSON: I wish to speak with the most unqualified approval of the cold bath treatment, from my own experience. There is one point in the history of typhoid fever that will always prevent our getting the statistics down to a desirable point of lessened mortality. There are a certain number of cases in which the temperature may never reach 102.5° and yet are fatal; these will probably not come under the influence of the cold bath treatment as at present conducted. I have now a case which threatens to die in which the temperature is constantly below 102°. Some statistics published by German authors, of typhoid fever treated during the Franco-Prussian war, show an exceedingly large number of fatalities in a series of cases where the temperature did not reach 102°. These cases probably occur often enough to keep the mortality at from five to eight per cent. in spite of any antipyretic treatment that may be adopted.

Dr. W. G. THOMPSON: Two years ago I undertook the Brand method and have since treated forty-eight cases by it, with results so satisfactory that I have reached the point where if I had the disease myself I should insist on being treated this way. I am surprised that Dr. Wilkins did not emphasize more the benefit of friction. It seems to me that the value of the Brand method of treatment, from the physiological standpoint, is certainly a double one; we apply a shock of cold to a very large surface of the body, which is a strong stimulant, and then we supplement this by a mechanical stimulant over an equally large surface. It does not seem to me that the reduction of the temperature is the principal good obtained. I have seen in this series of forty-eight cases three instances of hemorrhage of the bowels occur, but I could not attribute them directly to the baths as they had no relation to the time of the baths. There were only three deaths in these forty-eight cases, or about seven per cent. I should like to ask Dr. Wilkins and also Dr. Osler whether they have regarded the occur-

rence of menstruation during the administration of baths as a contra-indication for their continuance.

DR. TYSON: I desire to call attention to the cause of death in two cases of typhoid treated in this manner. The first case, a man, died a week or so after the bathing had ceased, the temperature during that time not reaching 102.2°. He died of embolic pneumonia, succeeding to numerous abscesses caused by large hypodermic injections of strichnia given by the assistants who thought he was in danger of heart failure. The second was a case of peritonitis, succeeding perforation. He was admitted on the tenth day of the disease and died on the seventeenth day. The cold bath treatment evidently does not prevent perforation.

DR. STOCKTON: It occurs to me that there are not a few cases which have benefited by the employment of baths even though the temperature at no time reaches 102.4°. I have seen cases where it seemed to me that the cold bath, under these circumstances, had favorable results. I also think we find undoubted benefit in the employment of the cold baths where the temperature does not remain lowered after them for any length of time.

DR. G. WILKINS: I believe friction is very important. The cold bath and friction has the efficacy of not only cooling the blood but the further effect of imparting tone to the vessels which has been lost by high temperature.

With regard to menstruation, my recollection is that it is not a contra-indication, but I have had no cases in which it has occurred.

I have had none of those cases to which Dr. Atkinson has referred — cases of continuous low temperature — but I do not see any objection to the administration of a bath in these cases, especially when combined with friction.

(To be continued.)

AMERICAN SURGICAL ASSOCIATION.

ANNUAL meeting held in Boston, May 31, June 1, and 2, 1892.

TUESDAY, FIRST DAY. — MORNING SESSION.

The Association was called to order by the President, DR. P. S. CONNER, of Cincinnati, who delivered the

ANNUAL ADDRESS.¹

The first paper was that on

THE TREATMENT OF UNCOMPLICATED FRACTURES OF THE LOWER END OF THE HUMERUS,

by DR. JOHN B. ROBERTS, of Philadelphia.

The following are the conclusions presented:

(1) In the treatment of fractures of the lower end of the humerus, the divergent angle between the axes of the arm and forearm must be preserved; and hence, dressings which interfere with the normal difference in level of the radius and ulna are not permissible.

(2) Fractures of the lower end of the humerus of ordinary severity are, as a rule, more successfully treated in the extended than in the flexed position.

(3) Because the "carrying function" is less liable to be impaired.

(4) Passive motion at an early date is harmful;

and should be deferred until union has occurred and the dressings have been finally removed.

(5) Good results as to anatomical conformation and as to motion are generally to be expected and can usually be obtained.

(6) Recent fractures in which satisfactory coaptation is not obtainable under anesthesia may with propriety be subjected to exploratory aseptic incisions. Old fractures, in which deformity and impairment of function are marked, may, within certain limitations, be subjected to refracture or osteotomy, for the relief of these conditions.

DR. JOHN E. OWENS, Chicago, said that he had never treated fractures of the lower end of the humerus in the extended position. The treatment of such fractures in the extended position seems to recommend itself for the following reasons: in the extended position there is no room in the olecranon fossa for neoplastic deposits; the great super-abundance of soft tissue in front of the joint when the arm is flexed marks the symptoms; the soft tissue in front of the arm presents more opportunity for laceration and cicatricial contraction; in the extended position no traction is made upon the vessels and nerves; that the natural angularity between the arm and forearm is preserved.

The speaker had experienced considerable timidity in the treatment of these fractures at the elbow on account of the impaired mobility which often results. The natural position of the arm in relaxation is that of flexion. He had treated these fractures in the flexed position. The extended position may cause tilting forward of the upper end of the lower fragment or its rotation forwards or hyper-extension may be caused.

Passive motion is resorted to in four or five weeks to an extent short of causing suffering. The material used for the splint is plaster-of-Paris. He had treated many of these fractures in cases where the injury resulted from railroad accidents where suits for damages are common, but he knew of no case where the question of defective treatment entered successfully.

DR. JOHN H. PACKARD, of Philadelphia, remarked that it was often difficult to tell the exact character of a fracture at the elbow-joint even under the most favorable opportunities for examination. He thought that the carrying function was rarely perfectly maintained under any plan of treatment. After fracture running into the joint there is liability to the formation of adhesive lymph. He thought that passive motion should be resorted to before the organization of the adhesive lymph. He advocated treatment of these fractures in the flexed position and described a splint of sheet zinc which he had used with satisfaction.

DR. CHARLES B. PORTER, of Boston, thought that the treatment advocated in the paper violated one of the first principles in the treatment of fracture, that is, to place the muscles in a state of relaxation. In the extended position the muscles which should be relaxed are not at rest. He had never seen any statistics in regard to the results of treatment of fracture in the extended position, in comparison with those in the flexed position. Until these are forthcoming, the profession will be unwilling to accept this as the best method of treatment. He therefore gave his adhesion to the treatment of these fractures in the flexed position rather than the extended position. Before the fracture is dressed, it should be adjusted under ether and then not looked at for two or three days and if found

¹ See page 565 of the Journal.

in position not again dressed for a week or ten days. In old fractures where there is sufficient deformity to demand osteotomy, resection of the elbow is better and by it a very useful arm may be secured.

DR. J. FORD THOMPSON, Washington, D. C., did not approve of the plan of treating fractures of the lower end of the humerus in a right-angled splint. In his treatment he adopted that plan of treatment which permitted the axes of the fragments being brought into relation with each other. This he had found to be the extended position. In two cases of compound fracture he had been unable to bring the fragments into line until the forearm was extended. The difficulty about the straight position is that it is disagreeable and uncomfortable to the patient. He considered plaster-of-Paris to be the best dressing.

DR. A. G. GERSTER, of New York, held that the bad results which are often seen after fractures at the lower end of the humerus are not necessarily due to the method of treatment. In several cases where he had had an opportunity to examine the joint he had found that the trouble was due to the throwing out of callus at points where the callus had been stripped off. Bad results are also often due to insufficient examination. Anesthesia is not employed and the dislocation which may accompany the fracture is not recognized. In the treatment of the fracture after replacing the fragments, such methods must be employed as will hold them in place. The flexed or extended position must be employed as necessary. He had found that, as a rule, the fragments were best held in place by treatment in extension. He does not employ passive motion and considers it useless and often harmful.

DR. STEPHEN H. WEEKS, of Portland, Me., said that it was his custom to treat supra-condyloid fracture of the humerus in a position of flexion, but he was satisfied that satisfactory results are secured by different methods of treatment.

DR. T. J. DUNOTT, of Harrisburg, thought that the manner in which the injury had been received had a great deal to do with the ultimate result. He was inclined to think that the flexed position would give a good result in many of these fractures associated with severe injuries. He prefers to treat the arm in such a position that the radius and ulna are parallel. In many cases where great injury is done to the soft parts, no splint can be applied, and under such circumstances the arm should be laid on a pillow and have water and laudanum applied for some days until the tumefaction goes away. If necessary, incision into the tense tissues is made.

DR. W. H. CARMALT, of New Haven, said that in some cases the ulna acted as a wedge between the two fragments at the lower end of the humerus forcing them apart, and reported a case which he had recently treated in the flexed position, using extension by means of weights and obtained a satisfactory result.

DR. J. COLLINS WARREN, of Boston, had observed the difficulty mentioned by Dr. Carmalt, but had attributed it to drawing forward of the condyles rather than to sinking in of the ulna. Dr. Bigelow had laid down the excellent rule of going through the movements for reducing a dislocation at the elbow in these cases. In this way the danger of overlooking a dislocation is avoided, and if there is simply a fracture, the manipulations mould the bone into place. The flexed position with an internal angular splint seems to be the best method.

AFTERNOON SESSION.

THE TREATMENT OF UNCOMPLICATED FRACTURES OF THE BASE OF THE RADIUS,

by DR. JOHN B. ROBERTS, of Philadelphia.

The following conclusions were presented:

(1) Fractures of the lower end of the radius vary comparatively little in their general characteristics, because but one form is usual.

(2) Muscular action has little, or nothing, to do with producing or maintaining the deformity.

(3) Immediate reduction of the fragments is the essential of treatment.

(4) Many of the splints devised for the treatment of this fracture have been constructed in ignorance of the pathology of the condition.

(5) The ordinary fracture of the lower end of the radius usually requires no splint, and should be dressed with a wristlet of adhesive plaster or bandage.

(6) When a splint is required, a narrow, short, dorsal splint, fixing the wrist, is all that is necessary.

(7) The method of dressing here advocated is the best, because it annoys the patient as little as possible by avoiding cumbersome appliances, and permits free voluntary movements of all the finger-joints.

(8) Passive motion is unnecessary until union has occurred and the dressings have been finally removed.

(9) Good use of the wrist and fingers is early obtained, and the anatomical conformation is restored as well as, and perhaps better than, by other more complicated dressings.

(10) Old fractures, which have been improperly treated by omission of immediate reduction, may with considerable success, be subjected to retraction at the end of six or more weeks. At later periods, readjustment may be possible only by osteotomy, which is a legitimate means of treatment.

DR. JOHN H. PACKARD, Philadelphia, had, in 1879, read a paper on this subject before the American Medical Association, in which he took the ground that the great difficulty in many of these cases arose from non-reduction. If the fracture of the lower end of the radius commonly known as Colles's fracture, is once reduced, there is little tendency to reproduction of the deformity. Many physicians think that all that is necessary is to apply the proper dressing. The most important step in the treatment is reduction. He did not agree with the fifth proposition, that no splint is required. He employs an anterior splint padded to fit the curve of the radius and reaching to the ball of the thumb. The patient can use the fingers freely. In ordinary cases who will take proper care of the arm, this simple splint suffices.

DR. CHARLES B. PORTER, of Boston, emphasized the necessity for complete anesthesia, then complete reduction and breaking up of the impaction, and then the application of a posterior and anterior splint; after a week or ten days, he allows motion of the fingers, and in two weeks motion at the wrist. He considers passive motion unnecessary except in old people where there is a rheumatic or gouty tendency.

DR. J. FORD THOMPSON, Washington, dwelt upon the disastrous results that often followed failure to reduce the displacement, or the use of improper dressings. After reduction of the fragments, he applies an anterior and posterior splint, secured lightly to the arm. He had not found it necessary, as a rule, to use either to accomplish reduction. In cases where there

was severe pain following the application of the ordinary splint, instant relief followed the application of a plaster splint, the hand being carried well to the ulna side. In several cases where the hands were useless from the inflammation of the sheaths of the tendons, he had tried to break these up under repeated administrations of anaesthetics, but the results had not been very marked.

DR. JOSEPH RANSOHOFF, of Cincinnati, said that in some cases the reduction could not be effected so readily as had been described. He had had three or four cases in which extension would not overcome the difficulty, and in such cases hyper-extension has been resorted to. In the treatment he is partial to Lewis's splint. After a week or ten days passive motion is resorted to.

DR. CHARLES B. NANCREDE, of Ann Arbor, called attention to the fact that a certain amount of the bone-tissue at the seat of fracture was destroyed, so that some deformity will necessarily follow. Reduction is the most important measure in the treatment. The fragments are then to be held in place by suitable apparatus.

FIBROID TUMORS OF THE UTERUS,

by JOHN HOMANS, M.D., of Boston.

Fibroid tumors were defined as aggregations of normal uterine tissues in abnormal situations and masses. They may cause symmetrical or more or less one-sided enlargement; they may be in the walls of the uterus or protrude towards its outside or towards its inner cavity; they may be incorporated with the uterus or connected with it by broad attachment or by a pedicle, or they may be entirely separated from it and get their nourishment from the vessels of the omentum or mesentery. They may be dense and edematous, or filled with lymph-spaces, or they may in very rare instances be fibro-cystic. It is probable that a certain number of the tumors which have been described as fibro-cystic belong to the class of fibroids with dilated lymph-spaces. True fibro-cysts are very rare.

In size these tumors vary from that of a mere dot to masses weighing fifty or more pounds. Their growth is slow. They are of common occurrence. In the past fifteen years the author had seen about 520 fibroid tumors.

Operations to relieve women with fibroid tumors are rarely necessary. The writer had operated on only 60 of these 520 cases, eleven per cent. The conditions which should guide us in recommending removal of the tumors are, when they threaten life by hemorrhage; when they are unbearable from their weight or the inconvenience they cause; when in a young woman they cause distress and shame from the alteration in her figure; when they cause much pain; when they cause serious obstruction of the circulation, or interfere with the action of the digestive or eliminative organs; when they cause obstruction of the bowels; or when their pedicles have become twisted and sometimes the whole uterus becomes twisted on its axis.

Death by hemorrhage is rare. The speaker knew of only three instances. In fibroids complicating pregnancy, the tumor may threaten to render delivery impossible, but nature will generally get the obstruction out of the way if you give her a chance.

The solid fibroid tumors rarely have adhesions, and are removed without much difficulty. Of fibro-cystic tumors the speaker had met with only eight in the 520

cases. None of these were successfully removed. One woman recovered from an incomplete operation. The others all died. The author had reported an extraordinary case of twisting of the uterus as the pedicle of a large fibroid tumor. The uterus was twisted one and a half times on its axis. The case was fatal, no operation having been done.

The natural history of ninety per cent. of fibroid tumors is to remain stationary after reaching a certain size and after the menopause to become cretaceous and atrophied. About ten per cent. require removal. The average age at which the speaker had operated was thirty-nine years.

Treatment by ergot alone is usually ineffective; combined with curetting it helps to stop hemorrhage. Treatment by high doses of electricity, a la Apostoli, sometimes stops hemorrhage, almost always relieves pain and gives strength, but rarely diminishes the size of the tumor. In four cases the speaker had practised removal of the ovaries for the cure of fibroid tumors. In one woman, forty-four years old, the tumor disappeared in a few weeks, and menstruation at once ceased. In another, thirty-three years old, the catamenia gradually ceased after three years and the tumor remained about the same. In another, thirty-four years old, there was irregularly recurrent bleeding for eight months after operation. A fourth case, thirty-six years old, was not at all relieved by the operation. He was inclined to regard this method as unreliable.

Curetting often cures the hemorrhage completely. This is followed by the application of tincture of iodine. The surgical treatment at the present time is almost wholly by removal of the tumor, with or without the uterus. If the tumor has been protruded into the cavity of the uterus, it should be enucleated and removed under careful antisepsis. Other tumors requiring removal must be removed by abdominal section. The operation may be finished in several ways. Sometimes the wound in the uterus can be closed by stitches or the pedicle may be treated by the extra-peritoneal method after constriction with the serre-nœud. Sometimes the stump is simply tied, as is the pedicle of an ovarian tumor, and then dropped. Sometimes the stump is turned into the vagina. All the different methods depend for their fundamental success on asepsis and on securing the vessels of the broad ligament, no matter in what way the pedicle or neck or body of the uterus is ultimately disposed of.

The condition of most patients from whom fibroid tumors have been removed is very comfortable. Some suffer from "hot flashes." Others grow extremely fat. A certain proportion, particularly those in whom the pedicle has been treated extra-peritoneally, suffer from ventral hernia.

Sometimes the bladder is cut off by the wire ecrasur, but in the only case he had seen the bladder healed in a few weeks by keeping it drained; and during the ten years that have elapsed since the operation, the bladder has been perfectly normal.

The length of the incision does not complicate the operation, provided there are no adhesions. Very rarely insanity follows the removal of a fibroid, as it does other surgical operations. The author had never seen this complication follow hysterectomy. He had seen two cases of tetanus in the case of other operators, but had had no case himself after hysterectomy. He had had one case follow ovariotomy.

He invariably sees that patients who have recovered

from abdominal hysterectomy are fitted with a firm abdominal supporter, and impresses upon them the necessity of being careful about carrying heavy loads or straining themselves.

DR. A. VANDER VEER, Albany, said that in looking over his notes he had found that the age from thirty to forty-eight years has been most prolific in the development of these tumors. The hemorrhage which is usually the symptom that attracts the attention of the patient, is dependent not so much upon the size of the tumor as upon its location. The hope that after the menopause is reached the fibroid will subside is not always verified. In some cases, the tumor seems to take on a more active growth at this time. As to treatment, curetting, with packing with iodoform gauze, will often stop bleeding. When this fails, in small fibroids, oophorectomy invariably cures except in soft myomas. The danger in treatment rests with the size of the tumor. It is the large ones that give the mortality after operation.

DR. J. IRVING MEARS, Philadelphia, held that where the only reason for the removal of the tumor was the large size of the abdomen, giving rise to unpleasant remarks, we should not be guided by the patient's desire that the operation should be done. He related the case of an unmarried woman, who desired the growth removed on account of the distention of the abdomen which it produced. He refused, and she passed into the hands of another practitioner who did operate, the patient dying five hours later. Dr. Mears divided these cases requiring operation into two classes. We are justified in operating where the hemorrhage endangers life; and we are justified in operating when the pressure symptoms are such as to make life unbearable. There are, however, many cases in which, under palliative treatment, life may be prolonged, the patient rendered comfortable and be able to enjoy life. He had found electricity palliative, but not curative. The tumor is sometimes reduced in size.

DR. GEORGE W. GAY, Boston, spoke of the treatment of fibro-cystic tumors, and referred to the use of tapping. He reported one case in which he began tapping in 1879, repeating it every two or three weeks for four years—ninety tappings in all were made. The patient is now in good health with a large abdomen, but had not been tapped for years. Other similar cases were reported.

DR. ROBERT ABBÉ, New York, referred to the value of the Trendelenburg posture and the early securing of the arterial supply of the uterus in these operations. He was rather surprised at Dr. Homans's assurance that death from hemorrhage was rare. He had thought the contrary. It is the symptom that frightens the patient and alarms the surgeon. He had had fair success with electricity, and would advise it in many cases. The tumor will grow but the hemorrhage will cease.

DR. JOHN HOMANS, Boston, said that the use of strong currents of electricity to the interior of the uterus caused some change to the mucous membrane, checking bleeding, but it did not prevent conception. It was his custom to advise patients with fibroid tumors not to marry. Cases bearing upon this point were related.

(To be continued.)

CHOLERA in a severe epidemic form is reported from the Cashmere valley in India.

Recent Literature.

A System of Practical Therapeutics. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia, assisted by WALTER CHRISTIE, M.D., late Physician to St. Clements Hospital, and Instructor in Physical Diagnosis in the University of Pennsylvania. Vol. I. Philadelphia: Lea Brothers & Co. 1891.

This comprehensive system of therapeutics is intended to present to practitioners the views of those best qualified to discuss the treatment of disease, and to include the result obtained by investigators who have done much to advance therapeutics both as an art and a science. Volume I begins with a masterly introduction on "General Therapeutic Considerations," by Prof. H. C. Wood. It covers only thirty odd pages but it deserves to be read and re-read until its precepts become a part of the reflexes of every physician.

An article on "Prescription Writing and the Combination of Drugs," by J. P. Remington, Ph.D., contains much that is serviceable about incompatibility and prescription writing, but a portion of it is too pharmaceutical in character for a work of this kind. Details as to filling capsules, cutting lozenges, sealing cachets, decoction vessels, etc., with illustrations of each, serve to dilute rather than strengthen the article.

Following this is a good article on "Electro-Therapeutics," by A. D. Rockwell, M.D., in which the use of electricity in nervous diseases and gynecology is discussed at length.

An eminently practical and excellent article on the "Rest Cure for Neuralgia and Hysteria," by John K. Mitchell, M.D., deserves commendation, although it contains nothing especially new.

The article on "Swedish Movements and Massage," by Dr. Benjamin Lee, is illustrated by numerous cuts, and the pages devoted to this subject and its applications would make up a fair-sized treatise.

Dr. E. M. Hartwell has written an excellent article on "General Exercise," for medical purposes.

In "Climate," by Dr. S. Edwin Solly, the general principles of climatherapy are well outlined; the chief considerations which should govern one in the selection of a climate are rehearsed, and a valuable collection given of the reliable observations which have been made on the effects of climate upon phthisis.

"Hydrotherapy and Mineral Springs," by Dr. Simon Baruch, follows climate. The writer devotes a large share of his space to the technique of hydrotherapy. Under "Mineral Springs" analyses of many mineral waters are tabulated.

Every practitioner will find his views of disease and its prevention broadened, and he will be inspired with more pride in his profession after reading what Dr. H. B. Baker, Secretary of the Michigan State Board of Health, writes in regard to "General Sanitation." It shows a trained mind and large experience.

Following this are articles on "Disinfection," by George M. Sternberg, M.D.; and on "Antisepsis and Asepsis," by Prof. J. William White.

"Nutrition and Foods, including the Treatment of Obesity and Leanness," by I. Burney Yeo, M.D., deserves especial study. This article contains as much matter as is to be found in some works on dietetics.

The most voluminous article in the book is on

"Tuberculosis," by Dr. Solomon Solis-Cohen. It covers over 200 pages, and includes preventive treatment, superalimentation, description of various forms of pneumatic apparatus and various medicines which have been or are used in this disease. He holds that tuberculosis is a curable disease, but this statement is afterwards qualified. He appreciates fully the importance of attention to details in the treatment of this disease, and furnishes the physician with an abundance of suggestions that will assist him in the thoughtful and persistent care of his patients.

The treatment of "Scrofulosis and Rachitis" is well outlined by Dr. Walter Christie.

The articles on "Acute and Chronic Articular Rheumatism, Rheumatoid Arthritis, and Gout," by Professor James Stewart, are excellent and very practical.

An article on "Scurvy," by Dr. John B. Hamilton, Supervising Surgeon-General, United States Marine-Hospital Service, is concise and interesting.

A very excellent article on "Diabetes Mellitus," by Dr. Frederick A. Packard, ends the volume.

Without going into too much detail it is impossible to give anything more than an outline of the contents of this book. It has been conceived and carried out on broad lines, and contains much that should be read by all medical men.

Atlas of Clinical Medicine. By BYRON BRAMWELL, M.D. Vol. I. Part IV. Edinburgh: T. & A. Constable, 1892.

Part IV completes the first volume of this handsome work, which we noticed lately at some length. The text treats of small-pox, globulinuria, three new cases of Friedreich's ataxia, chronic insanity, hilarious mania. The plates depict small-pox, melancholia and mania. There is also an extended index. The second volume, to be issued from September, 1892, to May, 1893, will consist of three instead of four fasciculi, will contain at least 128 folio pages, and at least thirty plates. The subscription price for these volumes — \$7.50 apiece — is very moderate.

Essentials of Anatomy and Manual of Practical Dissection, together with the Anatomy of the Viscera. Prepared especially for students of medicine. By CHARLES B. NANCREDE, M.D. Fourth edition, revised and enlarged; with an appendix containing "Hints on Dissection," by J. CHALMERS DA COSTA, M.D. Philadelphia: W. B. Saunders, 1891.

This is a compendium, and as such to be condemned. A number of colored plates have been added, and some very poor representations of bones with the names on them according to Grey. The best part is that on dissection, which the compiler honestly states is not original. The whole is a poor affair. T. D.

Deafness and Discharge from the Ear: The modern treatment for the radical cure of deafness, otorrhœa, noises in the head, vertigo and distress in the ear. By SAMUEL SEXTON, M.D., assisted by ALEXANDER DUANE, M.D. New York: J. H. Vail & Co. 1891.

This brochure of eighty-nine pages is, as its title would indicate, not a scientific work, but an exposition of the success of the author in the performance of the operation suggested by Kessel for the removal of the osseous auditus; there is no precise description of the operation given, and the perusal of the book as a whole suggests the impression that it was written rather for popular than for professional reading.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JUNE 9, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

TOO LONG VACATIONS.

PROF. CHARLES F. THWING, in the *North American Review* for June, arraigns the present system of summer vacations as being too long. The college student suffers from so long a vacation through the loss of interest in his college work. His attention for a whole quarter of a year is directed to pursuits other than scholarly. His discipline is broken. He feels himself to be on a vacation, and vacation is usually intellectual vacuity. The vacation becomes dissipation, — moral, intellectual. Forces that are needed in college are not recruited. Hardihood, endurance, concentration, pluck, grit are not nursed through so long a period of inactivity. Laziness is the direct result of summer listlessness.

Recreation does not become re-creation. The daily newspaper is the strongest intellectual fare and the severest physical work he does is playing tennis. Professor Thwing thinks that if the student were to have only a month of such a kind of life, it would be well, but to stretch out these methods over three months is bad. Resting is one thing, and a very good thing, but resting prolonged becomes rusting. Rusting eats the tool not used. Students, like tools, lose as much by August rust as by February wear. Let every student have all the rest, recreation, diversion and amusement required for keeping his forces in the best condition, but he does not need one-fourth of the year. A healthy student can get as much vigor out of two months as out of three. Eight weeks in the woods will give all necessary power quite as well as thirteen. A short vacation is better for a tired and healthy man than more; than a long one spent in laborious diversions. By transferring five weeks from the vacation to the working period of the college, and by a little extra work, we might cut the college courses to three years without a serious shortening of the time spent in study, and also without any depreciation of the worthiness of the course itself.

The evils of the long vacation are more conspicuous in pupils of the common schools than in college students. These pupils are of the common people. More of them have parents whose purses are small than parents whose bank accounts are large. They spend their summers at home. They indulge in no outings more expensive or more prolonged than a visit to some relative for a fortnight, and their long vacation is no more recreative to jaded energy than a short vacation, and it is far more fraught with physical and ethical perils. Lawlessness is often characteristic of boys in vacation. They return to their books in the middle of September, not with an appetite whetted by proper abstinence, but with a distaste created by a barbarian life. Every teacher knows that at least a month is required to restore his classes to as good a working condition as was theirs at the close of school in June.

Professor Thwing regards the ordinary thirteen weeks as too long a vacation even for the teachers and professors, who would find nine weeks sufficient in which to recruit for their work. There will, however, be exceptions, for to many teachers in the colleges the vacation is the occasion for doing work other and harder than that of the college routine; and as a general thing it may be said that "no class of professional laborers are more laborious, none more deserving of long periods of rest than the teachers; and of all teachers, those in the public schools are most laborious and most deserving."

On one point there can be no disagreement; the relatively short vacation of the doctor is not half long enough to give him the rest and recreation which he needs. An absence from home and from work of three months *once in twenty years* would be a boon to many overworked members of the profession who hardly ever lay aside the harness even for a day. But vacations must be had—and if they are destined to be *short* they must be *frequent*—vacations which shall be characterized by absence of all fretting and worrying about loss of time and loss of income, or atheroma from cankering care and parenchymatosus degenerations will come all too soon.

The evil with the medical profession then is *too short vacations and too few of them.*

THE EXHIBIT AT THE ANNUAL MEETING OF THE MASSACHUSETTS MEDICAL SOCIETY.

It must have occurred to many who witnessed the admirable exhibits of the State Board of Health, the Institute of Technology, the New England Kitchen, etc., at the Meeting of the Massachusetts Medical Society, that the substitution of the instruments, the methods, and the results of sanitary science, for the commercial preparations displayed in former years, had a more than obvious significance. To a thoughtful observer, it revealed in the most striking way the prevailing tendency not only to forestall as far as possible the need for remedies by preventive medicine, but also

to enrich the art of medicine by the application of sanitary science.

It is most encouraging to observe as an offset to the disappointments which curative medicine sometimes entails, that we have before us the fresh triumphs of preventive medicine. Foremost among the boards of health of America stands the State Board of Health of Massachusetts. By the establishment and support of the Lawrence Experiment Station—the first of its kind in the United States—it has set an example which must soon be followed by the other States. By its scrupulous oversight of adulterations in foods and drugs; by its studies upon questions of water-supply and sewerage profoundly affecting the public health; by its prompt and thorough investigations of epidemics; by its intelligent co-operation in the collection and publication of vital statistics, and by its high function as chief sanitary referee for the cities and towns of the Commonwealth, it worthily represents the most enlightened sanitary science of the time. A fresh conviction of this truth must have come to all who studied the simple but original exhibition of its sanitary work to which we have referred.

The exhibit of the Institute of Technology was, in a measure, a surprise. Few, probably, of those who saw it, comprehended fully its scope. It dealt not merely with sanitary chemistry, and heating and ventilation—for these this great scientific school has long been famous—but especially with sanitary biology. A notable exhibit under this head was cryptogamic botany considered, not chiefly from the ancient point of view of *materia medica*, but in the modern aspects of etiology and parasitism. The parasites of certain plants were shown, as were also some of the low organisms that infest water-supplies, with scavengers, such as the "sewage fungus" and yeasts, monads and common bacteria. Next to cryptogamic botany was bacteriology, with cultures of milk, water and air, as well as some of the pathogenic bacteria. The apparatus in this department attracted much attention. It is evident that the biologist in modern sanitary science has his place, henceforward, with the chemist and the engineer, and that all of these are powerful coadjutors of the scientific physician.

The Massachusetts College of Pharmacy gave an instructive educational exhibit, which included an extensive series of crude drugs, microscopic preparations, diagrams, models, books, etc., illustrating the structure of drugs, together with chemical and pharmaceutical apparatus.

Space does not allow us to do more than mention the interesting exhibit of the New England Kitchen or the Walker-Gordon Laboratory, in which highly successful efforts to advance the science of nutrition were clearly illustrated. Taken all in all the exhibitions this year were a marked success, and furnished the abundant assurance that Massachusetts is keenly alive to the promise and the potency of hygiene and sanitary science, as well as to the conservation of the public health.

MEDICAL NOTES.

SOCIETY MEETINGS. — The following medical societies will hold their annual meetings during the last half of June : June 14th, Medical Society of Delaware, at Dover ; June 15th, Minnesota State Medical Society, at St. Paul ; June 20th, American Association of Andrology and Syphiology at Richfield Springs, N. Y. ; American Laryngological Association, at Boston ; New Hampshire Medical Society, at Concord ; June 21, Colorado State Medical Society, at Denver ; June 28, Medical Society of New Jersey, at Atlantic City.

CHANGES IN DIFFERENT MEDICAL FACULTIES. — Prof. James Tyson has resigned as Dean of the Medical Faculty of the University of Pennsylvania but retains the professorship of clinical medicine. Dr. John Marshall has been appointed Dean. Dr. Charles McBurney has resigned the professorship of surgery in the College of Physicians and Surgeons, New York, and has been appointed professor of clinical surgery. Dr. Robert F. Weir has been appointed a professor of surgery to succeed Dr. McBurney.

THE CHICAGO WATER-SUPPLY. — We have heard a good deal on both sides recently as to the purity of the water-supply of Chicago. The *Chicago Times* has lately printed a report of the state of the lake which is discouraging. The flow into the lake of the Chicago River is about 400,000 cubic feet per minute. The water from this river is black and bad smelling and contains much of the sewage of the city. The influence of this flow is seen in the lake almost as far down as the crib from which the water-supply is taken. If the river continues to flow into the lake, it will in time be dangerous to take water from the lake even at several miles distance. The one safety is in creating a constant flow from the lake through the river to the Mississippi basin. With the exception of a ridge of land eight miles west of the city, there is a gradual drop down to the tributaries of the Mississippi River.

NEW APPLIANCES OF THE MEDICAL DEPARTMENT OF THE ARMY. — The medical department of the army is soon to be equipped with one hundred new ambulances of a different pattern from the ones now in use. The vehicle will be about three hundred pounds lighter than the present one. New medical and surgical boxes have also been designed, and their contents will be condensed as much as possible. These will be placed under the seat of the driver of the ambulance. Two oblong boxes, one on each side of the wagon, will be used for carrying water. The floor of the wagon has grooves, into which the feet of the litters are placed for sliding them into position. Each wagon contains two litters. Leather-covered seats, capable of being folded out of the way, extend along each side of the ambulance. The litters can be folded into a compact bundle when not in use and slung on the outside of the wagon. As far as possible the contents of the medical chest consist of compressed tablets. The weight of the chest is one hundred pounds. The

lower half is fitted with small drawers containing bandages, dressings and the like. The surgical chest weighs ninety-six pounds and contains tablets of anti-septic preparations, ether, chloroform and adhesive plaster. The drawers contain instruments and different surgical material. A folding packet, containing the necessary instruments for an ordinary emergency case, may be taken out by the surgeon in case of necessity. One hundred of these cases have already been distributed. The medical and surgical cases are so arranged that they may be slung, one on each side of an animal. Cots, chairs and tables, which are capable of being condensed into a very small space, for use in the field, are also provided.

VITALINE. — A good deal has been heard of this quack preparation in Russia recently. It was concocted by one Gatchkowsky, and was advertised as a miraculous panacea and rejuvenator. In spite of its exaggerated claims, the tide of fashion turned towards it, and it became a popular fad. It was given both by subcutaneous injection and internally. Finally General Gresser, the Prefect of St. Petersburg and a very important personage, was given an injection of it, from the effects of which he died. The inventor was immediately seized, and finding himself in danger, confessed that his specific was only a mixture of borax and glycerine, and that the death must have been the result of a dirty syringe.

WHIPPING AND HYSTERIA. — A trial which has excited much notice in Germany has resulted in the conviction of Dr. Wiederholz, the head of an establishment for the treatment of nervous diseases. A lady of fifty-one years, a patient in the hospital, was subject to acute hysteria. After trying to control her by other methods, the defendant had whipped her, on three different occasions. The action was brought by the patient's husband, and the question was argued whether whipping an hysterical patient was justifiable treatment. Professor Tusczek, who was called as an expert, said that it was scientifically inadmissible to use corporal chastisement in the medical treatment of nervous patients. Professor Pellmann said that he was personally opposed to the therapeutic use of whipping, that in State Hospitals it was absolutely forbidden. The defendant was condemned to three months imprisonment.

NEW ENGLAND.

A SOCIAL REUNION. — Dr. B. E. Cotting, of Roxbury, entertained the board of managers, the editorial staff, past and present, and the collaborators of this JOURNAL, together with some specially invited guests, at his house Wednesday evening, June 8th. The occasion was the twentieth anniversary of the reorganization of the JOURNAL. About fifty members of the profession participated in Dr. Cotting's hospitality.

THE BOSTON CITY HOSPITAL CLUB held its annual meeting and partook of its annual dinner at the Copley Square Hotel, Tuesday evening, June 7. After-dinner speaking was dispensed with, and the company adjourned at eight o'clock to listen to the

Shattuck Lecture, which was delivered by the Vice-President, Dr. J. F. A. Adams, of Pittsfield. The Club voted in favor of having a supper next year instead of a dinner, to avoid a conflict between the reunion and the lecture. The following officers were elected: President, Dr. R. H. Fitz, of Boston; Vice-President, Dr. J. A. Gordon, of Quincy; Treasurer, Dr. S. H. Ayer, of Boston; Secretary, Dr. R. A. Kingman, of Boston. Member of executive committee for five years, Dr. Chas. D. Sawin, Charlestown.

CHOLERA INFANTUM AND DIARRHEA. — The Boston Board of Health has issued a circular, printed in English, Italian, Hebrew and Russian, to be distributed in different parts of the city where cholera-infantum is most found, giving simple directions for the care of milk, as follows: The milk must be kept fresh. As soon as the milk comes, put it in a glass bottle; put the bottle in a kettle with a block of wood under it to prevent the bottom coming in contact with the kettle; put water enough in the kettle to come half-way up the side of the bottle; heat the water as hot as possible without boiling; then take the kettle from the fire and cork the bottle; let the bottle remain in the kettle for half an hour; then put the bottle in a cold place. This makes the milk safe without boiling. If possible, use a rubber stopple instead of a cork. The bottle and the stopple must be cleansed every day with boiling water.

OFFICERS OF THE MASSACHUSETTS MEDICAL SOCIETY. — Dr. J. C. White, of Boston has been elected President, and Dr. Francis A. Howe, Vice-President of the Massachusetts Medical Society.

SMALL-POX IN NEW BEDFORD. — It is reported that two cases of small-pox have recently been found in New Bedford.

NEW YORK.

THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL has purchased a site for its new buildings at the corner of Second Avenue and 20th Street. They will have a front of 98 feet on the Avenue and 110 feet on 20th Street and will be six stories in height. The architecture will be of the Italian school, and the first story is to be constructed of Indiana buff limestone. The upper portions will be of pale brown brick and terra-cotta.

ANOTHER DEATH FROM CHLOROFORM has been reported. The patient was a lad nine years of age, and the anesthetic was given at a physician's office for the performance of a minor operation.

RECOVERY FROM MORPHINE POISONING. — A remarkable case of recovery from morphine poisoning has occurred at the Gouverneur Hospital. The patient, a young Spaniard, took no less than eighteen grains at a single dose, for the purpose of committing suicide. When he was taken to the hospital the respirations had become reduced to one a minute. Atropia and the cold douche were used with good effect in the treatment, which had to be kept up unremittingly for three days.

Miscellany.

THE SUCCESSFUL TREATMENT OF CHLOROFORM SYNCOPE BY MASSAGE OVER THE HEART.

MAAS¹ reports two cases in which patients, apparently dead from chloroform syncope, were resuscitated by simple compression in the region of the heart. In both cases respiration and radial pulse had entirely stopped and the pupils had dilated. The manipulation of the heart was in both cases carried out for over an hour. As a result, both patients suffered from mental derangement, difficulty in swallowing and in speech, all of which passed off very slowly. The manipulation was conducted as follows:

The operator, standing upon the left side of the patient, pressed with quick, strong movements deep down in the region of the heart with the fingers of the right hand, while the ball of the thumb was placed above the left clavicle. The number of compressions was 120 or more a minute. The left hand should seize the patient upon the right side of the thorax. Soon after beginning these compressions the pupils became smaller and the paleness of the face disappeared.

THE NEW RIFLE PROJECTILES.

PROFESSOR BARDELEBEN has recently delivered an address in Berlin on this subject.² The modern rifle sends bullet with a narrow cylindrical form and pointed apex which at a distance of 1,000 metres has the power to pass through several human bodies or to disable two horses. Its line of flight differs but slightly from the line of sight. It has an inner core of lead enclosed in a casing of steel which prevents the lead from becoming deformed and spreading at the point of contact. This change is of much interest for military surgery. The bullet is lighter than any of the lead bullets, but is sent with a greater velocity. On account of its velocity and its small surface of contact, it merely punches out a hole causing very little commotion of the neighboring parts. It is more likely to cause fatal hemorrhage than the old bullet. If the new bullet wounds at all it will have sufficient power to pass through any part of the body. Colonel Boonen-Rivera, in his report on the civil war in Chili, the war in which Maunlicher rifles have been used, says that the number of dead on the battlefield was four times larger than that of the wounded. The effect of these bullets on bone has been made the subject of a series of experiments. Up to a distance of 400 metres the bone is invariably shattered, and at greater distances either clean perforations or oblique fractures result. In the next war the ratio of recoveries of those who can be removed still living from the field will be larger than formerly.

The new projectile is by no means so humane as it is sometimes called, since within similar periods of time and under equal conditions it kills and wounds more men than the old bullet. But the wounds which it causes, if they are not of a directly fatal nature, open to the surgeon, as a general rule, a far more promising field for exercising his skill and activity than those which were caused by the old bullet.

ETOLOGY OF ACUTE CIRCUMSCRIBED
CÖDEMA.

BAUKE¹ in an article on this condition comes to the following conclusions: Circumscribed oedema of the skin, in the majority of cases, is found in patients suffering from some disturbance of the nerves. In some cases a hereditary influence can be traced. These swellings of the skin may follow certain psychical disturbances such as alcoholism but they may appear at the same time as neuralgias, Graves' disease or nervous digestive disturbance. The author believes that this condition should be considered as purely neurotic or functional, caused by the disturbance of the vaso-motor centres. Treatment should be directed to the general condition, the many digestive troubles or nervous symptoms.

MR. JOSEPH A. TUCKER.
RESOLUTIONS OF THE VISITING STAFF OF
THE BOSTON CITY HOSPITAL.

In the decease of the late Mr. Joseph A. Tucker, President of the Board of Trustees of the Boston City Hospital, the institution has lost a valuable friend and a wise counsellor.

The physicians and surgeons desire to express their high appreciation of his interest in everything relating to the welfare of the patients and the comfort and convenience of the Medical and Surgical Staff.

A man of sound judgment, of strict integrity, and kind feelings, ready at all times to entertain plans for the benefit of the hospital, ever loyal to its high reputation, and anxious to maintain the same, watching alike the interests of the city, of the inmates, and of the profession, he not only earned universal respect and esteem, but endeared himself to every one connected with the institution.

The Staff, recognizing their own loss, hereby tender their warmest sympathy to the family and friends of the deceased.

GEORGE W. GAY,
J. ORNE GREEN,
M. F. GAVIN,

The above was presented at a meeting of the Visiting Staff, held May 31, 1892, adopted, and it was voted that a copy be sent to the family of Mr. Tucker, to the Trustees of the Hospital and to the *Boston Medical and Surgical Journal*.

EDWARD J. FORSTER, M.D.,
Secretary of the Visiting Staff.

THERAPEUTIC NOTES.

CHOLERA INFANTUM. — Meinert² considers it essential in the treatment of gastro-intestinal catarrh of infants to prevent the increase of bodily temperature, and to replace, as quickly as possible, the loss of water in the body. He recommends cold baths, compresses and fresh air; every five minutes warm water, or sugar and water, or some herb tea. Milk should be diluted at first ten times, later up, to three times. In cholera nostras, also, he has obtained good results by large quantities of water.

TEST-TUBES FOR EXPLORING WOUND CAVITIES. — Fulton³ advises the use of test-tubes for exploring different wound cavities. The closed end is pushed into the wound and a beam of light directed into it from a head mirror. It can easily be made aseptic and is easily directed. It may be used in the brain, provided

the external wound is large enough, and a bullet found and withdrawn with very little injury to the brain.

NIEHAUS METHOD OF TREATING ERYsipelas. — This author recommends painting the healthy skin about two hands breadths away from the disease with contractile collodion. This should be applied several times until the skin becomes markedly contracted. In several cases he has seen the inflammation stop as soon as it has reached this wall.

Correspondence.

A P OSAL OF THE "BOSTON DIRECTORY."

BOSTON, June 4, 1892.

MR. EDITOR: — The publishers of the "Boston Directory" have issued a circular for physicians, offering to insert in connection with the names in the classified list of physicians, the office hours and telephone numbers for one dollar each in addition to the price of the Directory. To those who do not order the Directory the price is three dollars.

The proposal made in this circular does not seem to me one which the thoughtful members of our profession will care to embrace. My criticism of the plan is briefly this: So far as it is an advertisement physicians have no right to it, and so far as it is demanded for the convenience of the public the publishers of the Directory should be ready to make the innovation at their own expense.

Respectfully yours,

V.

RECORD OF MORTALITY
FOR THE WEEK ENDING SATURDAY, MAY 28, 1892.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 28, 1892, TO JUNE 3, 1892.

Leave of absence for fifteen days to take effect in the early part of next month is granted MAJOR ROBERT M. O'REILLY, surgeon, U. S. A., Fort Logan, Colorado.

MAJOR DAVID L. HUNTINGTON, surgeon, U. S. A., having reported in accordance with Par. 9, S. O. 167, c. s. Headquarters of the Army, is assigned to temporary duty in charge of the office of the medical director, Headquarters, Department of Arizona, pending the absence of the medical director, COLONEL JOSE R. SMITH, surgeon, U. S. A.

Upon the return of CAPTAIN BENJAMIN MUNDAY, assistant surgeon to Fort Sully, S. D., FIRST-LIEUTENANT ALLEN M. SMITH, assistant surgeon, will proceed without delay to Fort Yellowstone, Wyoming, and report to the commanding officer for temporary duty with troops in the National Park during the season. Par. 1, S. O. 80, Headquarters, Department of Dakota, St. Paul, Minn., May 24, 1892.

CAPTAIN C. N. B. MACAULEY, assistant surgeon, U. S. A., granted leave of absence for three months.

SOCIETY NOTICES.

AMERICAN NEUROLOGICAL ASSOCIATION.—The eighteenth annual meeting will be held at the New York Academy of Medicine, June 22d, 23d and 24th.

NEW HAMPSHIRE MEDICAL SOCIETY.—This Society will hold its one hundred and first anniversary meeting, Monday and

Tuesday, June 20 and 21, 1892, at Concord, G. A. R. Hall, 15 Warren Street.

AMERICAN LARYNGOLOGICAL ASSOCIATION.—The fourteenth annual Congress will be held at Boston, Mass., June 20, 21 and 22, 1892. The sessions will be held at the rooms of the Medical Library Association, 19 Boylston Place. The profession is cordially invited to attend.

AMERICAN ASSOCIATION OF ANDROLOGY AND SYPHILOLOGY.—The sixth annual meeting will be held at the Spring House, Richfield Springs, N. Y., June 21 and 22, 1892.

The meetings of the Association will be held in one of the parlors of the Spring House.

Members desiring rooms may engage them in advance by writing to the proprietor of this hotel at Richfield Springs, N. Y.

RECENT DEATHS.

RALPH C. HUSE, M.D., M.M.S.S., died in Georgetown, Mass., June 1st, aged forty-nine years. He graduated from the Harvard Medical School in 1866, having previously served in the army during the war. Since graduating he has practised in Georgetown. He was Vice-president of the Essex North District Medical Society.

CHARLES E. DELVERGNE, M.D., died in Brooklyn, June 4th, aged thirty-five years. He was lecturer in the practice of medicine in the Long Island College Hospital, and surgeon of the Thirteenth Regiment.

JOHN E. KIMBALL, M.D., of Saco, Me., died June 2d, aged seventy-three years. During the war he was surgeon of the Twenty-seventh Maine Regiment.

Address.**THE MEDICAL PROFESSION AND THE COMMONWEALTH.¹**

BY FRANK WINTHROP DRAPER, M.D.

(Concluded from No. 23, page 568.)

II. But the true test of the value of laws lies in their faithful execution and judicious application. Let us inquire, now, concerning the relationship of our profession to the Commonwealth's executive department.

In two instances, Massachusetts has selected its supreme executive magistrate, the governor, from the medical profession and from the fellowship of this Society. Dr. John Brooks was elected governor in 1816, and continued in office, by annual re-election, until 1823. He was succeeded by Dr. William Eustis, who died in office in 1825.

The second office in the gift of the people, that of lieutenant-governor, has been held by three members of this Society, David Cobb, Henry Halsey Childs and Elisha Huntington.

The executive council of the Commonwealth has had many medical representatives in its membership in the course of its history. They have done excellent service in advancing the interests of our profession whenever occasion offered. This was especially the case in 1877, when the assistance of the late Dr. William Cogswell was of great value in the reform of the methods for conducting investigations of deaths by violence.

In municipal administration, our profession has shown its adaptability for public affairs in numerous instances. Repeatedly, medical men have demonstrated their acceptability in the office of mayor and in various subordinate positions in city and town government.

So, too, we may recall the admirable services of our brethren in the conduct of school-administration and in the interests of free education under the fostering care of the Commonwealth.

Again, in the management of the public institutions belonging to the State, medical men have found a congenial field for the exercise of their wise judgment and executive ability. Ever since the establishment of the first lunatic hospital by the State in 1832, at Worcester, the boards of trustees of these and similar foundations have welcomed the acquisition and assistance of physicians as an essential element of their success. If one desires a demonstration, let him compare the State Almshouse at Tewksbury, as it is to-day, with its scandalous condition before 1876; its discipline, its fine hospital service, its freedom from abuses, are in marked contrast with the methods and results which characterized its management before a physician took charge of it under the authority of the legislature.

Why should not the executive efficiency of men trained as physicians be utilized still further in our public institutions? Doctors of medicine who can manage great hospitals, can govern penal reformatories; and convicts, as well as lunatics, would be none the worse if their full sanitary supervision were in the hands of specially-trained officials. Who can doubt that the discipline of a convict prison would be im-

proved if it were manifest that judicious care were taken to maintain the health of the inmates by the humane and practical methods of medical resident officers?

There is one chapter of the Massachusetts laws whose administration has always been an agreeable duty for the members of our profession. The statutes relating to the public health have been especially interesting to medical men, and the intelligent practical application of them has always had its best agents among physicians. Ever since the Board of Health of Boston, ninety years ago this summer, fitted up an observation hospital on Noddle's Island and invited Dr. Benjamin Waterhouse and other physicians to demonstrate upon the patients therein the immunity from small-pox infection which Jenner's recently discovered operation of vaccination bestowed, Massachusetts has found among her physicians the most zealous advocates of sanitary legislation, and the most faithful servants in executing her enactments. To the public, this paradox has always been a mystery. Why medical practitioners should desire earnestly to hinder or control the spread of disease, when their livelihood and material prosperity depend on its presence and their reputation for skill and success is directly related to its prevalence, is a problem which the ordinary intellect is unable to solve. The reason is that the vulgar apprehension has not grasped the difference between a vocation and a trade. The enterprising tradesman is not accustomed to place obstacles in the way of the successful development of his business, and he cannot understand why physicians do not follow his example. But we are not engaged in the pursuit of a trade, and our methods are on a higher plane than those of mercantile or of mechanic industries. We look to the welfare of humanity as our first and fundamental object and the practitioner who forgets this and seeks primarily the gains which are the objective reward of business methods is not true to the high purposes of his profession. The majority of physicians follow the more unselfish course and are therefore ready always to aid and to adopt measures which will protect the people from preventable suffering. It is, therefore, not surprising that they are earnest allies of the State in the administration of sanitary laws.

And what a comprehensive array of enactments affecting the public health, the statute-books of Massachusetts present! The silence and indifference of the State with regard to curative medicine is in the sharpest possible contrast with the number and variety of laws relating to preventive medicine. Recall the almost bewildering array of laws which are at this moment in force, designed to promote health and resist the encroachments of disease. The board of health of your city or your town has the power, under the statutes, reinforced by decisions of the Supreme Court, to interfere with personal and property rights in the most arbitrary fashion, if only the interference is in the name of the public health.

But the cynic will ask, of what use is all this cumbersome, and complicated sanitary machinery? Of what value has it been to the State? Do not epidemic diseases prevail just as they did before all this legislation was piled up for our admiration? Has not pandemic influenza stalked defiantly around the world again and again in the last three years, without the least hindrance from any source? Do not scarlatina and diphtheria enter our households and take possession in spite of

¹ The Annual Discourse delivered before the Massachusetts Medical Society, June 8, 1892.

all precautions, official and personal, devised to bar them out? Do not the children die by hundreds in August, and the grand-parents perish by the score in March, just as they did a century ago? Has tuberculosis been controlled?

To all such pessimistic questioning, ample answer has been made in the impressive address to which you listened three years ago,² and in the thoughtful essay³ of last evening. It is unnecessary for me to add to their authoritative statements. But it is not improper to remind the sceptic that the general mortality-rate has been made to diminish; that the average duration of life has been appreciably increased; that in communities which use vaccination with reasonable fidelity, small-pox is rare enough to be a luxury. Is it of no consequence, moreover, that dwelling-house architecture has followed the admonitions of physicians and sanitarians and that ventilation and drainage are no longer left to chance? Is it of no importance that the water-supplies of the State are more carefully protected from pollution than ever before, and that every new supply is critically tested in all its relations, physical, chemical and biological, before it is accepted? These are some of the queries that are suggested by doubts of the unbeliever in sanitary teachings and practice. To you, who have always been in harmony with the progressive spirit in Massachusetts which is embodied in her health laws, obstructive criticism will appear unworthy of serious reply. Preventive medicine looks to the future hopefully. Many of its problems will be solved by the trained bacteriologist whose greatest achievements are still before him. And in all measures — scientific, practical, administrative — the Commonwealth, in the future as in the past, will look to us and our successors as its best allies and most efficient agents for the protection of the people from harmful influences affecting life and health.

There is one other department of the State's affairs to which I wish to refer briefly, because in its administration our profession has been conspicuous. I allude to that chapter of the Public Statutes entitled "Of Medical Examiners." The Massachusetts law relating to inquests is no longer on trial as a questionable innovation; it has passed the experimental stage and is now as permanent as any part of the judicial system of the Commonwealth. The practical experience of fifteen years has demonstrated that the legislature of 1877 enacted a law of exceptional value, thoroughly adapted to fulfill the purposes for which it was designed. And the reason for this is easy to comprehend. When the general court determined that the venerable but discredited and abused system of investigating violent deaths by means of coroners and their juries had outlived its usefulness in Massachusetts, it was under obligation to substitute a legal mechanism that should be simple, practicable, economical and trustworthy. And this it did with such consummate success as to challenge admiration. It provided a procedure that accomplished the desired end promptly and without friction. It differentiated the purely medical elements of the inquiry from those which were essentially judicial. It created a medical officer whose sole function should be to determine, in any case of mysterious or violent death, the anatomical proofs of unlawful acts entering into the cause of death; and it made his conclusions upon this purely medical question the basis

for further inquest-proceedings by judges trained in the methods of taking and sifting evidence and required to solve the problem of accountability in the case. The initial stage, then, of the inquest is always the medical determination of the cause and manner of the death, and for this determination the law provides ample resources.

That the Massachusetts method of conducting these inquiries is acceptable is shown by the entire absence of real criticism, as well as by the cordial approval of jurists who have studied its details. It has commanded itself to the authorities of other States, who find in it the indications of a great advance in comparison with the clumsy and inverted coroner system. It is quiet in its operation. It does not, by the exercise of noisy authority, upset and demoralize households overshadowed by recent grief. Its results are certain and tangible. It secures for use at trials for homicide the testimony of trained men well fitted by experience to be witnesses. It has absolutely eliminated all scandal and sensationalism from inquest proceedings. It has saved money to the county treasuries, at the same time affording better service to the people.

From this allusion to a special medico-legal function of great responsibility which our Fellows are discharging acceptably, the transition is easy to a consideration of the relationship which our profession, in general, bears to the third great department of the Commonwealth's government, the judicial department.

III. To state the proposition broadly, the medical man finds himself in a court of justice under the same exigencies which occur to the ordinary citizen, service on the jury alone excepted. He is either a plaintiff seeking reparation for alleged wrong, or a defendant meeting a charge of wrong doing, or a witness summoned to testify in an issue to which others are the parties. Although these are the three varieties of necessity which take him as they take others, out of the routine of daily life, and subject him to novel experiences more or less unpleasant, he is conscious that his vocation as a physician places him in a peculiar attitude unlike that of the layman. And it is these peculiarities characterizing our position in court that I now ask you to consider with me.

As a plaintiff, the physician is a spectacle of extreme rarity. I think it can be claimed with confidence that medical men, whatever their other characteristics may be, are not noted for litigiousness. They are generally too busy to find in the behavior of their fellow-men the occasion for law-suits. Although there is a certain hyperesthesia which is said to apply to the profession in connection with the subject of medical etiquette, this never finds its way to the gates of the temple of justice; and in the ordinary affairs of life the doctor of medicine is seldom found on the hither side of the abbreviated Latinism which in the court docket stands as a low barrier over which the parties to a suit defy each other. The doctor in court as a plaintiff, then, need not detain us longer.

But with the doctor in court as a defendant, strenuously bending his energies and using his resources to resent an imputation upon his skill and care, the case presents a theme of serious interest, for it concerns the whole domain of our legal rights as medical practitioners. Most of the suits in which physicians are the defendants are actions instituted by former patients to recover damages for alleged malpractice. This fact suggests, at the very outset, some consideration of the

² The Annual Address for 1880, by Dr. H. P. Walcott.
³ The Shattuck Lecture for 1892, by Dr. J. P. A. Adams.

obligations which the law imposes on physicians and surgeons in their treatment of the sick and injured persons who employ them.

To the medical man as he stands in the presence of a person who has summoned him for professional aid and counsel in time of suffering, the law says: " You were under no legal obligation to respond to the summons which called you to this bedside. But having responded, and having undertaken the care of this case, you have assumed certain obligations which the law fully recognizes, and which you cannot avoid, except at the risk of losing both money and reputation.

" Your obligation is that of an implied contract which, though less formal and specific than an express contract executed in writing, is not less binding in its nature.

" Under the obligations of this contract, you do not warrant or insure that all the results of your attendance shall be satisfactory, that there shall be a perfect recovery, or that your treatment shall effectually stand in the way of unexpected complications.

" But you engage, under the law, to treat this case in such a way that any injury which the patient suffers, in its course or subsequently, cannot reasonably be traced to a neglect of competent and ordinary care and skill on your part as its proximate cause."

Such are the principles established by the common law as the intangible environment of the medical or surgical attendant for his guide and control under the usual circumstances of his employment. They are the rules which underlie and govern those actions of tort, wherein the claim is set up that negligence and unskillfulness on the part of the medical attendant have caused injury and distress to his patient, and that money will be the proper remedy to heal the wrong imputed to him. And it is reassuring to record the fact that these rules and principles, however difficult they may seem to be as practical guides, have been in effect a shield rather than a menace to the interests of defendant physicians, and that the cases are few in number in which it can be said that unjust and unfounded verdicts have been returned by juries upon the issue of imputed negligence and unskillfulness.

But while this is true concerning the issue of suits for damages, it is also true that the law interposes no obstacle in the way of initiating such suits. Let us suppose that the medical attendant has done all that the law requires in the care of his case, that he has to the best of his ability used ordinary and reasonable skill and diligence and has avoided all measures that could be criticised as experimental, he may, nevertheless, through circumstances and conditions over which he has little control, find himself a defendant in an action of tort brought by his patient. Perhaps the dislocated shoulder which he reduced months ago, with proper attention to all surgical details, persists in giving pain and in refusing to resume its mobility. Perhaps the fractured femur is restored to duty with a permanent and irremediable though unavoidable shortening. Perhaps the broken forearm, when taken out of the splints, has an uncomely deformity in spite of the most assiduous care. In any of these events, whatever has happened out of the ordinary course, it is easiest to blame the attending physician for it; and the next step is equally easy, the initial step in the proceedings for what is called " getting satisfaction." The story is an old and familiar one. Too often the motive that initiates the suit and urges it forward is a

most unworthy one, and is scarcely to be distinguished from the wickedness of blackmail. Too often it is nurtured and stimulated by lawyers more hungry for plunder than ambitious for a good name. Too often it is encouraged by the unfriendly words and actions of professional rivals. Over these prosecutions, the physician is powerless to bring any control; however strong his defence may be, he cannot prevent a trial, with all its annoyances, risks and costs, except by adopting the course of paying money to settle the claim out of court, — a course which any self-respecting medical man will not adopt, though sorely tempted to escape thereby all the wretched miseries of a jury trial.

It has often been suggested that, in view of their liability to unwarranted claims for malpractice, medical men would do well to organize co-operative defence unions for their own protection. Such a suggestion has much to make it attractive, and it has actually borne fruit in England in a flourishing and fully equipped association prepared to assist its members when they are brought to bar as the victims of irritable, or avaricious, or depraved human nature. But while such a fellowship might serve to deter the unscrupulous from bringing suits against physicians, in such suits as are pressed to trial, the appearance of a medical defendant backed by the money and the sympathy of a numerous company of his professional brethren might have a reactionary effect upon juries, who are notoriously ready to render verdicts against corporations and corporate interests.

Let me turn, now, to a far more familiar relationship between medical men and the courts of law — that sustained by physicians as witnesses. Rightly considered, the function of a medical witness establishes one of the most honorable positions in the service of the Commonwealth which a member of the medical profession can discharge. That the function has been abused and has experienced a measure of disrepute, is quite true. That there are certain features of it which are deplorable and most unsatisfactory is also true. But it is likewise true that, with all the criticism and disparagement of which it has been made the subject, medical evidence will continue to be an indispensable element in judicial proceedings, and the medical witness, if he be properly equipped for his service, has it in his power on every occasion to command the respect of all who observe him, and to be, in the court of justice as in the sick-room, the representative of sound learning and of manly deportment.

It has been customary to classify medical witnesses as of two distinct varieties, according to the character of their testimony; they are regarded as ordinary witnesses if they testify to facts, and as expert witnesses if they express opinions or undertake to interpret facts. But if we recall the usual methods under which medical witnesses are employed, we shall see how artificial is such an attempt at classification. The truth is that nearly every piece of medical testimony is a composite of facts and opinions in which the facts largely predominate. But they are medical facts, the correct determination and statement of which require medical knowledge, skilled training, and a special aptitude. When the chemist exhibits to the jury the arsenical mirror which is the result of his analysis of suspected organs or remnants of food, he is submitting, not opinions, but incontrovertible facts. When Prof. Austin Flint testified that in his microscopic and chemical

examination of the material found under the finger-nails and on the clothing of a degraded criminal accused of the murder of a woman and the mutilation of her body, he detected crystals of tyrosine and other substances which must have come from no other part of the intestinal tract than that found cut open in the victim's abdomen, he was giving an indisputable physiological demonstration of objective facts, which fastened the guilt of the homicide upon the prisoner. When Prof. Jeffries Wyman, in the memorable case in 1850, established by his evidence the identification of a mutilated human body, the work that he did was again a demonstration based upon accurately observed anatomical material.

The same principle is seen in the numerous civil suits growing out of imputed negligence, whereby accidental injuries result. The testimony of medical men connected with these cases is largely directed to the description of symptoms and conditions of a purely physical and objective character. Even in the comparatively rare cases in which a medical man is engaged to answer purely hypothetical questions, and to give his opinion upon assumed facts, of which he has no personal proof, the examination does not end with this exhibition of the expert's technical office, but wanders away into the various regions of medical knowledge pertinent to the questions at issue.

The conclusion, then, which I wish to draw from these considerations is that all medical testimony is of the nature of skilled service, and deserves appreciation as such. It has been held repeatedly that knowledge, in science or art, is its possessor's capital, accumulated through years of study and application; and that neither the Commonwealth nor any individual can make any lawful requisition upon that capital without substantial reimbursement. This is the well-recognized and universally applied rule governing the employment of medical experts, who go to court to state opinions with facts. Why should not the same rule attach to the service of surgeons and physicians who, heeding the peremptory summons, respond as witnesses to give evidence of clinical facts, of physical appearances, and all those other matters the correct observation and description of which require a definite amount of knowledge, the fruit of much patient study or long experience? The demand which in the name of the Commonwealth is made upon medical men, wasting their time in tiresome delay, interrupting their professional routine of duty, subjecting them to disagreeable and irritating experiences, extorting from them facts acquired under the confidential relations of the sick-room, is not one which, under prevailing conditions, is answered with cordiality. It is among the unpleasant incidents of professional life. It reminds us that of all departments of our practical work, the medico-legal service is the only one which we cannot evade, or transfer to others. The call of a judicial summons is imperative, and physical disability will alone excuse its neglect. When, therefore, we consider the nature of medical testimony, and the degree of technical knowledge required for its correct presentation, we do not exceed propriety if we ask that the State shall in some way provide fit methods for the adequate reward of such skilled service, rendered under compulsion.

One other feature of medical testimony solicits attention; it relates to the deportment of the witness in court. The ideal medical witness possesses these quali-

ties: his demeanor is dignified and unconstrained; he has large stores of well-seasoned knowledge; he is quick in apprehension, firm and immovable in his convictions, but conservative and judicial in reaching them; he has a retentive memory, a reserved courage and an imperturbable temper; he is terse, direct, clear and concise in statement, and especially is an adept at translating every technical term into words and phrases clearly intelligible to every jurymen; he abhors garrulity, flippancy and trickery; he aims to be candid, impartial, disinterested.

Sometimes, though very rarely, one sees a physician on the witness-stand who represents faithfully all these requirements; he is the object of our emulation and envy. Much more commonly, however, medical testimony illustrates characteristics quite in contrast with the ideal. The physician whose methods on the witness-stand we do not desire to copy, is garrulous, affected, pedantic, flippant, ready to engage in controversy, dogmatic, and above all saturated with partisanship. Of all these faults, the last is the most common and conspicuous and the one which has brought the greatest reproach on medical men as witnesses; it is this which has led judges on the bench to disparage and belittle medical experts; which has caused writers on jurisprudence to discredit their value; and which, in practice, has induced juries to ignore their testimony altogether in trying to reach a verdict. But while admitting that partisanship is a too common element of medical evidence, I insist that it is an evil for which medical men should not be held responsible. It is the unavoidable fruit of the conditions under which the modern practice of the law is pursued. The physician in the sick-room does not exhibit the disposition here depicted; but place him under the novel and subtle influences of the court-room and he becomes another creature. A case, for example, occurs which offers an opportunity for the use of a medical expert. You receive a polite invitation from the counsel, to serve him in that relation. You do not inquire very closely into the grounds that have determined the selection; you feel complimented, at all events, and you consent to be retained. Now, having fully committed yourself to the service of your employer, your independence is almost necessarily laid aside. You are expected in preparing for the trial to develop all the elements in the case favorable to your employer's side only. The advocate consults with you, nourishing in you a controlling partiality, and doing all in his power to stimulate a cordial interest in his client's cause. The witness thus approaches the trial, expert chiefly as a partisan medical advocate. Against the insidious influences which promote this surrender of mental equipoise, few physicians could successfully defend their judgment.

Then at the trial itself, still more compulsory influences encompass him. He now finds himself in the arena, marshalled with others to defend his own side, to defeat the opposing side. He is harassed by the technical limitations of the rules of evidence. Through the inability of lawyers to conduct acceptably an examination on medical subjects, he is made inadvertently to state views which, under other circumstances, he would not think of supporting. Professional pride compels him to defend stoutly his position, a retreat from the ground being deemed worse than the blunder which took him there.

Now, what can be done to modify, or, if need be, to

revolutionize these unsatisfactory methods? As may readily be inferred from what has been presented, the first thing to be desired is the removal of the medical witness from the influences and temptations of partisanship; he must be lifted far above the plane of bias. To secure this end, the best way, because it is the most in accord with American notions of fairness, is that which would provide that the medical expert in any action at law, civil or criminal, should be the choice of the two parties interested in the litigation; or, in the event of their disagreement or neglect, the choice of the court.⁴ The advantages of such an innovation, both theoretical and practical, are too plain to be mistaken. Theoretically, such a plan would secure experts in fact as well as in name, since it would obviously be for the interest of all concerned that the best available medical judgment should be obtained upon technical questions involved in the issue on trial. Instead of the present deplorable exhibitions, so amusing to lawyers, so discreditable to our profession, so subversive of justice, we should see a true representative of medical science, appearing in court as the interpreter of the facts established in the evidence. We should see him, with the same judicial independence which the presiding justice himself must display, passing judgment, without fear or favor, on matters which legitimately fall to his office as an expert. There would be little danger that this altogether honorable function would fall into unworthy hands under such a system; the man chosen would, from the necessities of the case, be well known as the possessor of special knowledge fitting him to comprehend and to elucidate the points presented in the testimony. The man of pronounced and peculiar views, the man of hobbies, would not be sought; his judgment is already discounted.

In practice, the expert thus selected would make such investigations as the case demanded, would listen to all the testimony, and at the proper time would report his conclusions, either as oral evidence, or, preferably, in the form of a written statement. Here would occur an opportunity for professional distinction. The name of medical expert, instead of conveying with it a questionable flavor, would become a term of good repute, attracting rather than repelling the master-minds in our profession; while the many-sided questions presented in legal suits and actions would offer occasions for medico legal reports such as have made Germany and France confessedly the leaders in forensic medicine.

But at just this point, the typical barrister, with a gesture and in tones familiar to those of us who have ever served as witnesses, says: "Stop a moment! I object!" And when asked to state his objection, he replies: "I object because such a scheme would interfere with the constitutional right of the individual citizen to defend his life, person, property or character by producing 'all proofs that may be favorable to him.' I object because when I undertake to prosecute a suit at law or when I am engaged to defend a client, I wish to know precisely what the evidence favorable to my cause is to be; I have no intention of remaining wholly ignorant of the medical conclusions up to the time of the expert's appearance in court. I am in court theoretically to see that justice is administered; but I am

there in reality to do what I can to win a verdict for my client, and I wish, in order to secure that end, to employ all lawful means, including medical evidence of my own choosing; and if this evidence is skilfully warped and stretched to meet well the exigencies of my claim, it will be so much the more useful and acceptable." This is the lawyer's view of the matter; and it is this spirit which has hitherto stood as an insuperable obstacle in the way of a much-needed reform. It is a purely selfish spirit held by a large part of the legal profession, but repudiated by a few conspicuous and honorable exceptions.

Meanwhile, we as physicians have a plain resource. When required to discharge the duty of medical witnesses, let us diligently aim to illustrate a high standard. Let us avoid well-recognized errors to the utmost of our ability. Let us decline to act simultaneously as medical advocates and medical witnesses. Let us endeavor to give our testimony with the same candor and the same independence which would characterize our statements if instead of the peculiar environment of a court of justice, we were in the presence of an audience of friendly, but critical, medical associates. Difficult as such a duty is, it is not impossible of performance.

IV. This review of the relationship which our profession holds toward the Commonwealth will be incomplete without some reference, in conclusion, to a still higher obligation resting on us. It is the obligation of loyal, patriotic citizenship, involving duties superior to any of those which I have undertaken to discuss. Men sometimes speak of their citizenship as a privilege, to be used or laid aside with easy indifference. Properly considered, it is much more than this: it is a living trust, a priceless heritage, involving duties as well as rights. In the presence of educated physicians, there is no need to emphasize this. They recognize their obligation and their opportunity,—their personal obligation of earnest loyalty, their opportunity, through the places they hold in the community and in the household, to raise the level of civic virtue by precept and example. To them, the service to the State which the best type of citizenship presents is not expressed in political zeal, in greed for office, or in an active partisanship which in medical men is always especially offensive and objectionable. It means, on the other hand, absolute independence of all machine methods in politics. It leaves practical politics to professional politicians, but it never fails or omits to register its convictions through the agency of the ballot. It is found in sympathy with all reasonable methods of moral and social reform, but avoids impracticable radicalism and sensationalism. It stands for popular education and defends the public schools from all assaults, overt or insidious, that would impair their usefulness and freedom. It insists on fidelity and honesty in official station. It aims to aid in shaping a healthy public opinion upon all matters pertaining to the welfare of society and the elevation of mankind. It protests against the fastidious indifference which too often marks the attitude of educated men toward civic affairs. When the nation's life is assailed, it is found at the front represented by such men as Derby and Otis, and Sargent, and Hooker, and Bell and Lyman, adding new lustre to the proud title of Massachusetts volunteers.

Fellows, these closing years of the nineteenth century are making an extraordinary record of progress in all that pertains to the science and the art of medicine.

⁴ The practicability of this method was demonstrated by the New Hampshire Supreme Court in a case which occurred during the preparation of this discourse.

The brilliant, almost audacious, achievements of modern surgery and the beneficent triumphs of practical and preventive medicine inspire our admiration and stimulate our zeal. In the rapid movements of our noble profession along all the lines of advanced development, we find it difficult to keep our leaders in sight; star-eyed science certainly does not encourage loitering on the part of her votaries. But while we strive to keep in touch with this spirit of progress in all that belongs to our domain as physicians, let us not forget the claim which the Commonwealth may properly make upon us as citizens. Let us seek earnestly, each in his own community, to illustrate the highest ideals of loyalty and fidelity. So may we, in a double sense, as physicians and as citizens, discharge our duty to humanity.

Original Articles.

THE AMERICAN PHYSICIAN.¹

BY WILLIAM EVERETT, PH.D.

I FEEL that there is a peculiar right in a society of physicians to call on any man for a speech, when I reflect how completely it is owing to their mercy that one is able to speak at all, or even to exist.

When I sit down to this well-provided board, and am allowed to eat as much or as little as I want to, I cannot but reflect on the times when the doctors of the elder generation would not let me eat half enough, and the doctors of my own wanted me to eat a great deal too much; and I rise to thank them for all their mercies in preserving my life against the consequences of my own folly.

In old times, gentlemen, you are well aware that your profession was associated with that of the barbers, who in more ways than one tried to avert "the natural shocks that flesh is heir to." I suppose no man ever got up out of a barber's chair, and heard the cry of "next," without being devoutly grateful that his Figaro had not revived the recollections of his predecessors, the barber-surgeons, and experimented on the precise distinction between the carotid and maxillary arteries.

It is said that the illustrious James Otis, when stricken with dementia towards the end of his life, was under very severe petticoat government, and on one occasion returned thanks after dinner in the form: "We thank Thee for all Thy mercies, and especially that we have not had our noses bitten off." I thank you, gentlemen, to-day, individually and collectively, that I survive to this hour, in possession of the great majority of my physical organs, and the enjoyment of their normal functions.

But I desire to say again, as I have said in public before, that I have exceedingly little sympathy with the popular jokes on the medical profession. They are not even chestnuts,—they are nothing but horse-chestnuts, bitter, but utterly devoid of nourishment. I believe that no theory can be more false than that Nature cures her own ills, or the ills in which man's ignorance and wilfulness involve her, without the aid of science. Worse than false, that theory is wicked which believes that the ignorant practitioner has any secret revealed to him, which the man of medical

science does not attain much better by study, by experiment, by observation, by instruction.

Quackery and patent medicine could not survive for an instant, if they did not furnish excellent means for evading the prohibitory laws, and soaking their votaries' frames in alcohol and opium, under the name of bitters and sarsaparilla. I believe, sir, that your educated physician is no ignorant tamperer with half-known drugs and less known bodies; he is the true son of Apollo, the god of light and prophecy. Talk of your Faith Cure and your Christian Science! the true faith cure comes when the sensible patient trusts himself implicitly to the accomplished physician; the true Christian Science is that promulgated by the great army of healers who tread in the Master's steps, who go about doing good, and turning the Sabbath to its nobler use.

I have been in my life, sir, often in the hands of physicians; and I have been disposed to bless the sickness which taught me the meaning of devotion, of patience, of friendship. I have found that they knew every secret of my frame; I have found that they were competent to deal with those deeper secrets which anatomy and physiology, chemistry and bacteriology do not reveal. They were able to deal with the very cases wherein Shakespeare declares the patient must minister to himself. They could extirpate the nerves of morbid sensibility; they could apply a ligature to an aneurism of self-esteem, and divert the current of ambition to a healthier passage; they could dissolve the rasping calculi that obstructed the channels of generous purpose, and they could detect the foramen between the corrupted and the purified chambers of the soul, which is apt to infect the nobler passions of man long after the fetal heart has closed. Yes, sir, after their skill has set me on my feet, after they have nerv'd my flaccid arm, brightened my lack-lustre eye and cleared my tuneless voice, I have loved to seek their company, no longer for the paid services of a physician, but the priceless comfort of a friend. I may not introduce here the names of the living, but I should be destitute of all sense of reverent obligation, if I did not record my dues to Henry Holland and James Jackson; and I trust it will be many years before the members of the Massachusetts Medical Society fail to follow one who drops a tear of admiration and love over the grave of Frederick Winsor.

The skill and kindness of the medical profession is one of those eternal facts to which the heart of man bears unshaken testimony. That single line in Homer (you all know Greek; you're not fit to be doctors if you don't),

ἰητρός γαρ ἀνὴρ πολλῶν ἀντάξιος ἀλλαν,
"One healer counts for many another man."

those three blessed words of Paul, "the beloved physician," tell more truth than all the satires of Rabelais and Molière.

Even in the days of starving and blood-letting which seem so strange and cruel to us, the physician was still revered and loved for his kindness. I know no nobler tribute to the profession than that of Sir Walter Scott:

"I have lain on the sick man's bed,
Watching for hours for the leech's tread;
I have listed his words of comfort given,
As if to oracles from heaven;
I have counted his steps from my chamber door,
And blessed them when they were heard no more."

Yet in the light of modern science, it seems amazing

¹ Remarks made at the Dinner of the Massachusetts Medical Society, June 8, 1892.

that the citadel of Sir Walter's constitution survived the alternate assaults and starvings whereby it was besieged. Yet even under the thin gruel and draining lancet he and his contemporaries loved and trusted their doctors :

" Pleased to the last, they cropped the floury food,
And licked the hand just raised to shed their blood."

Gentlemen, I beg you to hold fast to this sacred attribute of kindness. I have had some fear in this respect of our younger friends, who like Sol. Gills, are so " chock full of science," that they are apt to look upon the human frame too much as a field for experiment rather than as the residence of a sensitive, quivering soul. They are so proud of their new processes, that they like, I am afraid, to experiment on *corpora cardia* as well as *corpora vitta*. I confess I have a preference for physicians of at least my own age, who have more knowledge of patients, if they have less of diseases. I feel nervous about entrusting a case of colic to my young friends and former pupils for fear they should suspect typhilitis, and perform laparotomy before I could turn round. I am afraid in those famous hospitals of Europe, whatever else they learn, they find as Dr. Holmes once said at this very board :

" Kindness untroubled by our grave M.D.'s."

I read an interesting paper in your *Medical and Surgical Journal* the other day (which I read every week, and immediately feel the symptoms of all the diseases described there), wherein a rising practitioner declared he actually discovered, if he administered ether, especially to children, gently and slowly, instead of forcibly and abruptly, he not only got rid of some distressing tracheal irritations, but positively produced more perfect anesthesia and found the operation proceed more favorably, than if he clapped the towel peremptorily over the reluctant nostrils. I should hope so! But it is sad that any of our young doctors should have ever been trained to think otherwise, or should suppose that mechanical roughness of operation can facilitate their work, instead of, in fact, hindering it.

It may be well, sir, for purely pathological or physiological purposes, to send our medical students to Europe. It may be that Prussia is the best climate in which to track the bacilli which are most likely to infest the air of Boston, or that an Austrian hospital, in wards crammed with what your illustrious *confere*, Dr. Oliver Goldsmith, called "the rude Carinthian boor," presents exactly the field in which to prepare for the diseases of New England. It may be that European practitioners and teachers have a keener eye, a defter hand, a more powerful spirit of guidance than our own. But you cannot acquire among them, what if one does not keep them up there is danger of losing, those qualities so precious for a physician, in which America yields to no nation in the world. The time, I believe, will come, sir, when Europe has learned to know us better, that Vienna and Berlin and Paris and Glasgow will send pupils here to study the highest standard of a physician's dealings with his patient, unknown in the old world; that humanity which treats with equal courtesy and gentleness the poorest and meanest son of God; that chivalry, lost to the monarchies and commonwealths of Europe, but living, thank heaven, among us, which treats every woman with tenderness and propriety, and sees a sister and a princess in every daughter of the great King. It is possible, sir, that for scientific training to the physi-

cian's work we yield to other nations; in moral and sympathetic fitness, I believe we surpass them all, and that we should allow nothing to deprive us of this glory.

THE FOUR YEARS' COURSE AT THE HARVARD MEDICAL SCHOOL.¹

BY R. H. FITZ, M.D.

In examining the handsome and instructive catalogue of the Harvard Medical School Association, recently published by that body, evidently under the personal supervision of its talented and versatile President, Dr. Chadwick, it appears that more than two-thirds of its members are residents of Massachusetts. I am easily convinced that nearly all of this 700 are members of our greater Society whose annual meeting we delight in attending. It is therefore eminently fitting that a teacher in the Harvard Medical School, however ill prepared he may prove, should make some report of its progress to those who have been satisfied with it in the past, and who, it hopes, will be proud of it in the future.

Only once before in its existence has so radical a step been taken as during the present year. Many of you remember the powerful address of that most illustrious of American surgeons, Henry J. Bigelow, delivered before this Society, in 1871. The discussions in the medical faculty which preceded that discourse were those which led to the establishment of the graded course of medical study extending over three years. The success of that step, then so uncertain even in the minds of some of its oldest and best friends, is now a part of the medical history of this country.

In the meantime a generation has been born and has attained its freedom. Our *Alma Mater*, Fair Harvard, although she denies the right of suffrage to her medical offspring, has decided to keep them a year longer under her maternal care. Perhaps by this means she may learn to place such confidence in their interest and devotion as to be willing to take their advice and aid even in so important a matter as in the selection of overseers. Let us hope that the graduates of the four years' course in the medical school may be considered no less worthy of this honor than their younger brothers who have spent a like number of years at her side, perhaps, in preparing to enter the Medical School.

In and after September, 1892, every student entering the Harvard Medical School, before receiving its degree of Doctor of Medicine, will be required to complete a four years' course of graded medical study. The statement is simple enough but the result has been arrived at only after years of discussion and of patient waiting for the time when such a policy might be regarded as other than suicidal.

It has not been undertaken as a forlorn hope to rescue the school from a stress of financial depression, but has been agreed upon in a season of prolonged, pecuniary prosperity, and at a time when the number of its students is the largest ever assembled.

It has not been announced with the thought that it might result in large benefactions, or as the condition of gifts which would ensure its success. On the contrary, it has been decided upon in the face of a probable diminution in the number of students, a loss which

¹ Remarks made at the Dinner of the Massachusetts Medical Society, June 8, 1892.

may result in a considerable pecuniary sacrifice on the part of its teachers. All honor to them, and especially to those who are largely dependent for their support upon the fees derived from students, and who anticipate, not without reason, the possibility of a reduction in salary to meet the necessary expenses of maintaining and perfecting the improved plan of education.

The essential features of this plan consist, first, in giving up the teaching of general chemistry to the preparatory schools, and in demanding evidence of a knowledge of this subject as a requirement for admission. It is felt that medical chemistry alone should be taught in medical schools, and the time hitherto given to instructing the student in the former subject will, hereafter, be given to enlarging his knowledge of the latter. A wholly new course is to be established, one in clinical chemistry, which is designed to familiarize the student, more than ever before, with the chemical knowledge and manipulations so essential in the recognition of disease.

A second important use is to be made of the gain in time obtained by requiring a satisfactory knowledge of general chemistry when the student is admitted. He will be compelled to train himself in those bacteriological methods especially needed in diagnosis and treatment. He must personally undertake, in the laboratory, to render aseptic his hands and instruments, his dressings and the field of operation. He will be taught experimentally, by personal failures as well as successes, the essentials of modern, surgical, obstetrical and, one may say, general practice. Whatever methods are of value in the recognition of disease-producing bacteria, he must learn, and by appropriate trials, show his familiarity with them.

Finally, a much demanded improvement in clinical teaching is contemplated. Separate courses of instruction will be offered to the beginner and to the advanced student, each adapted to the degree of development which he has attained.

It will also be attempted to give to every student individual opportunities of watching the progress of a certain number of cases of disease in the hospitals, from the time of the admission of the patient to his discharge. He will be expected to keep full and accurate records of these cases and to be prepared at all times to present the evidence which he has accumulated. The end in view is to make every graduate a hospital pupil as well as a medical student.

From this necessarily brief statement of what is planned it is evident that the school will offer the student more than he has ever before received. It will demand from him a better preliminary training, and it will give him, in return, a more profitable employment of his time.

From you, its graduates and friends, it asks only approval and encouragement, and, in the light of past experience, it rests assured that it does not ask in vain.

A PREMATURE announcement that M. Pasteur had succeeded in stopping the attacks of confirmed epilepsies by anti-rabic inoculations found its way a short time ago into the daily papers of Paris. The possibility of this has been entertained for some time, and that in a recent case sent to the institute, attacks probably epileptic have disappeared. As yet no positive results have been obtained.

THE ELECTRICAL TREATMENT OF PELVIC INFLAMMATION.¹

BY W. L. BURRAGE, M.D.

THERE being many practitioners who are sceptics as to the value of electricity in the treatment of the diseases of women, I will begin by quoting from our latest and probably best books on gynecology, namely, the sixth edition of "Thomas on the Diseases of Women."

In this work there is an entire chapter devoted to "Electricity as a Therapeutical Agent." In the chapter we find the following: "It is true there are still many gynecologists who do not believe in its particular efficacy (electricity) partly because they have either had no experience with it or because many of the most startling results have been reported by gentlemen who were not gynecologists, but electricians, or, better, electrologists, who possibly may have been mistaken in their diagnosis and in the results which they claim to have obtained. Still we feel confident from our own experience that we have in the two varieties of the electrical current most potent agents for relief from suffering, and perhaps even cure, in many cases of pelvic disease in the female."

So much for electrical treatment in general. A little further on in the same chapter we read: "Chronic pelvic cellulitis and peritonitis, pelvic neuralgia, local and reflex, pelvic lymphadenitis and lymphangitis—in all these three conditions the local and reflex pains are mostly due to inflammatory indurations and adhesions of the tissues involved. The vaginal roof is hard and rigid, the uterus immovable, perhaps displaced, and the uterine ligaments tense and inelastic. If not of too long duration and particularly if the exudation represents a distinct swelling, the galvanic current may effect decided results."

Gynecological electro-therapeutics conducted with anything like scientific methods dates its beginning from the initial work of Apostoli, only ten years ago. In this country the names of Engelmann, of St. Louis; Mundt, Rockwell, Gunning and Goelet, of New York; Baker, of Boston; Lapthorn Smith, of Montreal; Massey, of Philadelphia; and Martin, of Chicago, are most familiar as workers in the field. My own experience with electricity in gynecology extends over two years, during which time I have made about a thousand applications, including those made in private practice and at the Electro-Therapeutical clinics at the Free Hospital for Women.

Thanks to the introduction of better instruments, to the exact measuring of doses, and to greater attention to detail we are now experimenting intelligently and arriving at definite results, impossible under the old regime.

As regards the treatment of pelvic inflammations with electricity, we have to consider two stages of inflammation, the acute, and the sub-acute or chronic. In the acute stage most authorities are against treatment with galvanism. Experimentally, I have tried galvanism in one case of acute pelvic inflammation with salpingitis. The patient had thirty-six milliamperes, negative, for five minutes. The pain was increased, the temperature went up from 100° to 102° and she was made much worse.

Apostoli advocates bipolar faradism, first vaginal,

¹ Read before the Section for Obstetrics and Gynecology of the Suffolk District Medical Society, March 9, 1892.

and after increased tolerance, intra-uterine, using the coil of fine and long wire and prolonging each sitting until the relief of the pain. I have found the bipolar vaginal current lessen pain markedly both in the acute and the chronic stage. I cannot see the advantage of intra-uterine application and have not used it.

In the sub-acute and chronic stage, where there are found no fever, no chills, no sweating, no evidences of pus forming, galvanism, the continuous current, has been, in my experience, of the greatest benefit both as to the relief of symptoms, and in the dissipation of the pathological exudate. As regards the many cases in which we are unable to diagnose with certainty the presence of pus, it seems to me that the doubt is not a contraindication to the use of electricity. I have not seen it do harm and other observers bear testimony to the same effect. If pus is present we do not expect as much benefit from the use of electricity, that is all.

Massey in his book on "Electricity in the Diseases of Women," second edition, page 175, says: "The existence of pus in a tube or elsewhere in the pelvic may be a contraindication to this form of electrical application (vaginal galvanism), but if so I have never had evidence of the fact." He cites instances of pyosalpinges relieved by vaginal and intra-uterine galvanism.

Treatment with electricity should not be made use of to the exclusion of the time-honored methods of treatment of pelvic inflammation, for example, hot douches, painting the vaginal vault with Churchill's tincture of iodine, and glycerine tampons. I have seen the best results where electricity has been combined with those measures.

The action of the galvanic current on the tissues through which it passes may be divided into two parts, the polar, and the interpolar. At the negative pole, if the metal of the electrode is brought into direct contact with the tissues and a high intensity used, a soft, easily bleeding eschar is formed; hydrogen gas, set free by the electrolytic effect of the current on the water, and alkalies, probably the alkaline bases, liberated from combination with acid molecular, gather here. At the positive pole the eschar formed is dry and non-hemorrhagic, and oxygen gas and acids collect.

The foregoing points can be demonstrated as facts. As to the interpolar action, namely, what takes place in the rest of the tissues traversed by the current we are dependent on theory. It is supposable that the laws that govern the phenomena of the electrolysis of inorganic compounds, hold with reference to the chemically more complex organic compounds of the body tissues. We lack the proof. That electricity should resolve exudates of low vitality and promote nutrition of tissues of high vitality at one and the same time does not appear to me to be an inconsistency. It is probable that the phenomena of electrical osmosis—the passage of fluid through porous material in the direction of the current, from the positive to the negative pole, plays a part in the action of the galvanic current in removing plastic and serous infiltrations.

The form of electrical treatment that commends itself most strongly consists in the application of moderate intensities, from 25 to 75 milliamperes, vaginal rather than intra-uterine, and for periods of time varying from five to ten minutes at a sitting; the sittings to be held twice a week or even every other day

according to the tolerance in the given case. After a preliminary application or two of perhaps 25°, it is my aim to use a progressively higher intensity that causes not more than an easily endurable amount of pain.

With vaginal galvano-puncture for pelvic inflammations in the stage of infiltration, as practised and recommended by Apostoli, I have had no experience. To my mind the puncture adds an unnecessary risk to the treatment, the risk that attends any surgical procedure of the same character in structures already in a state of inflammation, and this, for me, overbalances the advantage derived from bringing the electricity in more intimate contact with the exudate. As for draining pus-tubes and abscesses by vaginal galvano-puncture, I consider it bad surgery. If an opening is necessary it should be of sufficient size and made according to surgical principles.

Let us now run over the steps in the treatment of a case of non-acute pelvic inflammation. The operator should be provided with a good battery or source of a sufficiently strong current. Anything from a portable battery giving a voltage of 50 to the Edison 110 volt incandescent current will answer. He must have a current controller or rheostat, a milliamperé-meter and three electrodes, an abdominal dispersing, a vaginal, and an intra-uterine. Suppose that for battery he has one composed of from 40 to 60 Law cells, for rheostat the Bailey, for milliamperémeter the MacIntosh, for dispersing electrode the Goelet clay, for vaginal electrode the carbon or brass ball covered with clay, absorbent cotton and gauze, and for intra-uterine electrode a two and one-half inch tip of block-tin at the end of a hard rubber handle.

The patient should be on a suitable table or raised couch, on her back with knees flexed. Exceptional cases can be better treated in the Sim's position. If the treatment is to be intra-uterine she should have a small vaginal douche of corrosive (1 to 5,000), or the vagina should be thoroughly swabbed with cotton soaked in the corrosive solution. The internal electrode should be surgically clean.

First test the apparatus. For this purpose connect the negative (zinc) pole of the battery with the meter by means of an insulated conducting cord, and the meter with the abdominal dispersing electrode with another cord. With a third cord connect the positive (carbon) pole of the battery with the rheostat and the rheostat with the vaginal or intra-uterine electrode by means of a fourth cord. See that the plates of the rheostat are raised so that they do not touch the water. Bring the abdominal and vaginal electrodes in contact, that is, short circuit the battery. Turn the handle of the rheostat until the plates touch the water, and note the behavior of the needle of the meter as you raise or lower the plates. If you are satisfied that the current is passing steadily and that you have perfect control over it, bring the rheostat back to the condition of greatest resistance by raising the plates and break the circuit by separating the electrodes.

Having thus tested the apparatus the operator is ready to begin the application. Apply the clay electrode, previously well soaked in water and warmed, to the abdomen, its lower edge being at the symphysis pubis. Disconnect the vaginal electrode from its conducting cord and introduce it by hooking back the perineum with the forefinger of the left hand, or, if the introitus is tight, pass a Goelet speculum, and,

pressing strongly backward slide the ball tip along it into the vagina. The tip, by the way, should be an inch in diameter to prevent injury to the vagina from the caustic effect of the electricity at the active pole. It should rest at the point nearest to the inflammatory effusion. The intra-uterine electrode is introduced by locating the os uteri with the left forefinger and passing the point along the finger until it enters the os. Now take a final glance at the rheostat to make sure it is in a position of greatest resistance, and connect the conducting cord with the internal electrode. Note the exact time on your watch. Hold the internal electrode with the left hand while the handle of the rheostat is turned with the other. It is well to have the patient place one of her hands on the clay to improve the contact with the skin of the abdomen.

Keep an eye on the milliampercô-meter and on the patient's face. For the first dose, 25° to 35°, positive, for five minutes is generally sufficient. After two or three applications, you can change to negative in the vagina, and gradually increase the dose according to the toleration to 70° or 100°. The positive pole is used in the beginning because it is less painful than the negative. It is seldom necessary to prolong the treatment more than ten minutes. Five minutes is a good average. Increase and decrease the current slowly, using a minute of the five for this. Disconnect the internal electrode before removing it. The treatment may be given twice a week or oftener.

When an endometritis accompanies the pelvic inflammation, as it often does, it is well to make the treatment intra-uterine after tolerance has been acquired by vaginal applications. The positive pole, intra-uterine, is especially indicated when there is a tendency to flowing. Should there be excessive pain as a feature in the case, the faradic current from a coil of fine and long wire applied with the bipolar vaginal electrode, using as strong a current as the patient can bear, and for a period of time until the cessation of the pain, will be found to be of great service.

I want to emphasize the importance of beginning electrical treatments with mild currents. Aside from the need of this caution from a strictly medical point of view, this is the age of the deadly trolley-wire and electrocutions, and the man on the Common, who dispenses painful shocks of faradism for ten cents, adds his mite to a widespread dread of electricity. Two patients out of three are prejudiced against it. It is necessary to show them that electricity is not the awful agent they supposed.

With your permission, I will read a few cases illustrative of this method of treatment.

CASE I. E. F. R., forty years old; married eighteen years, widow five years; two children, twenty-two and twenty years of age; one doubtful abortion. Was referred to the electro-therapeutical department at the Free Hospital for Women, by Dr. W. H. Baker in March, 1891. She had been examined under ether in that institution by Dr. Baker February 26, 1891, and the diagnosis made of old tube on the left side, size of a small lemon, sub-involution of uterus and retroversion with adhesions. Her chief complaint was pain in the left groin. She was easily tired; never very strong since the birth of her first child. Both labors were instrumental. Four years previously she had had an operation for lacerated cervix and for two years she felt better. For the last two years had felt as bad as

ever. Catamenia regular; painful of late, obliging her to keep her bed. Flow increased in amount to ten napkins, formerly three to four.

March 7th when I first saw her I found the uterus in the second degree of retroversion; not freely movable; a mass behind and to the left, size of a small orange. Endometritis and a long anterior lip to the cervix, the result of a trachelorrhaphy performed two years before. The uterine canal measured three and one-quarter inches. There was no especial sensitiveness. A beginning was made with negative vaginal galvanism on that day (March 7th). She had 30°, negative, six minutes. March 11th, 30°, negative, five minutes, and March 14th, 40°, negative, five minutes. March 18th, the intra-uterine electrode was passed to the fundus, and a current of 40°, negative, was given for five minutes. This treatment caused considerable pain, both at the time of the application and on the two days following, so on March 21st, I introduced the bipolar intra-uterine electrode and administered faradism to the point of toleration, from a small Gaiffe battery. Eight minutes was the length of the treatment. She had no more pain, and the catamenia came on two days ahead of time. There was the usual amount of pain with the flow, but the pain in the left groin had disappeared and did not return.

April 1st, she had 50°, positive, six minutes, intra-uterine; and April 8th, 55°, positive, four minutes, intra-uterine. Subsequently, she was given two negative treatments of 35°, for from five to seven minutes.

May 6th, two months after the first treatment, having had eight galvanic and one faradic application, the mass on the left side had entirely disappeared and there was left only a slight thickening in the broad ligament on that side. I was able to replace the uterus bimanually, and she was advised to have a pessary fitted. She then passed from under my observation.

CASE II. E. A. H., widow, forty-four years old, was referred to me for electrical treatment from the indoor department at the Free Hospital for Women, in April, 1891. She had been examined under ether in the hospital March 17th previously, by Dr. F. H. Davenport, who made the diagnosis of endometritis, old tube or enlarged ovary on the left side size of a small lime, a hard and adherent retroverted uterus. He curedtted her for the endometritis at this time.

She was a thin, nervous woman, a hard worker at her profession, that of a masseuse. Her mother died of cancer of the breast; in other respects the family history was negative. She had had five children, whose ages ranged between twenty-three and fourteen years, and seven abortions, most of them induced. She had suffered for many years from leucorrhœa, which for the last two months had been thick and yellow and of a bad odor. She had been in poor health for three months since an attack of acute pain in the left lower abdomen coming on at the time of menstruation. Her chief complaint was pain in the left groin that had persisted since the above-mentioned attack. She had lost some twenty pounds in weight, was nervous and tired; appetite poor, and bowels constipated. The catamenia, usually painless, had been very painful during the preceding three months. There was no excessive flowing.

April 8th I saw her first, and confirmed Dr. Davenport's diagnosis. The abdominal walls being then very lax, I was able to palpate the enlarged ovary or

tube on the left side distinctly, the fundus uteri was in the second degree of retroversion and sensitive to gentle pressure in the cul-de-sac. It was firmly glued in place by adhesions. There was an abundant mucoid discharge issuing from the lacerated cervix. On account of her occupation she was unable to take treatment regularly.

During the six months from April to October, she had eighteen applications of intra-uterine galvanism, from forty to fifty milliamperes at a sitting; eleven were negative, and seven positive. There was marked benefit from the first treatment. She was able to do more work and felt better in every way. In a month the leucorrhœa had ceased. In spite of the fact that she worked incessantly, was on her feet a large share of the time, and in addition had two severe colds, she improved in general strength, and got rid of her pain completely.

June 3d, I noted that the ovary or tube on the left was smaller, the uterus more movable and less sensitive to vaginal pressure.

August 22d, the ovary or tube was still smaller, and thickening in the broad ligaments was the only representative of past inflammatory action.

October 28th, the thickening had entirely disappeared; there was no enlargement of tube or ovary to be felt, and the conditions for examination were as favorable as at the first examination six months before. The uterus was apparently replaceable, but as there was a vestige of the tenderness in the cul-de-sac on deep pressure, it seemed best to advise packing before replacing and adjusting a support. She was referred to one of the out-patient surgeons of the hospital with this end in view.

January 27, 1892, she reported to me that she had felt so well that she had not thought it worth while to have the uterus replaced. She had gained twenty-two pounds in weight since September, her catamenia had been regular and painless, she had had no leucorrhœa and no pain in the groin, and had not felt so well for ten years.

During February I saw her again, and physical examination showed the same condition of the pelvic organs as in October.

The result here can fairly be attributed to electricity, as she had no other treatment beside occasional hot douches.

I will not try your patience by reading more cases. The two I have read will serve as fair samples of a large class of cases that every gynecologist meets. Subacute and chronic pelvic inflammation are among the most important factors in uterine disease. The detection of their presence and their proper treatment are of the greatest moment to the patient and may avert years of suffering. If electricity is a valuable therapeutic agent in these affections, and of that there is not the least doubt in my mind, it should not be neglected because for its application there are required special apparatus and a working-knowledge of electrophysics.

Effie. — That is the new doctor, and those are his children.

Maud. — How ugly his children are!

Effie. — Well, naturally! Of course, doctors have got to keep the ugly ones themselves, you know.

— *Punch.*

Clinical Department.

REPORT OF A CASE OF PURULENT SALPIN-GITIS.¹

BY GERTRUDE W. VAN PELT, M.D.

MRS. B., twenty years of age, octoroon, came for treatment in June, 1891, because she had never menstruated. She had been married two years, and was anxious to become pregnant.

Family History. — She is the youngest of twelve children. Her sisters all menstruated regularly. One sister is said to have died of quick consumption, after a cold taken during her first menstrual period. With this exception there is no possible history of tuberculosis in the family. Father died of some heart trouble, mother of cancer of the uterus.

Patient had always been well until five years before, when she began to have attacks of pain in the back, dizziness and nose-bleed, which attacks came about every four weeks. For a time after marriage, she was better of all her symptoms, but for a year they had been present again, and were increasing. Moreover, she was losing flesh and strength.

On examination uterus was found in good position, with a depth of two and one-fourth inches; ovaries were not found. She had some leucorrhœa. Diagnosis made was, endocervicitis — probable endometritis — undeveloped uterus.

She was treated twice with the galvanic current, the negative pole being within the uterus, with a current strength of 25 milliamperes. These caused pain for a few days each time; and on the 20th of the month — the date she usually had her unpleasant symptoms — there was severe pain, which lasted several days. She was confined to her bed; and for her relief, hot douches, poultices, morphine, and applications of iodine were necessary. Also in the left cul-de-sac could be felt a rounded mass, about two and one-half centimetres long, which was very sensitive to pressure. All these symptoms, however, gradually subsided, and the mass became much smaller, and was only slightly sensitive. She then received one treatment of faradism, with a bipolar intra-uterine electrode, and a few days later, which was about the 20th of the following month, she had a slight discharge of blood for the first time in her life, and she had no nose-bleed, no unpleasant symptoms and was feeling very well. The faradic current was used six times during the next four months. She continued well, and the depth of the uterus increased to two and one-half inches. There was no flow again at the menstrual epochs, but less pain and general disturbance than formerly.

During all this time the mass in the left cul-de-sac did not entirely disappear, but it was very small, and gave no trouble. Suddenly, at one of the menstrual epochs, the pain became very severe, and the mass in the left cul-de-sac increased in size and became extremely tender. All symptoms steadily increased until she was operated upon, seven weeks later. At the menstrual epoch passed during this period, there was a sudden increase in the tumor, and an aggravation of symptoms. She grew very weak, had fever, tongue brown, and anorexia.

Dr. Cushing performed the operation at the Charity Club Hospital on January 17th, and although the

¹ Read before the Section for Obstetrics and Gynecology of the Suffolk District Medical Society, March 9, 1892.

tumor was found to contain enormous quantities of pus, and the patient was in so poor a condition, she has scarcely had a pain since, and has steadily gained.

After the operation it was learned that the husband had had gonorrhœa before marriage, but had supposed he was cured. Dr. Dexter very kindly examined the pus for gonococci, but they were not found.

The specimen is preserved in chloral, three ounces to one-half pint each of water and glycerine, which has kept very nicely the relative hardness of the different parts. The tube at the inner third is hypertrophied and hardened, looked comparatively bloodless when fresh, and the lumen is very small. The external two-thirds is soft and uniformly distended. There was pus within the tube. The mass behind and below it, which I suppose to be hypertrophied and degenerated ovarian tissue, is riddled with abscesses. On the right side the lumen of the tube is so small, that I have been unable to pass anything through it, and the ovary has numerous small serous cysts.

I suppose there is little if any doubt of the cause of the inflammation in this case, especially as there is a history of infection. The interesting questions unanswered, are: Was there any condition previous to the infection which rendered menstruation impossible? and after infection, by what road did the inflammation travel? Pozzi says, that when the tube and ovary are not fused together, as it were, uniting to form one common abscess, but when the abscess is in the ovary alone, that there has been a previous cystic condition of the ovary, favoring suppuration, by whatever avenue the inflammation may have travelled, whether through the tube, by contiguity of tissue, through adhesions, or by the lymphatics. When there has not been a pre-existing cystic condition of the ovary, he says the inflammation is periovarian. In connection with this statement, the condition of the right ovary seems interesting and suggestive.

I should like very much to have the ideas of the doctors present as to the pathological changes that have taken place.

Medical Progress.

REPORT ON THERAPEUTICS.

BY FRANCIS H. WILLIAMS, M.D.

(Concluded from No. 23, page 579.)

PIGMENTATION OF THE SKIN CAUSED BY CHRYSAROBIN.

It is known that when chrysarobin ointment is used in the treatment of psoriasis the affected parts of the skin appear white, whilst the surrounding healthy skin appears yellowish-red. Campana⁹ examined portions of the skin microscopically and found that the pigmentation in the surrounding skin was caused by the deposit of numerous blackish-yellow particles of chrysarobin within and between the epithelial cells in the basic layer of the horny epidermis.

TREATMENT OF HICCOUGH.¹⁰

Hiccup is sometimes a very troublesome symptom, and in some cases may be difficult to overcome. Leloir, in a case of a child twelve years old suffering from

persistent hiccup, applied digital pressure for three minutes to the left phrenic, between the two attachments of the sterno-mastoid; the hiccup stopped and did not recur. He has since used the method in a large number of cases, and always with success; in some cases pressure for a few seconds has been sufficient, in others a few minutes.

SUBCUTANEOUS INJECTION OF SALT SOLUTION IN DIARRHOEAL COLLAPSE.¹¹

Demieville recommends the subcutaneous injection of sterilized salt solution in the collapse produced by acute gastro-enteritis in infants. The apparatus required is simple. The salt solution used is a solution of chloride of sodium (0.6%). As the solution is rapidly cooled by passing through the tubing, it is well to employ a large reservoir, and to be sure that the solution as it leaves the needle is warm. The skin must be thoroughly disinfected, and also the needle and apparatus; the water should be boiled before use.

As to the quantity to be used, a case is related in which a child, aged four and one-half months, received about four ounces; the injections were made into the thighs, and were followed by gentle massage. The patient in the case mentioned appeared to be *in extremis* when the injections were given, but began to improve almost at once, and reaction was established in a few hours. The injection made the child cry, but did not seem to cause much suffering. The good results obtained by this method are believed to be due to the improvement produced in the circulation, especially in that of the nervous centres.

ATROPINE IN ENURESIS.¹²

Dr. Kerley gives an account of a trial with atropia in twelve chronic bed-wetters in the New York Infant Asylum. The ages of the patients ranged from four to ten years. They had been through the usual routine treatment with strychnia, belladonna, etc., without improvement.

They had always been troubled with enuresis; all wet two or three times during the night, and three once or twice during the day in addition to the nocturnal incontinence. The plan of treatment followed was that used by Dr. William Perry Watson. A solution, consisting of one grain of sulphate of atropia to one ounce of distilled water, was ordered; and of this one drop was given for every year of age of the patient, at 4 and 7 p.m. One-half of this quantity was given, however, in each case for the first few days, no unpleasant symptoms followed, and then the full amount was given.

Physiological symptoms were produced in three, but were slight and of no importance. After six weeks of treatment slight improvement was noticed in four,—would go one or two nights in a week without wetting; at the end of the third month these four wet but once or twice a week. Seven were practically well at the end of the fifth month, rarely wetting.

The treatment, however, was continued as before two months longer, when the dose was reduced one-half; this was given two months, and then stopped. It is nine months since the treatment was discontinued, and there had been no return of the trouble. The remaining five, which includes the three girls, showed

¹¹ Suisse Romande, No. 1, 1892; British Medical Journal, February 26, 1892.

¹² Archives of Pediatrics, No. 88, 1891.

but slight improvement at the end of the fifth month of treatment, wetting nearly every night.

During the next three months the improvement was gradual, and at the end of the eighth month they wet not oftener than twice a week. During the tenth month there was only an occasional wetting. The dose was reduced one-half, and after one year of continuous treatment there was no wetting. The atropia was stopped, and there has been no return of the enuresis in six months. Eighteen months ago there were twelve chronic bed-wetters of the worst order; to-day they are well,—the only medicine used was atropia, given as above.

INJECTIONS OF AMMONIO-CITRATE OF IRON IN CHLOROSIS.¹²

Dr. Alvazzi, of Turin, has successfully treated chlorosis by means of injections of ammonio-citrate of iron. For three months various preparations of iron had been given in considerable doses without benefit, and the patient had become so weak as to be unable to leave her bed. The red corpuscles, which were pale, averaged 4,000,000, per cubic millimetre, and there was slight leucocytosis. As the internal administration of iron had failed, it was determined to try injections of the ammonio-citrate according to the following formula: Ammonio-citrate of iron, grains 17; distilled water and laurel water, one and a quarter drachms each. The injections were given with an ordinary Pravaz's syringe. One-sixth of a grain of the salt was given once a day, the amount being gradually increased till on the ninth day it had reached two grains, still given in one injection. On the sixteenth day, no ill effects having been observed, two injections of two grains each were given each day, and after thirty days the patient was discharged cured. Two or three of the injections were given under the skin, but this having on each occasion caused severe pain, all the others were made into the substance of muscles. The injections were given with strict antiseptic precautions, and were always followed by somewhat vigorous and prolonged massage at the seat of the injection. Pain seldom lasted long, and no abscesses or even swelling followed the injections nor did the temperature rise. When discharged, the red corpuscles had recovered their natural color, and averaged 4,350,000 per cubic millimetre, and the proportion of white corpuscles was normal. The haemoglobin had risen from thirty-five to over ninety-five and the girl's weight had increased from 72 to 84 pounds. Her appearance and general health had improved immensely.

HYDRASTININ IN UTERINE HEMORRHAGE.

Falk, in 1890, showed that hydrastinin acts to diminish the size of the blood-vessels, is not a dangerous drug since it does not affect the heart and is free from any toxic action upon the general system.

Dr. Abel¹³ now gives the result of the successful employment of hydrastinin in his gynaecological clinic. It is, of course, useless to try it in uterine haemorrhage due to polypi, or to carcinoma; its field of usefulness is in another class of cases, such as patients suffering from metritis and parametritis.

It is necessary to give the drug subcutaneously, since, when given by the mouth its action is not satisfactory. Eight to sixteen minima of a ten per cent. solution is

the amount for one injection. Directly after it has been administered the patients complain of a burning pain locally, which does not last long and may be mitigated by cold applications. After some hours there appears at the site of the injection a black and blue area, sometimes as large as a half-dollar, now and then much larger, which disappears slowly and there remains an induration which persists for a longer period and for some time the spot is painful to pressure.

Notwithstanding obvious drawbacks Dr. Abel recommends its use. It has been used to stop haemorrhage during pregnancy and without the risk of bringing on miscarriage.

Reports of Societies.

AMERICAN SURGICAL ASSOCIATION.

(Continued from No. 23, page 586.)

ANNUAL meeting held in Boston, May 31, June 1, and 2, 1892.

WEDNESDAY, SECOND DAY.—MORNING SESSION.

The morning session was given up to a visit to the Massachusetts General Hospital, where a number of interesting cases were shown and the methods of work demonstrated.

AFTERNOON SESSION.

DR. DANDRIDGE, of Cincinnati, read a paper on

THE SURGERY OF THE TONGUE.

The paper was confined to a consideration of operative procedures in malignant disease. Our knowledge of lingual cancer was first reviewed. As a rule, it appears in the form of epithelioma. It runs its course in about a year and a half. In many cases it develops from an indifferent lesion which has been subjected to continued irritation. Neighboring glands are usually affected, and this may occur within three months or not for six or nine months after the appearance of the disease. In ulcerated epithelioma the diagnosis will most often hesitate between that and tubercular and syphilitic ulcer.

The history of operations for cancer of the tongue was then considered and the author expressed his agreement with the following propositions laid down by Treves:

(1) The organ should be removed by cutting with the scissors or knife.

(2) The removal should, as a general rule, be effected through the mouth.

(3) Every means should be taken to reduce the hemorrhage to a minimum.

(4) When the floor of the mouth is involved, or the glands extensively involved, the incision should be carried out through the neck.

The following methods were then described in detail: Whitehead's, Moren's, Baker's, Kocher's and Volkmann's.

Whitehead's. In this operation a gag is used, care being taken to avoid pressing back the jaw and impeding respiration. The patient is in a sitting position. A ligature is passed through the anterior part of the tongue and scissors are used for the section. If the frenum and the anterior pillars of the fauces are completely divided, the tongue can be drawn freely

¹² British Medical Journal, August 29, 1891.

¹³ Berliner Klin. Woch., No. 3, 1892.

from the mouth. The organ is then separated by free cuts with the scissors until the main artery is reached. This is seized with forceps before division. Before completely severing the tongue, it is desirable to pass a loop of silk through the glosso-epiglottidian fold, in case it may become necessary to make traction on the posterior floor of the mouth. The parts are then rendered as aseptic as possible by swabbing over with 1:1000 biniodide of mercury solution, and painted with iodoform styptic solution — Friar's balsam, in which the spirits are substituted by a concentrated solution of iodoform in ether, one part in ten of turpentine having been added to the ether. This varnish is repeated daily. The patient is not kept in bed but encouraged to go in the open air. Whitehead has reported 104 cases of total removal of the tongue by this method, with 20 deaths, or 19.20%. Of 61 patients, 15 survived the operation one year, four, two years, three, three years, four, five years, and one, six years.

Baker's operation. In this operation two threads are passed half an inch from the median line of the tongue on each side. The attachments of the tongue on the side are divided with scissors, keeping close to the lower jaw. The mucous membrane is next divided along the median line and the two halves of the tongue separated by the finger. The diseased half of the tongue is then removed with the cecraser. After this, glands should be searched for and removed either from the floor of the mouth or by external incision.

Kocher's operation has been commended in cases in which the floor of the mouth and the sub-axillary glands are involved, but is too serious an operation for cases where the disease is confined to the tongue. Tracheotomy is first done and the fauces plugged. An incision is then made along the anterior border of the sterno-mastoid muscle. From the first, an incision is made from the middle of the sterno-mastoid muscle to the hyoid bone, and along the anterior border of the digastric to the jaw. The flap is turned up and the facial artery and vein and the lingual artery tied. The sub-axillary fossa is then completely cleaned out. The attachments of the tongue are now divided, and it is drawn through the opening and removed, either in part or in whole, by scissors or galvano-cautery. If the whole tongue is removed, the lingual artery of the opposite side must be ligated through a separate incision. The tracheotomy tube is allowed to remain and the wound is kept packed with gauze soaked in carbolic acid solution. This is changed twice a day, at which times food is given. In fourteen cases thus operated on there was only one death.

Volkmann's method has been attended with extraordinary success, there having been only two deaths in ninety-one operations. The patient is seated in a chair. If the tongue can be brought forward a resection is made with knife or scissors and the mucous membrane brought together, or if a strip of healthy tongue is left it is turned around so as to make a short broad organ. If the disease is too extensive to admit of this method, a traction thread is passed through the tongue and it is drawn forward. The canine or first molar tooth is extracted and an incision made downward from the corner of the mouth and the lower jaw divided. The portions of bone are separated, and the attachments of the tongue divided. The cut surfaces are covered with mucous membrane and the bone wired. A drainage-tube is placed in the tonsillar fossa and brought out at the lower portion of the incision.

In the after-treatment of removal of the tongue for cancer, the three great factors are: (1st) let the patient be well fed; (2d) let all discharges escape from the mouth; (3d) keep the cavity of the mouth sweet and clean.

The author next referred to the palliative treatment to be employed in cases where operation was not indicated, or where the patient refused surgical interference. For the pain a powder consisting of, iodoform (one grain), morphine (one-sixth to one-half a grain), and borax (three grains), has been recommended applied directly to the painful spot. Cocaine has naturally been resorted to either by application to the surface or by hypodermic injection, but there is danger of the establishment of the cocaine habit. The excision of a portion of the lingual nerve was highly recommended, but the relief thus afforded may be only temporary. For the relief of salivation and fetor, various antiseptic mouth-washes may be employed. Where there is difficulty in swallowing, on account of the pain, relief may be afforded by painting the surface freely with cocaine just before the administration of food, or a soft rubber tube may be passed into the esophagus.

The following conclusions were considered justified:

- (1) Sufficient experience has been accumulated to show that the removal of cancer of the tongue prolongs life and adds to the comfort of the patient and further affords a reasonable hope of a permanent cure.
- (2) All operations should be preceded by an effort to secure thorough disinfection of the mouth and teeth.
- (3) In the treatment of continued ulcers and sores on the tongue, caustics are to be avoided and all sources of irritation removed.

(4) Persistent sores on the tongue should be freely removed by knife or scissors, if they resist treatment.

(5) When the disease is confined to the tongue, Whitehead's operation should be employed for its removal.

(6) In this operation, the advantage of preliminary ligation of the lingual artery is not definitely settled, but the weight of authority is against its necessity.

(7) The advantage of leaving one-half the tongue in unilateral disease, must be considered undetermined, but the weight of positive experience is in its favor. In splitting the tongue into lateral halves, Baker's method of tearing through the raphe should always be employed.

(8) A preliminary tracheotomy adds an unnecessary element of danger in the removal of the tongue in ordinary cases.

(9) When the floor of the mouth has become involved, or the glands are enlarged, Kocher's operation should be employed, omitting the spray and preliminary tracheotomy.

(10) Removal of the glands by a separate incision after the removal of the tongue, must be considered insufficient.

(11) Volkmann's method still rests on individual experience. Its just value cannot be determined until it has been subjected to trial by a number of surgeons.

(12) Thorough and complete removal should be the aim of all operations, whether for limited or extensive disease.

(13) By whatever method the tongue is removed, the patient should be up and out of bed at the earliest possible moment, and should be generously fed.

DR. D. W. CHEEVER, of Boston, referred to the

question of diagnosis of ulcers of the tongue. In the first place we have dyspeptic ulcers. These appear in successive crops. They are not indurated, and can be made to heal by simple treatment. Secondly we have the syphilitic ulcers. Previous history is at times of service. In doubtful cases two weeks of anti-syphilitic treatment should be employed. Third, lupus or tubercular disease. This is not so common as cancer. The test of the examination for the bacillus is not always successful. The tubercular ulcers form and reform; some heal and leave scars. Cancer does not heal, but goes on extending. In lupus the sublingual and submaxillary glands are early infected. True cancer is almost always at the side of the tongue; the infection of the glands is usually speedy.

While he advised removal of enlarged glands, he did not think that the neck should be treated at the axilla. As to duration, he thought that malignant affections of the mucous membranes are more speedy in their recurrence than malignant affections in the skin and glandular structures. In cancer of the tongue the disease, as a rule, recurs in four to six months. In simple cancer of the tongue without gland involvement, preliminary tracheotomy is not needed. He operates with the patient in the sitting position, and not thoroughly etherized. He had never tied the lingual artery for cancer. Partial amputation of the tongue, where the disease is limited, seems to have been as successful as the total removal. Recurrence is almost always in the glands and rarely in the stump. Reference was also made to the remarkable recovery of the power of talking in cases when the tongue was completely removed.

DR. L. McLANE TIFFANY, of Baltimore, said that, in considering the operative interference, we should distinguish between cases where the disease involved the anterior portion of the tongue and where the disease has begun more or less posteriorly and there is glandular involvement. In the latter case he prefers division of the lower jaw, either at the symphysis or at the side. He thought it wise to remove the glands beneath the tongue, even if not enlarged. In this way we get rid of one of the routes of systemic infection. Where the posterior portion of the tongue is involved, permanent recovery is rare; where the glands are involved, it is still more rare. He had obtained his best results where he had divided the jaw and secured drainage from below. The incision is not closed, and ample opportunity for drainage is provided. The operation is done with the patient on the side and the head near the edge of the table, full anesthesia with chloroform being employed. Where the tongue is excised for tubercular ulceration, the ulcer rarely recurs although the general tubercular disease may progress.

DR. T. F. PREWITT, of St. Louis, remarked that the solution of the operation depended largely upon the extent and location of the disease of the tongue. Where the cancer is limited to the tongue, an operation through the mouth is sufficient. If the floor of the mouth be involved and the disease extend out to the bones, something more is needed. In one or two instances he had resected portions of the jaw. He did not think that the primary hemorrhage was to be dreaded, but he had seen death from secondary hemorrhage in a case of diseased arteries.

DR. W. H. CARMALT, of Philadelphia, had found a great deal of advantage from preliminary tracheotomy. The most frequent cause of death after oper-

ation is septic pneumonia from the inhalation of infective material. Tracheotomy not only facilitates operation, but it obviates the danger of septic pneumonia. In his last case he had operated, doing tracheotomy and packing the fauces. The patient did well. At the end of four days he removed the tracheal tube and allowed the patient to breath by the mouth. The next day the temperature was up to 102°. The tube was immediately reintroduced and the fauces packed, and in twenty-four hours the temperature was again normal. In cases where the glands are involved, he advised the Kocher operation. In regard to after-treatment, he had found that patients bear the presence of the esophageal tube better than its reintroduction.

DR. R. F. WEIR, New York, had removed the tongue five times by the Whitehead operation and five times by the Kocher operation, and had removed one-half the tongue ten times by Whitehead's operation. Where the floor of the mouth or the glands are involved, he prefers Kocher's operation. He considered it good surgery, where there were signs of glandular enlargement in the submaxillary spare, to cut down in front of and behind the sterno-mastoid muscle and examine the condition of the lymphatic glands in this situation. In the Kocher operation he prefers tracheotomy, and does it a few days before if there is sufficient time. He considers it a great advantage, both at the time of operation and afterwards.

DR. A. G. GERSTER, New York, had extirpated the tongue in various ways in nineteen cases. He thought that the more thorough and radical the operation the better were the results. He advocated removal of the affected glands and the use of tracheotomy. This enables the operation to be more thoroughly done, and with more comfort to the surgeon and less danger to the patient. In this region, as in every other region of the body, thorough operation requires thorough anaesthesia.

DR. T. J. DUNOTT, of Harrisburgh, reported a case where the tongue was greatly enlarged, and protruded from the mouth. The operation was done several years ago, and the patient is still living and well.

DR. JOS. RANSOHOFF, Cincinnati, reported one case on which he operated by the Mordant Baker method four and one-half years ago, and there had been no relapse. In other cases on which he had operated, he had not obtained the same success. In every case where he did not do a Kocher operation he made an incision in the submaxillary triangle, in order to put in a large drainage-tube reaching to the floor of the mouth. This opening gives an opportunity for the examination of the glands. If there is enlargement, the gland can be turned out or the incision enlarged if necessary.

CONDITIONS DEMANDING EXCISION OF THE GLOBE OF THE EYE,

by DR. W. H. CARMALT, New Haven, Conn.

As a rule, the question of the propriety of enucleating an eye will be referred to the specialist, but there are cases of emergency in which the general surgeon is called upon to act promptly. In the consideration of this subject we are at once confronted with it from two different standpoints, according as we have to deal with blind eyes or with those in which there is a more or less useful degree of vision.

In the case of blind eyes the objections to the operation are two, (1) the danger of the operation *per se*,

and (2) the cosmetic appearance. Meningitis has occurred in some cases operated on in the acute stage of suppurative panophthalmitis. In these cases, the removal should be made as soon as the evidences of suppuration are unmistakable. In cases of lacerated or penetrating wounds with loss of vision, the operation is better done before suppuration occurs, or as soon as the evidences of suppuration are sufficiently plain. There is no one condition for which eyes are so frequently excised as in sympathetic ophthalmia (threatened or actual). The pathology of the sympathetic process is still a matter of controversy. In a case presenting the irritative symptoms indicating the beginning of sympathetic ophthalmia, with the other eye lost from injury, or certain forms of disease yet to be mentioned, it is the duty of the surgeon to advise in the most unqualified manner, the enucleation of the blind eye. The irritative stage is usually short. It is more or less rapidly followed by diminution of vision due to an organic lesion. In the acutely inflammatory stage of the sympathetic disease, the removal of the "excitor" is not so beneficial to the "sympathizer," and may be harmful, adding fuel to an already flaming fire. In these cases the operation should be postponed until the active process is subdued. It must also be remembered that in a small number (perhaps about ten per cent.), the sympathetic inflammation may come on after the removal of the excitor; and in about two per cent. it has been thought to have been the result of operation. The conditions liable to give rise to sympathetic ophthalmia are (1) injuries, (2) diseases. Injuries: (a) lacerating or perforating wounds, so severe that the result will inevitably be atrophy of the globe; (b) the lodgement of a foreign body in the interior of the globe; (c) a penetrating wound involving ciliary region. Diseases: (a) recurring or chronic irido-chorioiditis from whatever cause; (b) atrophy of globe following purulent keratitis or panophthalmitis, or in which ossific degeneration of the retina has taken place; (c) atrophy of the globe from any cause with painful ciliary region. Time does not confer immunity against sympathetic disease. There is considerable difference as to liability to the disease in the various injuries and diseases. This sequence is more frequent after injuries than after non-traumatic diseases; and of injuries nothing is so potent as the lodgement of a foreign body in the eye.

The pain which comes from the intra-ocular pressure of a chronic glaucomatous degeneration is frequently so excessive as to justify the removal of the offending organ, all other treatment having failed.

Various diseases of the eye leave the organ in conditions so inconvenient or repulsive in appearance that the surgeon's aid is sought for purely cosmetic purposes. Are there, however, no procedures that may be substituted and avoid so severe a mutilation? In earlier days of ophthalmology abscission of the anterior segment of the globe was often practised. In this operation more or less evisceration of the contents of the globe take place. As a matter of fact, the result is about the same as after enucleation, and sympathetic ophthalmia may follow the operation. The opinion of the author was decidedly against such risky procedures, enucleation of the misshapen eye, with the introduction of an artificial eye, is the only admissible operation. The modern expedient of tattooing a white cicatrix of the cornea without staphyloma has resulted in sympathetic disease.

The enucleation of blind eyes that are the seat of phosphenes, like many other operations undertaken to relieve a symptom of nerve irritation, is of doubtful utility.

In regard to the enucleation of eyes only partially blind, it goes without saying that a condition of things which can allow it to be seriously contemplated must apply with greater force to eyes already blind. The chances of accident or independent disease to the remaining eye are sufficiently great to justify the statement that nothing short of the certainty of ultimate blindness to both, or of death, can permit one to consider such a procedure.

Most of the intra-ocular tumors are sufficiently dangerous to life to demand the removal of the organ in which they are contained as the only hope that can be entertained of successfully combating their encroachment. They are of two classes, the granulomata and the sarcomata.

The extra-ocular growths are of greater variety of histological structure. In sarcomata of the orbit, removal of the globe is often required, even when not implicated in the disease.

Should an eye which retains an appreciable degree of vision be removed in order to arrest a threatened or prospective attack of sympathetic disease in the fellow? It is certainly unjustifiable to remove an injured but still-seeing eye, though it may be an excitor of sympathetic disease. The result of the operation has not been sufficiently successful, in averting the progress of the malady after it has begun, to warrant its recommendation. The only condition in which it was considered justifiable to remove a still-seeing eye for sympathetic disease, is where a foreign body remains in the eye. In these cases sympathetic disease is very apt to follow.

EXECUTIVE SESSION.

The following officers were elected: President, Dr. N. Senn, of Chicago; Vice-Presidents, Dr. W. W. Keen, of Philadelphia, and Dr. Chas. B. Porter, of Boston; Secretary, Dr. J. R. Weist, of Richmond, Ind.; Treasurer, Dr. John B. Roberts, of Philadelphia; Recorder, Dr. J. Ewing Mears, of Philadelphia; Members of Council, Dr. Roswell Park, of Buffalo, and Dr. R. F. Weir, of New York. Member of the Executive Committee of the Congress of American Physicians and Surgeons, Dr. L. McLane Tiffany, of Baltimore — Alternate, Dr. James McCann, of Pittsburgh.

It was decided to hold the next meeting in Buffalo, in May, 1893, and Dr. Roswell Park was elected Chairman of the Committee of Arrangements.

The following were elected to membership: Dr. John B. Deaver, Philadelphia; Dr. Frederick H. Gershoff, Portland Me.; Dr. Wm. S. Halstead, Baltimore, Md.; Dr. Charles B. McBurney, New York, and Dr. Henry R. Wharton, Philadelphia.

THURSDAY, THIRD DAY.

A number of papers were read by title. The morning session was held at the Boston City Hospital, where some interesting cases were shown.

In the afternoon, at the invitation of the President of the Board of Health, the Association inspected the method employed for the disposal of the city sewerage and visited the hospital under the charge of the Board of Charities.

ASSOCIATION OF AMERICAN PHYSICIANS.

(Continued from No. 23, page 583)

THE Seventh Annual Meeting, held in the Army Medical Museum, Washington, D. C., May 24, 25, and 26, 1892.

FIRST DAY, TUESDAY.—AFTERNOON SESSION.

TREATMENT OF FOLLICULAR TONSILLITIS,

by Dr. G. M. GARLAND, of Boston, was read by title.

A BRIEF SUMMARY OF THE CLINICAL HISTORY AND TREATMENT OF 2,012 CASES OF ALCOHOLISM, OF WHICH 87 WERE MANIACAL,

by THOMAS S. LATIMER, of Baltimore.

No attempt is made to discuss the pathology of alcoholism, nor any of the symptoms, except those directly connected with debauch in the habitual drinker. Nearly all of these patients were arrested for drunkenness and disorderly conduct. They were all drunk when arrested, and many of them had not yet become sober when brought to jail. They were cases of almost continuous drunkenness, culminating at short intervals in a severe debauch, leading to some act of violence or to a condition of drunken stupor. All used some form of alcohol when obtainable, but many were habituated to the use of other intoxicants such as chloral, opium and cocaine. There were only two deaths. One of these was a patient who was brought in in a condition of alcoholic coma and died before I saw him. The second case died from the effects of a fall.

No distilled or fermented drink was given in any one of these cases. No drug but the bromide of potassium, except in a few cases where great cardiac weakness prompted the use of tincture digitalis (ten drops) and ammonium carbonate (five grains) or occasionally in very noisy subjects, where morphia (one-fourth of a grain) and atropine one one-hundredth of a grain) were administered hypodermically, at night.

The study of the foregoing cases leads me to the following conclusions:

- (1) That the clinical phenomena attending excesses in the use of alcohol are the direct result of overstimulation, and are not due to the abrupt withdrawal of the stimulus.
- (2) That though ability to swallow and retain stimulants is frequently wanting, the desire for them almost uniformly persists.
- (3) That alcohol in any form or quantity is unnecessary in the treatment of such cases and is usually hurtful.
- (4) That the absolute and immediate withdrawal of alcohol is of the first importance in the treatment of all the symptoms due to its excessive use, even in cases characterized by great feebleness and inability to partake of food.
- (5) That forced feeding is rarely necessary, and is of doubtful utility in most cases.
- (6) That for the protection of the patient no kind of bonds is called for, and, when necessary for the protection of others or for the contents of the room, they injuriously affect the mental state of the patient.

DR. G. M. GARLAND: I would like to ask if vomiting of blood is at all frequent in alcoholism. I have had two cases in my own practice where vomiting of large quantities of blood occurred, and in one case with fatal result. The fatal case was a young man of about twenty-five years of age and of superb physique. He

had been on a debauch for four or five days. He endeavored to stop on a Saturday forenoon and at eleven that night began to vomit blood. He died at ten o'clock the next forenoon. The autopsy revealed no lesion in the alimentary tract.

DR. T. S. LATIMER: I have observed vomiting of blood in but one case, and that was obviously from the throat from retching.

DR. WILLIAM OSLER: Such a case occurred in my practice in Philadelphia. A man who had been on a prolonged debauch had eaten heavily and taken a great deal of stimulant at his club-house. On his return to his home, at 1.30, he was taken with severe vomiting and hemorrhage of the stomach, from which he died before eight in the morning. I would like to ask Dr. Garland if there was any evidence of liver or portal engorgement in his case, and if the esophageal veins were engorged.

DR. G. M. GARLAND: I do not know about the esophageal veins. Nothing was found in the abdomen.

PRACTICAL RESULTS OF BACTERIOLOGICAL RESEARCHES,

by DR. GEO. M. STERNBERG, Lieutenant-Colonel and Surgeon, U. S. A.

Science does not demand practical results, but investigates for the purpose of establishing facts and explaining phenomena; but medicine is eminently practical in its aims, and practising physicians, as well as intelligent laymen, meet every announcement of a new discovery in pathology with the question, "Does it aid in the care of disease?"

Heretofore, the bacteriologist has been compelled to admit that the discovery of the specific cause in a considerable number of infectious diseases has not resulted in the discovery of a specific treatment for these diseases. But recently experimental evidence has been obtained which gives us reason to believe that in a number of infectious diseases, at least, the toxic bacterial products, which give rise to the morbid phenomena characterizing these diseases, may be neutralized in the infected individuals by the administration of anti-toxines, obtained from the blood of immune animals.

The practical results of bacteriological researches in the field of preventive medicine are also briefly referred to.

The establishment of aseptic surgery on a scientific basis also depends on bacteriological researches relating to the pyogenic micrococci commonly concerned in wound infection. And the treatment of localized infectious processes, when these are accessible to local treatment, has been favorably influenced by the exact knowledge relating to antisепtic and germicidal agents obtained by the researches of bacteriologists.

Reference is made to the recent experimental evidence relating to anti-toxines in the blood of animals which have an acquired immunity against virulent cultures of the bacillus of tetanus, the micrococcus of croupous pneumonia, the bacillus of diphtheria, the bacillus of tuberculosis, and against the virus of rabies; also to the recent experiments of Ehrlich, showing that animals may acquire an immunity against the pathogenic action of certain vegetable toxalbumins—*seria* from the castor-oil bean, and *seria* from the jequirity bean.

Finally, an account is given of experiments recently

made by Dr. Sternberg, in Brooklyn, which show that the blood of a calf which has been vaccinated, and consequently is immune against vaccinia, contains a substance which neutralizes the specific virulence of vaccine lymph, either bovine or humanized.

Dr. Sternberg closes his paper by stating that it is his intention to follow up this line of investigation, and to endeavor to isolate the anti-toxine of vaccinia; also to test the question of its possible specific action in neutralizing the small-pox virus in infected individuals before or after the development of the disease.

DR. W. H. WELCH: The most striking results which have been obtained by the application of this method (the use of anti-toxines) are those reported by Italian observers. These reports are open to some doubt. Dr. Kitasato has expressed a great deal of scepticism. He considers, as do other authorities in Berlin, that no positive results have been obtained in the application of the method to human beings. The final experimental results reported by Dr. Sternberg are very interesting, and I congratulate him on his interesting communication.

DR. F. P. KINNICUTT: It is difficult to judge in regard to the reported results of these cases from Italy. The last case, the sixth one, is the fullest and perhaps the most convincing of the reports that have been published. It was a well-developed case of tetanus. The urine on the evening before the inoculation or injection of the anti-toxine of tetanus was injected into a series of five or six guinea-pigs and mice. In all it is claimed that death followed in twenty-four hours with well-marked symptoms of tetanus. On the third day after the injection of twenty-five centigrammes of the anti-toxine, the urine when injected into a series of animals was absolutely without result. The blood also was injected before and after the treatment with the tetanus anti-toxine. Those animals inoculated before, are all claimed to have developed tetanus and died within twenty-four or thirty-six hours. Those inoculated three days afterwards with blood from the same patient, who had shown most marked symptoms of improvement, produced no effect.

Some tetanus anti-toxine is being prepared in the pathological laboratory of the College of Physicians and Surgeons, in New York, and a few of us are very much interested in securing cases of tetanus in which to use it.

DR. V. C. VAUGHAN: I wish to express my high appreciation of Dr. Sternberg's paper, and especially of his own experimental work with regard to vaccine. Of course the number of experiments is too limited yet for positive conclusions to be drawn.

There are many ways in which immunity can be secured, and we must distinguish between producing an immunity and curing the disease. There is no evidence that the two are the same although the Klemperers try to make it appear so in their work. I think the action of Koch's tuberculin should make us a little slow about accepting and drawing positive conclusions from experimental work. Experimental immunity and experimental cure is one thing, and cure in man is another thing.

DR. HENRY M. LYMAN: The results of laboratory experiments have been rather discouraging as showing the transient character of much of the immunity obtained by the inoculations alluded to. Vaccination against small-pox seems to be almost the only case where permanence of immunity is secured.

G. M. STERNBERG: I did not purpose to say that it had been absolutely demonstrated that tetanus could be cured by anti-toxine; I merely reported the cases. Why Dr. Kitasato should be so very conservative about the results obtained upon man when they correspond so entirely with the results which he and others have obtained on the lower animals, I do not understand. I think that the future of scientific medicine is in this direction, and that we have entered upon a field that is to be cultivated vigorously and which will give results that will knock conservatism from under our feet before many years.

I believe that there is something in the blood of the immune calf that neutralizes the vaccine virus. This rests upon very few experiments, but these are so satisfactory and decided that I am thoroughly convinced that I shall get similar results on repeating them.

THE TREATMENT OF EXPERIMENTAL TUBERCULOSIS BY KOCH'S TUBERCULIN, HUNTER'S MODIFICATIONS, AND OTHER PRODUCTS OF THE TUBERCLE BACILLUS.

by E. L. TRUDEAU, Saranac Lake. (Read by W. H. Welch).

The present research has been undertaken with a view to obtaining some more definite evidence,—first, as to the curative effect said to be exercised by Koch's tuberculin over inoculated guinea-pigs; second, as to the curative value and dangers in experimental tuberculosis of the modifications of tuberculin prepared by Hunter.

As the result of carefully conducted experiments with Koch's tuberculin upon guinea-pigs, the details of which are given, Dr. Trudeau has concluded that injections of tuberculin exercise a marked remedial influence on the tubercular lesions of the guinea-pig, and can cure the primary one. But contrary to Koch's belief, they cannot "protect the tissues from further invasions of the germs." For infection in these animals may spread from one point to another, even while a cure of the primary lesions is being effected by the treatment.

Koch, from the first, has insisted that the curative substances are inseparable from those that produce fever and local reaction. Klebs, on the other hand, asserts that he has produced from tuberculin a material entirely free from fever-producing or dangerous effects, capable of destroying the tubercle bacillus in the living bodies of men and animals, and of curing the disease. As yet, however, he has furnished no evidence which can be subjected by others to scientific tests.

Hunter, in a recent communication on the chemical constituents of tuberculin, gives the results which he has attained in producing a modified form of this substance, in terms so clear and concise as to invite other investigators to test his conclusions. As a result of his research, he proposes two modifications which he designates merely as B. and C. B., both of which bring about in lupus certain reparative changes tending to cure but unaccompanied by fever, and each varying greatly in the degree and intensity of the local reaction it produces.

Dr. Trudeau found no difficulty in the manufacture of Hunter's two modifications, and conducted experiments in the same way as in his experiments with tuberculin. From the evidence obtained the following conclusions seem justified: (1) In Hunter's modifications the curative principle of tuberculin has been

retained. This is especially true of modification B. (2) The fever-producing elements have been to a certain extent eliminated, but C B. may favor, rather than hinder, the tendency to generalization. (3) Modification B. is as efficient and safer than either C. B. or crude tuberculin. Thus far Dr. Trudeau's clinical experience with modification B. has confirmed this conclusion.

Experiments were also made with the object of proving whether the remedial principle of tuberculin is to be sought in the bacilli themselves, or in the culture medium in which they have grown. The liquid cultures of the tubercle bacillus were filtered through hardened filter paper. To this filtrate one per cent. of carbolic acid was added to preserve it and it was then ready for use. This fluid contains all the soluble albumoses and toxines, but no bacterio-protein, and nothing which may have been extracted from the bacilli by heat, as in the manipulation for producing Koch's tuberculin.

Bacterio-protein solution was obtained from the mass of bacilli left on the filter paper by the process described in detail.

With these two solutions several sets of tubercular guinea-pigs were treated. Another method of experimentation carried out, was the inoculation of rabbits in the anterior chamber of the eye according to the plan proposed by Cohuheim and Salamonsen and adopted by Baumgarten for the study of tuberculosis.

The conclusions derived from these experiments are:

(1) Solution of bacterio-protein obtained as described, from well washed bacilli have a doubtful, and at best, feeble remedial influence on experimental tuberculosis. (2) They produce suppuration and serious constitutional impairment, which may result in organic disease and death.

(3) The liquid culture medium in which tubercle bacilli have developed, but from which they have been removed by filtration, contains the elements which bring about reaction, and cure, in tubercular tissue.

(4) Experimental tuberculosis in the rabbit's eye can be cured by injections of the filtered culture medium.

(5) The permanancy of such a cure has not yet been established.

DR. KINICUTT: This is one of the most valuable contributions that has yet been made to the subject of Koch's discovery. Dr. Trudeau has certainly made a new departure. The last time when he was in New York, it was agreed that he experimentally, and I clinically, should undertake investigations with the modifications of tuberculin that had been proposed by Dr. Hunter. The preparations were made for both of us in the laboratory of the College of Physicians and Surgeons, and they consisted of the preparations B. and C. B. Since that time, purposely no communication has passed between Dr. Trudeau and myself in regard to the results of our work. We preferred to test individually the correctness or incorrectness of Dr. Hunter's observations and then compare our results and this is the first communication that I have received in regard to Dr. Trudeau's results. As they are entirely experimental it may be interesting to hear what results I have obtained clinically from the use of the same modifications.

The first proposition which Dr. Trudeau inserts in his conclusions is, that Koch's tuberculin does not cure experimental tuberculosis in guinea-pigs, although its specific influence on the primary lesion is indisputable.

My clinical experience of eighteen months has convinced me that tuberculin does contain a remedial principle; that tuberculin is a complex substance and the remedial principle is associated with other substances which are harmful in their nature.

His second proposition is that Hunter's modification C. B. contains less of the remedial preparation than tuberculin and is apparently quite as dangerous.

That same conclusion has been reached by me from clinical study. It not only seems to have less remedial principle but it is a dangerous modification to use. In a single case in my wards in which it was used, after an injection of eight milligrammes was given, an acute apex catarrh was developed which ran a favorable course and terminated at the end of the tenth day. It followed very certainly in consequence of this C. B. preparation.

The third proposition of Dr. Trudeau is that Hunter's modification B. is as efficacious as tuberculin and free from some of its bad effects.

That, too, has been my clinical experience. Dr. Hunter claims that this modification B. is as nearly as possible a pure albumose, that it is free from the alkaloidal substances which he believes to be the harmful properties in the crude tuberculin. The clinical results that have been obtained are as follows: Seven cases of well-marked pulmonary tuberculosis were very critically examined before and throughout their treatment. In two of the cases there has been no appreciable difference in the physical signs of disease during the two or three months that they have been under treatment; although there has been an appreciable difference in the physical condition, which is improved somewhat. In one case the improvement is most marked. In a fourth case the improvement is distinct but not as marked. In the fifth and sixth cases the improvement (and by improvement I mean an improvement in physical signs of disease) has been most marked; and in the seventh case — and it is the only case that I have seen in a pretty large experience in pulmonary tuberculosis — there has positively been an arrest of the disease. The patient, after having presented signs of infiltration at the apex of one lung, anteriorly and posteriorly, with abundant subcrepitation and other signs, is to-day absolutely free from them, and with the exception of impaired resonance he goes out of the hospital as a case of arrested tuberculous disease of the lung.

While these studies are too small to enable us to express a positive opinion as to any specific action which this modification may possess on tuberculous lesions, they are large enough to demonstrate that the modification C. B. has apparently a specific beneficial effect.

In regard to the liquid culture medium — of that Dr. Trudeau alone can speak. It is quite a new departure and certainly the reports that he gives to us are most noteworthy, and it seems to me that in his work more than in that of any one else in this country, we are to look forward to what I believe is certainly to come, that is, a specific remedial treatment of tuberculosis.

It may be interesting to the members of the Association to know that Dr. Trudeau has made some experimental investigations in regard to the alleged specific effect of croesote in experimental tuberculosis. His experiments have not been published but he has very kindly given them to me to publish in connection with some work of my own in this direction.

The summary of his experimental work was, that creosote given in the largest possible dose in guinea-pigs, had absolutely no effect either in controlling the development of experimental tuberculosis or in arresting its progress.

DR. W. H. WELCH: Dr. Trudeau, if here, would doubtless express his gratification with the similarity of Dr. Kinnicutt's results with his own. It seems to me a most gratifying turn in this subject, that it has passed out of newspaper notoriety, and we are getting down now to what we should have had in the beginning,—quiet laboratory work. There is every reason to expect results of practical importance.

Those who are familiar with the literature of the subject know that it has been recently claimed that it is exactly the bacterio-protein that possesses the curative action. Dr. Trudeau has shattered that view conclusively. This is a very gratifying result. It began to look as if the peculiar properties of the tuberculin were not due to the growth of the tubercle bacillus at all but were due to the growth of all sorts of bacilli.

As Dr. Kinnicutt has said, it is impossible to say anything in the way of criticism with regard to the experiments with liquid culture media.

(To be continued.)

MASSACHUSETTS MEDICAL SOCIETY.

THE One Hundred and Eleventh Annual Meeting was held in Boston June 8, 1892, the President, Dr. AMOS H. JOHNSON in the chair.

The report of the Treasurer showed that during the year the total receipts had been \$12,318.63. There is a balance in the treasury of \$10,456.98. The total funds of the Society now amount to \$68,701.

The committee on the subject of making permanent provisions for chronic epileptics reported that the matter had been brought to the attention of the Legislature, but owing to the fact that the subject of an institution for the chronic insane had taken precedence, the committee thought it would be well to defer action for another year. The subject was therefore recommitted to the committee.

DR. F. H. DREW read a paper on

AN OUTBREAK OF TRICHINOSIS IN CLOVERDALE.

Short papers on the subject of trichinosis were read by DR. C. W. MACDONALD and J. H. McCOLLUM.

DRS. H. L. BURRELL and E. W. DWIGHT presented a paper on

THE TREATMENT OF COMPOUND FRACTURES BY MODERN METHODS.

Appliances were shown and patients presented.

DR. S. W. ABBOTT read a paper on

THE REVISION OF THE MEDICAL NOMENCLATURE EMPLOYED IN THE VITAL STATISTICS OF MASSACHUSETTS.

The following resolution was presented and adopted :

That a committee of three be appointed by the President, to report at the next annual meeting of the Society, upon the question whether any changes are necessary in the classification and nomenclature employed in the vital statistics of Massachusetts, the same committee also to report what changes should be made, if any.

The President appointed Drs. C. F. Folsom, S. W. Abbott and F. W. Draper.

THE ANNUAL ORATION¹

was delivered by DR. F. W. DRAPER, of Boston.

The President then introduced the President-elect, DR. J. C. WHITE, of Boston.

THE ANNUAL DINNER

was served at one o'clock, there being about eight hundred Fellows present.

At the close of the dinner, the Anniversary Chairman, DR. E. H. BRADFORD, spoke as follows :

The task of welcome is never a difficult one; it is certainly not so to-day, at this anniversary meeting of our Society.

If there is truth in the old Latin saying, that there is no solitude like the absence of friends, surely there can be no festival like their company. If fellowship and organization give strength to all human institutions, and friendship is the cement of societies, our annual dinner needs no justification or explanation.

We meet each year in obedience to an old and worthy custom, hoping to place ourselves under the influence of collected ideas in the current of fresh thought, seeking the mental stimulus for the coming year. Each time has its new suggestions and problems. The causation and the effects of influenza; the nomenclature of disease; the importance of bacteriological investigations; the value of various surgical interventions; the valuable work in the prevention of disease done by our State Board of Health; the improved methods in the study and teaching of pharmacy and of the sciences of ventilation and drainage; the chemical investigations of air and water; the relation of applied chemistry to cooking,—all these topics have been especially brought to our attention this year, and their importance and value demonstrated.

But now, before we separate, we come together in the character of Fellows, to meet old friends and make new ones, to exchange congratulations for the health and welfare of those we meet of our organizations, and to extend a hearty welcome to our honored guests.

The first sentiment at our annual meeting is one of loyalty to our Society, an organization that has a worthy history and a valuable influence. To-day I have the privilege of presenting to you our new leader, one whom we honor and trust, President White.

DR. J. C. WHITE spoke of the great advances made in medical education since he became a teacher, in 1858. The Harvard Medical School then offered as good opportunities for medical instruction as were to be found anywhere in the country, yet there were only six desks in the school for laboratory work in chemistry, while now there are two spacious laboratories provided. Anatomy was then taught during only four months in the year, and even a part of that time was taken up with physiology, while now the anatomical course covers two years, and a year is devoted to physiology.

Then only a fugitive glance was given to histology, while now there is a laboratory for its study, and embryology is also taught; then a small room in the Massachusetts General Hospital was the only place where autopsies could be seen, now there are two hospitals with amphitheatres specially provided for students.

A new department of bacteriology has been estab-

¹ See page 555 of the Journal.

lished. In the clinical branches there are twenty teachers instead of two or three. Midwifery was then studied by books and lectures, while now a student is required to take charge of at least six cases before he graduates.

To this list of studies ten or more special departments have been added, and the term of study has been extended to four full years. He had no doubt that this advance would exert an important influence, not only in this city, but in other large cities as well.

As our Society owes its charter to the Commonwealth, so we are never to forget our duty as citizens. We are honored to-day, not by the presence of His Excellency, the Governor, who was prevented by the press of official work from joining us, but by his worthy representative, the Surgeon-General of the State, Dr. Kittredge.

The SURGEON-GENERAL, in responding for the State, brought the cordial greeting of the Governor, who was not able to be present on account of the press of official business. He then spoke of the military service of the State, and outlined a proposed extension of the usefulness of the medical staff. The service is of great value to the young practitioner who enters it, teaching him obedience, promptness, activity and other things useful to him in his profession. There have been two ambulance corps established of fifteen men each, one stationed in Lowell and the other in Boston. The corps are to be enlarged to fifty men, and placed at the service of the community at large. The men are trained to render first aid in case of accidents, and are equipped with all needed appliances. The address of every officer and man will be registered, and in case of a railroad accident or other disaster this trained corps can be dispatched at once to the scene to afford immediate help.

It has been said that republics are ungrateful, and that we Americans should do well to kill off our ex-presidents. Perhaps there may be truth in this, but the Massachusetts Medical Society is organized not to kill but to cure, and we all are united and banded to secure health and welfare for our retiring president, Dr. Johnson.

DR. AMOS H. JOHNSON reviewed briefly the changes which have taken place in medical practice since the foundation of the Society, one hundred and eleven years ago; the abandonment of old methods, the era of therapeutic scepticism, and the advantages and disadvantages of modern pharmacy. This Society has taken an active part in the advance of medical science, and has counted among its members several men who have contributed much to medicine.

In introducing our next speaker, I am reminded of an anecdote. Two Boston girls were talking, and one asked the other what kind of a doctor her father was, a homeopath or an allopath. "Oh, he is not that kind of a doctor: he is another kind of a doctor; he is a mugwump."

I have pleasure in introducing to you the original mugwump, Dr. Wm. Everett.¹

The medicine-man was once both a priest and a doctor. I, myself, have met a worthy gentleman who united in his own person at the same time the duties

and responsibilities of both the homeopathic physician of the village and the pastor of the village church. I did not learn whether his theology was homeopathic. We members of the Massachusetts Medical Society are more modest, we are glad to accord honor and welcome to the chaplain of the day, Rev. John Cuckson.

REV. JOHN CUCKSON spoke of the intimate relations existing between physicians and the clergy. Ignorant people should be protected from their own ignorance in medical matters by the State, which should see to it that any one professing to practice medicine is properly qualified.

We all of us respect lawyers, and fear them, when they put us upon the witness-stand and ask us questions in obscure anatomy and of the hypothetical case. You all remember the utterance of one of our honored and gifted members,

"Strong is the moral blister that will draw,
Laid on the conscience of the man of law."

That this is not true we shall learn from the Hon. Fred. Greenhalge.

HON. FREDERICK GREENHALGE, in speaking for the legal profession, entertained the Society with the humorous relations of the two professions. Seriously the medical profession is making advances on every hand. This great Society has a vital function, for it stands as a helper and sponsor for patient labor and investigation, and for the highest professional honor among physicians.

Two years ago the eyes of the medical world were "turned to Berlin." Delegates from all over the world went there, and addresses were made by great leaders in their departments. Billroth, in his address on surgery, referred to one American who had been foremost as a surgeon. We are fortunate in the presence of this surgeon, whose skill and achievements you all know, Dr. William T. Bull.

DR. WILLIAM T. BULL said that he had received his first inspirations in surgery, while an undergraduate in Harvard College, by watching the surgeons of the two Boston Hospitals. There have been established in Massachusetts, with the aid of the Society, some institutions which are superior to anything of the kind in New York. The coroner has been abolished, and his duties placed in the hands of men eminently qualified to discharge them; one of the best medical libraries in the country has been built up, and with it is combined a registry for nurses, which does much to lighten the labor of the physician; the Boston training-schools for nurses have taken a lead, which has made it necessary for New York on several occasions to send to Boston for assistance in founding a school. The requirement of four years in medical study is a movement forward which is being contemplated by Columbia College.

Dr. Holmes once said that performing an autopsy was like inspecting the remains of a fire-work the day after the Fourth of July. One of our honored guests has mastered this subject, and is now ready to speak of the Fourth of July itself, and of the day before. I take pleasure in presenting to you the new Professor of the Theory and Practice of Medicine, Dr. Fitz.²

MASSACHUSETTS MEDICAL SOCIETY.
SUFFOLK DISTRICT.
SECTION IN OBSTETRICS AND GYNECOLOGY.

DR. GEORGE HAYEN, SECRETARY.

REGULAR Meeting, Wednesday, March 9, 1892,
DR. C. M. GREEN in the chair.

DR. GERTRUDE VAN PELT reported

A CASE OF PURULENT SALPINGITIS.¹

DR. LENA V. INGRAHAM: I have been very much interested in the case. I was present at the operation. I think the specimen does not give an idea of the amount of pus which was present. The sac was so adherent that it seemed probable that some of it was left. I should think fully a pint of very thick pus flowed out over the abdominal wound. We found two small abscesses next to the lumen of the tube near the abdominal end of the tube. On close examination you will see that there are a great many abscesses and it seemed to me that it was possible that there had been a number of foci of inflammation in the ovary from which a number of abscesses started and that the walls of some had broken down and become two or more large abscesses with some smaller ones whose walls are still intact.

DR. BURRAGE read a paper on

THE ELECTRICAL TREATMENT OF PELVIC INFLAMMATION.²

DR. HARE: Personally, I am a strong believer in electricity in these cases. I have had the privilege of seeing many cases, and I have hardly ever failed to see them improve. I have had this winter two cases which were very interesting to me. One was the case of a woman forty years of age, who had an operation upon the cervix and for the cure of hemorrhoids, in May, 1890, and after that was never as well as before—was completely incapacitated from pursuing anything pleasurable in life. The first time I saw her she had on the right side a tube which could be readily felt, the ovary being about double its size and adherent. She had galvanism, in all, eight applications, after which the tenderness which at first was so much as to make examination very painful, had entirely gone and there was nothing whatever to be felt.

The second case dated from a year ago last November, at which time there was an attack of pelvic trouble on the left side which kept her in bed four months, and after getting up she never recovered to the extent that she could walk more than an eighth of a mile without resting and having severe pain. There was a mass on the left side, the size of a small lemon. She had the same treatment for about three months. She has gone home and nothing can be felt. There is no tenderness, and she walks one-half an hour to an hour without any pain whatever.

DR. REYNOLDS: I am very glad that this subject should have been brought up, not only because it is one in which I have been for some time interested, but because it seems to me strange and a reproach to Boston that so powerful a therapeutic agent, and one which is in such general use all over the world, should have been as much neglected as I think it has been here. Personally, I have grown to believe it the most powerful of all the conservative minor gynaecological methods. I think we notice at once, in Dr. Burrage's

paper, what has seemed to me to be characteristic of the writings of all the authorities who advocate the use of electricity in gynecology: careful statements of dosage and of the different therapeutic effects of the different currents, and I think it will be noticed that those who have failed to obtain good results with electricity generally speak of it as electricity *per se*. Considering that there are six to eight different actions of the current, according as it is used, it is evident why one should have good results and another not.

In one particular my experience has differed a little from that of the reader and that is in preferring to use the positive pole in the vagina on account of its being less painful. There is no doubt that the positive pole is sedative, is less painful than the negative, but upon the other hand, the skin of the abdominal wall is more sensitive than the vagina, and it has been my experience that patients complain much more of pain when the positive pole is used internally, that is, when the painful negative pole is external. I prefer to use the negative current internally throughout unless the patient is somewhat profuse at her menstrual periods, or is otherwise losing blood. The effect of the negative current in increasing the flow of blood is as marked as that of the positive in decreasing it. If she is losing too much blood we must use the positive pole; otherwise I prefer the negative. I think a further distinction in the use of the current than I understood the reader to draw is to be made; it is in the careful distinction between the galvanic current of high tension and that of low. So far as I know that distinction has only been emphasized by Englemann. Personally I think it is an important one. I believe use of the current of high tension concentrates the action of the electrical force on the tissues in immediate apposition to the electrode and the use of the current of low tension tends to disseminate it toward more distant tissues. For that reason where we use it for the dispersion of exudates I think it is important to work without a rheostat with large cells with small internal resistance, and to use every effort to decrease the resistance of the patient's body. I have been accustomed to use for an abdominal electrode what I think I very much prefer to the clay—that is the large woven-wire electrodes of Waitt and Bartlett covered by absorbent cotton and wet in warm water. It is not dirty, you can use a fresh surface for each patient, and as far as low resistance goes, I find that with these electrodes I can get a current of from 30 to 40 milliamperes with six or seven bichromate cells.

I think it is important to distinguish in the character of the electrodes used. It is a matter of the most ordinary observation that a metallic electrode cauterizes the surface extensively, while a moist non-metallic pole does not cauterize. I believe that where the metallic electrode is used and extensive cauterizing effect is produced there is far less intrapolar effect on the more distant tissues. That point also was first made I think by Englemann and so far as one can judge from clinical experience I believe it is a strong point. The use of the non-metallic electrode within the uterus presents difficulties. The introduction is difficult except in a pretty patulous uterus, and I have not infrequently been compelled to use the metallic one because I could not without pain and bleeding introduce the cotton-wrapped applicator. Where that can be introduced I think it is of much more value for electrolysis. In vaginal applications there can be no question that the

¹ See page 603 of the Journal.

² See page 600 of the Journal.

cotton-wrapped applicators which Dr. Burrage recommended are preferable.

I think a good deal can often be gained by preceding the galvanic current by the faradic current of high tension for from one to two minutes using a very fine, long coil. That has seemed to me to very much lessen the pain and somewhat lessen the fatigue which often follows these applications, and in that connection I should like to emphasize my belief in what I do not hear Dr. Burrage refer to, the importance of making the patient lie down a considerable length of time after each application of the current. Most patients are considerably tired after the treatment. If they get up out of the chair and at once go home I think they are apt to feel badly worn out the rest of the day and often longer, to feel disgusted with the treatment and not get as much good from it. But if they rest for 15 to 20 minutes after the application they are apt to miss all that tired feeling, to feel, if anything, better through the day, come back with great readiness, and be benefited much more by the treatment.

It is going a little outside of the subject of the paper, but before sitting down I want to add to the general subject of electrical treatment my belief that the galvanic current furnishes by far the best method of treating endometritis and endocervicitis. The application of tincture of iodine, carbolic acid, etc., is very disappointing, and their intra-uterine use not altogether free from danger. There is always the bugbear of driving fluid into the tubes. That won't happen with the electrode. They are unsatisfactory also because the only surface that is opposed to their action is that of the superficial portion of the uterine mucous membrane. The crypts in which the inflammation lurks and which are the source of its resupply are not affected by these chemical agents. When the electrode is passed into the uterus it affects all the surfaces with which the intra-uterine secretions are in contact, by simple electrical conduction. It affects the bottom of the crypts about as much as the uterine surface between them. That is the theoretical ground for believing in its superior efficacy and practically it seems to me a much more satisfactory and hopeful method of treating these inflammations. It is outside of the paper to speak of the faradic current of low tension in subinvolution of the uterus and laxity of the ligaments, etc., but that I believe also to be of much importance.

DR. VAN PELT: I am very much interested in this discussion because I have used this treatment considerably. I spent three winters with Dr. Apostoli, and have treated a number of cases at home. I believe very thoroughly in the application, and have had a great deal of success, I think, in cases that have not been benefited by the ordinary applications. I have not found the same difficulty in using the positive pole that Dr. Reynolds speaks of, and I have thought possibly it is because I use the clay electrode. The patients do not complain of pain over the abdomen. There is a point in connection with the electrodes that I would like to ask Dr. Burrage about, that is, the value of the clay on the outside of the vaginal electrode. I do not understand it.

DR. BURRAGE: I think it is supposed to spread out the current better than absorbent cotton and prevent injury to the vagina. It is a little bit dirty, but if the clay is included in absorbent cotton and then in the gauze, there is not very much chance of its coming

out. I dip the electrode into boiling water each time before applying, and it certainly acts better than coverings of absorbent cotton alone or chamois skin which I used before. With a current of 30 milliamperes I have made a very considerable ulcer in the vagina on several occasions, using a chamois skin covered electrode.

DR. REYNOLDS: I should like to state that for nearly two years I used the clay vaginal electrode prepared as Dr. Burrage has described, but for the last year I have used the cotton. The cotton is cleaner, its action has seemed to me to be in every way as satisfactory, and I have never made an eschar with it, though I once did with the clay.

DR. BURRAGE: In reference to the point Dr. Reynolds brought up about using the positive pole in the vagina, I have found also that it does cause pain in the abdomen if you use the wire-gauze electrode of Waite and Bartlett. I have used that electrode a great deal but with low intensities. With the higher intensities I have been unable to use it because of the irritation of the skin of the abdomen. With the clay I have not found that there is any increase in the amount of pain complained of when using the positive pole.

In reference to the rheostat, I like it better than the collector, although I have used both. There is next to no danger of getting a shock with the rheostat or current controller, and with the collector there is some danger. Now and then one of the cells happens not to be working properly, and as the lever passes over that one there is a shock.

As regards the faradic current preceding the treatment I have not used it in that way, but I have often used it after the treatment to allay pain, and have found it of great service.

As to the matter of patients lying down, at a large out-patient clinic it is a difficult matter to bring about unless you have very commodious quarters. Patients are directed to sit down and rest awhile, but as a rule I think they wait very little. At my office I have them lie down. If they are sensitive I have them wait an hour or two before going away, particularly after the first few treatments.

Recent Literature.

A System of Gynecology. Based upon a translation from the French of SAMUEL POZZI. Revised by CURTIS M. BERKE, M.D., Chicago, Ill. New York: J. B. Flint & Co. 1892.

The value of the original work of Pozzi is attested by the fact that two translations of it should have appeared within a few months of each other. The present one, unfortunately, suffers by comparison with the one edited by Dr. Wells, inasmuch as it is not complete, either in respect to the text or the illustrations. We have no doubt that the most important parts have been retained, still it hardly seems fair to call this Pozzi's System of Gynecology, and by no word of preface to intimate that it is not given entire. The only possible ground on which it can command itself to the profession is that it is somewhat cheaper than the superb two volume edition which we have reviewed earlier.

283 WASHINGTON STREET, BOSTON, MASS.

THE AMERICAN MEDICAL ASSOCIATION.

THE forty-third annual meeting of the American Medical Association, held at Detroit last week, was as usual largely attended. About eleven hundred doctors from all parts of the country were on hand, and the hotel accommodations of Detroit were taxed to their utmost capacity. The extremely cordial injunction of Gen. R. A. Alger — lately a "dark horse" at Minneapolis — who, paraphrasing the hospitable Spaniards, in his address of welcome, said, "If any of the medical guests did not see what he wanted, he had only to send for it, and if he did see what he wanted, he was to take it," was of little comfort to the late comer.

The city of Detroit is charmingly situated, and everything was done by its inhabitants to make the time which could be taken from the business of the occasion pass pleasantly. Good weather, however, may be desired and deserved, but cannot be had to order. A succession of heavy showers and the mugginess of August are not conducive to activity, and are not what one counts upon in June. Notwithstanding this unexpected drawback, the fact that this was the third time the Association had met in Detroit indicates the favorable regard which its members have for that city.

The President, Dr. H. O. Marcy, addressed the Association upon "Evolution in Medicine." He referred in a spirit of liberality to schisms in medicine, and deprecated any manifestation of jealousy between the national medical societies of this great country. There is room for all the work which they all may desire to undertake. The evil of intemperance and the scourge of consumption were touched upon. The establishment of a national board of health with representation in the cabinet by a secretary of public health, was advocated. Reform in coroner's laws was recommended, and supervision of food supplies and civic hygiene were strongly urged. The relation of the Association to the medical profession in foreign countries received attention, and hearty co-operation in international congresses was suggested.

In General Session provision was made for the election from the Sections of a General Business Committee to facilitate the transaction of the Association's affairs and to minimize the loss of time in general debate. The duty of the General Business Committee will be to give especial attention to the interests of the Association, and to promote the welfare of the various Sections; to consider all matters of business referred to it by the Association, and report upon them at the earliest possible moment, when the Association may adopt or reject the report as it may deem best.

On the second day, in General Sessions, the meeting was convulsed by a report of the Judicial Council, declaring that Dr. W. W. Potter, of Buffalo, was ineligible as a member of the Board of Trustees on account of his connection with the New York State Medical Society. This is the outgrowth of the old trouble about the Code. A wordy rumpus arose, but what threatened for a time serious trouble was finally shelved by reference of the whole subject to a committee of five which is to confer with committees of the same number from the New York State Society and Association.

The address on Surgery was by Dr. J. B. Hamilton, on the General Principles of the Surgery of the Brain; and the address on General Medicine by Dr. A. L. Gihon, U. S. N., on Intellectual Progress in Medicine.

The Association wisely avoided Chicago, and selected Milwaukee as the next place of meeting.

THE FOUR-YEARS' COURSE AT THE HARVARD MEDICAL SCHOOL.

SOMETHING more than a year ago it was announced that the faculty of the Harvard Medical School had taken the important step of increasing the compulsory course of study from three years to four. Editorial reference was made in the JOURNAL, May 28, 1891, to this change and to similar proposals which were then under consideration by the medical faculties of the University of Pennsylvania and of Columbia College. At that time the details of the new course at Harvard had not yet been arranged.

The change goes into actual operation in September of this year. A provisional announcement of the graded four-years' course of instruction, applicable to students entering the first class at that time, has now been issued.

General chemistry will be a requirement for admission on and after June, 1893. Medical Chemistry alone will be taught in the School. Students conditioned in general chemistry at the examination for admission will be furnished, in the School, during the first year, with opportunities for making up this condition.

Applicants for admission to the Medical School who shall have studied three years in recognized colleges technical or scientific schools, in which courses in anatomy, physiology, histology, and general chemistry

are a part of the instruction, may be admitted to advanced standing provided they pass an examination in these subjects.

The Lawrence Scientific School at Cambridge has established a course in anatomy, physiology, and hygiene, the first two years of which are approved as a preparation for the four-years' graded course in medicine now offered.

In the fourth year, in addition to the regular work of the year, not less than three hours of examination in electives are obligatory. Students intending to elect dermatology, neurology, or gynecology in the fourth year need not pass an examination in these subjects at the end of the third year, provided their choice is made at the beginning of the second half of the third year. Students electing ophthalmology, otology, or orthopedics in the fourth year are obliged to pass only the two-hours' examination in these subjects at the end of the year. Only one hour of these two can count as an elective. Candidates for the degree who shall have served satisfactorily as internes in the Massachusetts General Hospital, Boston City Hospital, Carney Hospital, or Children's Hospital, for a period of not less than one year, may be exempt from examination in the electives of the fourth year.

The fees for the first three years remain as at present, two hundred dollars for each year, and the fee for the full year to all students entitled to be classified as fourth-year students will be one hundred dollars. These fees cover all school expenses, except a sum not exceeding \$10 for anatomical and chemical material.

At the end of the four years of study the degree of Doctor of Medicine will be given to those students who have fulfilled its requirements. This degree *cum laude* will be conferred upon candidates who have obtained an average of over seventy-five per cent. in all the required examinations.

Students who began their professional studies elsewhere may be admitted to advanced standing; but all persons who apply for admission to the advanced classes must pass an examination in the branches already pursued by the class to which they seek admission, and furnish a satisfactory certificate of time spent in medical studies. No student may advance with his class, or be admitted to advanced standing, until he has passed the required examinations in the studies of the previous year, or a majority of them; nor may he become a member of the third class, until he has passed all the examinations of the first, in addition to a majority of those of the second year; nor of the fourth class, until he has passed all of the examinations of the first and second, in addition to a majority of those of the third year.

Further explanations of the change are given on another page (Dr. Fitz's paper) of this issue. We do not doubt that the results, and those not remote, will justify the School in the courageous and unselfish forward step it has made in medical education, and that the lead which it has taken will be soon followed by other schools of the country.

MEDICAL NOTES.

OFFICERS OF THE AMERICAN MEDICAL ASSOCIATION FOR THE ENSUING YEAR. — President, Dr. Hunter McGuire, of Richmond, Va.; First Vice-President, Dr. H. O. Walker, of Detroit; Second Vice-President, Dr. H. Brown, of Kentucky; Third Vice-President, Dr. Henry Janes, of Vermont; Fourth Vice-President, Dr. Jesse Hawes, of Greeley, Col.; Treasurer, Dr. R. J. Dunglison, of Philadelphia; Secretary, Dr. W. B. Atkinson, of Philadelphia; Assistant Secretary, Dr. Montgomery; Librarian, Dr. George W. Webster, of Chicago. To fill vacancies on the Board of Trustees: Dr. Alonso Garcelon, of Lewiston, Me.; Dr. Leartus Connor, of Detroit; Dr. Perry H. Millard, of Minnesota, and Dr. Patterson, of Washington. Members of the Judicial Council: Dr. N. S. Davis, of Chicago; Dr. John Morris, of Baltimore; Dr. H. D. Didama, of New York State; Dr. John B. Roberts, of Philadelphia; Dr. A. M. Emmert, of Iowa; Dr. W. T. Briggs, of Nashville, Tenn.; Dr. C. W. Voorhees, of Coldwater, Mich.; Dr. W. E. B. Davis, of Rome, Ga.; Dr. A. Morgan Cartledge, of Louisville.

Section on Surgery and Anatomy. — The following were elected officers of this Section: Dr. James T. Jenks, of Hot Springs, Ark., Chairman; Dr. Ernest T. Tapley, of Detroit, Mich., Vice-chairman; Dr. Liston Montgomery, of Chicago, Secretary.

Section of General Medicine. — The officers chosen are as follows: Chairman, Dr. Charles Stockton, Buffalo, N. Y.; Secretary, Dr. Charles Webster, Chicago; Executive Committee, Drs. Hobart A. Hare, Philadelphia, Isaac Atkinson, Baltimore, and N. S. Davis, Jr., Chicago.

DRUNKENNESS AS A VIRTUE. — Dr. George Foy, in a letter to the *London Medical Press*, refers to a book published in London, in 1723, as tending to show that the habits of the general public have changed very much during the last century and a half. The title of this book is as follows: "Ebrietatis Encionium, or the Praise of Drunkenness; wherein is authentically and most evidently proved the necessity of frequently getting drunk; and that the practice of getting drunk is most ancient, primitive and catholic. Confirmed by the example of Heathens, Turks, Infidels, Primitive Christians, Saints, Popes, Bishops, Doctors, Philosophers, Poets, Freemasons and other men of learning in all ages. By Boniface Oinophilus de Monte Fiascone, A. B. C."

NEW ENGLAND.

DEATH-RATE IN BOSTON FOR MAY. — There were 895 deaths reported in May making the death-rate 23.39. The number of deaths reported as due to consumption was 129; diphtheria, 39; scarlet fever, 34; typhoid fever, 9; pneumonia, 105.

BOSTON ASYLUMS. — The Suffolk County Grand Jury have presented a report to the Judge of the Superior Court on the subject of some of the public

institutions of Boston. A committee of the jury visited the Insane Asylums at South Boston, Austin Farm and the Charlestown Almshouse. They found and commented upon the same bad conditions which have previously been noticed by the special committee appointed by the Mayor, an account of which has been published in a previous number of the JOURNAL.

THE CONVALESCENT HOME OF THE CHILDREN'S HOSPITAL. — The new Home at Wellesley Hills was dedicated on the 16th by the Rt. Rev. Phillips Brooks. A large number of persons interested in the Home were present at the ceremony.

THE MASSACHUSETTS REGISTRATION REPORT FOR 1891 will be edited by Dr. F. A. Harris. For several years these reports have been edited by the secretary of the State Board of Health.

CHRISTIAN SCIENCE IN BEVERLY. — A good deal of excitement appears to have been caused in Beverly, Mass., by the death of three children who were said to have been under the medical care of Christian Scientists. The first two were believed to have died of diphtheria; in the third case, a death certificate, in which the cause of death was given as heart-failure, was not accepted by the Board of Health. The Board has announced that hereafter heart-failure will not be accepted as a cause of death.

RABIES IN LYNN. — One of the men bitten by a dog supposed to be mad, an account of which appeared in the JOURNAL of May 19th, has died. A portion of the brain and spinal cord have been sent to the Harvard Medical School for examination.

THE MAINE MEDICAL ASSOCIATION met in Portland on June 9th. The following officers were elected: President, Dr. Alfred Mitchell of Brunswick; Secretary, Dr. Wm. Cammett, of Portland.

NEW YORK.

COLUMBIA COLLEGE. — At the one hundred and thirty-eighth annual commencement of Columbia College, held at the Carnegie Music Hall, June 8th, there were 116 graduates in the Medical Department. The biennial prize of \$500, of the alumni of the school, for the best essay embodying the results of original investigation, was awarded to Dr. Wm. Hallett Parke, of New York, and two \$500 annual fellowships, also provided by the Alumni Association, to Drs. Parke and Alexander Lambert.

Miscellany.

THERAPEUTIC NOTES.

ANTI-SEPTOL¹ (cinchonine iodosulphate) represents one of the various recent attempts to obtain an efficient substitute for iodiform without the objectionable features of the latter. It is odorless, and is made by the addition of a solution of iodine and iodide of potassium to sulphate of cinchonine. Its use is largely confined to continental Europe.

¹ Squibbs Ephemeris.

ANTINERVIN² was introduced into medicine a couple of years ago as being analytically salicylbromanilid, and similar in its effects to acetanilid. Its recommended efficiency in diabetes has not been verified, and we hear little of it professionally. From a careful examination, it is now concluded to consist of a mixture of 50 parts acetanilid, 25 parts salicylic acid, and 25 parts of bromide of ammonium.

Correspondence.

LETTER FROM DETROIT. AMERICAN MEDICAL ASSOCIATION MEETING.

DETROIT, June 11, 1892.

MR. EDITOR. — During the past week it has been impossible to walk the streets of Detroit without every moment running against a man with a lapel button bearing the cabalistic device, "A. M. A., '92, Detroit." There were delegates everywhere. The number registered was between one thousand and eleven hundred. Many were accompanied by their wives, so that the total number probably reached fifteen hundred. The quantity of literary material provided was simply overwhelming. There were three hundred and fifteen papers on the programme, so that every third man went to Detroit armed with a paper. In five of the sections the papers prepared for the election of the members ranged between forty and forty-seven, and in some of the sections nearly the entire number was read. The section on State Medicine enjoys the distinction of having had the least number, only eight titles appearing on the programme.

The arrangements for the meeting were all that could be desired. The committee had secured the Opera House for the general sessions and meeting-places for the sections were provided in close proximity. The stage of the Opera House had been handsomely decorated with palms, hydrangeas and other flowering plants, behind which sat ensconced the genial secretary, Dr. William B. Atkinson, who has every detail of the Association work at his fingers' ends.

The sections began their morning sessions at nine o'clock and continued until eleven o'clock, when they were expected to adjourn to meet in general session, but some of the sections seemed to take more interest in their scientific work than in the medico-political work of the Association, continuing their meetings long after the hour of adjournment. The afternoon sessions were held from three to six o'clock. Several of the sections had exhausted their programmes by Thursday evening, while others were still at work on Friday afternoon. The section meetings were well attended during the first few days, but many of the members started for home Thursday evening or Friday morning, so that the last day's sessions showed the presence of only the more enthusiastic or more conscientious members. An immense amount of work was accomplished, and the man who went to Detroit with the idea of having an easy time, made a mistake. The work began at nine A. M., and continued with little interruption until six P. M., and every other available hour was taken up with the meeting of delegations, committees and the like. Some confusion was caused by the variations in the time as shown by the different watches. The watches of the western men showed central time, while those of the eastern delegates showed eastern time an hour later, while the meetings were regulated by Detroit city time which was about half an hour faster than the one and half an hour slower than the other.

A very pleasant incident in connection with the opening exercises was the presentation to the president of the Association by Dr. H. O. Walker, of Detroit, of a gavel fashioned from the wood of the celebrated Pontiac tree.

Dr. Marcy won for himself distinction as a presiding

² Squibbs Ephemeris.

officer. There were times when the Association seemed in danger of being capsized through the ill-balanced efforts of some of the members. Most of the storms or more correctly speaking, whirlwinds, arose in connection with questions relating to the status of delegates from the New York State Medical Society. The first occasion was when the report of the Judicial Council was presented declaring that the New York State Medical Society and the Medical Society of Erie County, New York, were not entitled to representation in the Association. There then arose a great hubbub, motions and amendments were hurled at the president with bewildering confusion, while several gentlemen with stentorian lungs were trying to express their views on the subject. An attempt was made to have the report referred back to the council, but the president decided that the report of the council was final, and in this decision he was sustained by the vote of the Association. Later on in the session the question was asked as to the status of the permanent members of the Association who were also members of the Societies mentioned above. This gave rise to another effort to graft upon the Association methods that would do credit to a political ward meeting or to a convention for the nomination of a president. In the end a conclusion was reached which seemed to give universal satisfaction. This provided for a committee of conference consisting of members from the American Medical Association, the New York State Medical Society and the New York State Medical Association, this committee to report at the next annual meeting; to this was added the proviso that in the meantime the permanent members of the Association who were also members of the Societies in dispute, but who had registered in good faith, should be entitled to the rights of permanent members.

It was then thought that the matter was ended, but the next day one of the gentlemen who had advocated the passage of the resolutions put his foot in it by calling for their reading. It was then found that the names of certain gentlemen from New York had been incorporated in the proviso. These names had not been read when the resolution was presented and voted upon. This gave rise to some pretty positive remarks, in which the insertion of the names after the adoption of the resolution was characterized as falsification of the record. Dr. Gihon who had presented the proviso referred to, attempted to gain the floor to reply, and a personal discussion was only prevented by the President insisting that as the hour had arrived for the delivery of the Address on General Medicine, Dr. Gihon should take the floor and address the Association on the subject of *Medicine*.

The social features of the meeting were extremely enjoyable, every effort being made by the profession of Detroit to make the visitors feel that they were welcome. On Tuesday evening a reception was tendered the members of the Association and their ladies at the Light Infantry Armory by the profession of the city. This was well attended and thoroughly enjoyed. On Wednesday evening there were receptions at the residences of the Hon. H. S. Pingree, Mayor of Detroit, Gen. R. A. Alger, Mr. George S. Davis and Mr. Frederick K. Stearns. During the day the ladies were entertained with carriage rides around Belle Isle Park and with yacht rides on the river.

Thursday afternoon the members of the Association and the ladies accompanying them, spent the afternoon in an excursion on the Detroit River and Lake St. Clair, at the invitation of the local profession. Two river steamers were lashed together, and from fifteen hundred to two thousand persons enjoyed the trip, which lasted four hours. Entertainment, solid, liquid and musical, was provided on board; and by the time the boat reached the wharf, there was little left but the musicians, while a stack of cases of empty Apollinaris and champagne bottles stood a silent witness of the appreciation of the party of the good things provided for their enjoyment.

The meeting of 1892 will long be remembered by the Association, as much for the generous manner in which it was received as for the extent and quality of its scientific work.

METEOROLOGICAL RECORD,

For the week ending June 4, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Baro-meter	Thermometer.	Relative humidity.	Direction of wind.	Velocity of wind.	Wet'rh'y.	Rainfall in inches.

Deaths reported 2,971: under five years of age 1,175; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 424; acute lung diseases 335; consumption 334; diphtheria and croup 111; diarrhoeal diseases 73; scarlet fever 68; measles 65; typhoid fever 45; cerebro-spinal meningitis 19; whooping-cough 13; erysipelas 13; malarial fever 10; small-pox 5; puerperal fever 2.

From measles New York 38, Brooklyn 12, Philadelphia 5, Chicago 4, Cleveland 3, Boston, Pittsburgh and Newton 1 each. From typhoid fever Chicago 14, Philadelphia 7, St. Louis and Cleveland 4 each, Pittsburgh 5, Boston 3, New York 2, Washington, Nashville, Lowell, Lynn, Salem and New Bedford 1 each. From cerebro-spinal meningitis New York 7, Chicago and Lawrence 3 each, Lynn 2, Boston, Cleveland, Washington and Malden 1 each. From whooping-cough New York, Chicago, Philadelphia and Brooklyn 2 each, St. Louis, Boston, Pittsburgh,

Washington and Nashville 1 each. From erysipelas New York and St. Louis 4 each, Boston 3, Philadelphia and Lowell 1 each. From malarial fever New York 5, Brooklyn 3, Cleveland and Pittsburgh 1 each. From small-pox New York 4, Brooklyn 1.

In the three countries of England and Wales with an estimated population of 10,188,449, for the week ending May 29th, the death-rate was 19.4. Deaths reported 3,797: acute diseases of the respiratory organs (London) 265, measles 203, whooping-cough 113, diphtheria 51, scarlet fever 49, diarrhoea 44, small-pox (London) 1.

The death-rates ranged from 8.7 in Derby to 27.5 in Sunderland; Birmingham 23.7, Bradford 17.1, Cardiff 18.0, Croydon 13.8, Hull 18.6, Leeds 15.6, Leicester 22.3, Liverpool 24.8, London 18.8, Manchester 25.2, Newcastle-on-Tyne 18.7, Nottingham 14.8, Plymouth 17.1, Preston 23.4, Swansea 19.2, Wolverhampton 25.6.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 4, 1892, TO JUNE 10, 1892.

APPOINTMENT.

To be chief of the Record and Pension Office of the War Department, with the rank of Colonel, in accordance with the Act of May 9, 1892, MAJOR FRED C. AINSWORTH, surgeon, May 27, 1892, to fill an original vacancy.

COMMISSION VACATED BY NEW APPOINTMENT.

COLONEL FRED C. AINSWORTH, chief of the Record and Pension Office, his commission is surgeon, with the rank of Major, June 1, 1892.

Leave of absence for four months, to take effect after June 30, 1892, is granted COLONEL ANTHONY HIGGIN, surgeon, U. S. A.

The following assignments to duty of assistant surgeons, U. S. A., recently appointed, are ordered:

FIRST-LIEUT. CHAMPE C. McCULLOCK, JR., will proceed from Charlottesville, Va., to Fort Sam Houston, Texas, and report in person to the commanding officer of that post for duty.

FIRST-LIEUT. FREDERICK P. REYNOLDS, will proceed from Elmsira, N. Y., to Fort Monroe, Va., and report in person to the commanding officer of that post for duty.

FIRST-LIEUT. ISAAC P. WARE, will proceed from North Abson, Me., to Fort Douglas, Utah Territory, and report in person to the commanding officer of that post for duty.

FIRST-LIEUT. ROBERT S. WOODSON, now at Fort McPherson, Ga., will report in person to the commanding officer of that post for duty.

FIRST-LIEUT. MADISON M. BREWER, is relieved from temporary duty in the Surgeon-General's Office, Washington, D. C., and will proceed to David's Island, N. Y., and report in person to the commanding officer of that post for duty.

FIRST-LIEUT. GEORGE D. DASHON, now at Columbus Barracks, Ohio, will report in person to the commanding officer of that post for duty.

FIRST-LIEUT. SAMUEL R. DUNLAP, assistant surgeon, U. S. A., is relieved from duty at Fort Supply, Indian Territory, and will report in person to the commanding officer, Camp Penn, Colorado, Texas, for duty at that station, relieving MAJOR JOHN O. SKINNER, surgeon, U. S. A. Major Skinner, upon being relieved by First-Lieut. Dunlap, will rejoin his proper station, Fort Clark, Texas.

CAPTAIN WILLIAM B. DAVIS, assistant surgeon, is relieved from duty at Fort Clark, Texas, to take effect upon the return of Major Skinner to that post, and will report in person to the commanding officer, Fort Sam Houston, Texas, for duty.

MAJOR EDWARD B. MOSELEY, surgeon, is relieved from duty at Fort Sam Houston, Texas, to take effect upon the arrival at that post of Captain Davis, and will report in person to the attending surgeon, Washington, D. C., for duty in his office.

Leave of absence is granted CAPTAIN FREDERICK V. WALKER, assistant surgeon, U. S. A., Fort D. A. Russell, Wyoming, until June 30th, to take effect on arrival at Fort D. A. Russell of CAPTAIN JULIAN M. CARELL, assistant surgeon, U. S. A.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 11, 1892.

E. R. STILT, assistant surgeon, detached from Naval Hospital, Philadelphia, and to examination for promotion, and then to Bureau Medicine and Surgery.

T. B. BAILEY, assistant surgeon, detached from Receiving-ship "Minnesota" and to examination for promotion, and then to Naval Hospital, Philadelphia, Pa.

J. C. BYRNES, passed assistant surgeon, ordered to special duty at Norfolk and Portsmouth, Va.

H. D. WILSON, assistant surgeon, ordered to the Receiving-ship "Minnesota."

G. B. WILSON, passed assistant surgeon, ordered to temporary duty at Naval Hospital, Chelsea, Mass.

INTERNATIONAL DERMATOLOGICAL CONGRESS IN VIENNA.

The second meeting of the International Dermatological Congress will be held in Vienna from the 5th to the 10th of September, 1892.

Many of the most distinguished representatives of dermatology and syphilography from all countries have promised to present papers and the indications are that the meeting will be a great success from a scientific standpoint.

The Committee on Organization, through the President, Professor Kaposi, has extended a cordial invitation to the members of the American Dermatological Association and of the New York Dermatological Society and others interested in dermatology in this country to be present.

The members' fee (five dollars) should be sent with titles of papers intended for presentation to the Secretary for North America, Dr. Prince A. Morrow, 66 West 40th Street, New York, or to the Secretary-general of the Congress, Dr. Gustav Riehl, Wien 1-20, Bellaria Straße 12.

BRITISH MEDICAL ASSOCIATION.

The thirty-sixth annual meeting of the Association will be held at Nottingham on Tuesday, Wednesday, Thursday and Friday, July 26, 27, 28 and 29, 1892.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

The ninth annual meeting will be held at Richfield Springs, N. Y., June 23, 24 and 25, 1892.

Several delightful excursions are arranged for members and their families who desire to see this picturesque country. Ample accommodations will be provided for members and their families at the Springs House, for the nominal charge of two dollars per day.

WILLIS E. FORD, M.D., Utica, N. Y., President.

J. B. WALKER, M.D., Philadelphia, Secretary and Treasurer.

APPOINTMENT.

WILLIAM HENRY HOWELL, Ph.D., M.D., of the University of Michigan, has been appointed Associate Professor of Physiology in the Harvard Medical School.

RECENT DEATHS.

WILLIAM R. BIRDSELL, M.D., died in New York, June 7th, aged forty years. He graduated in the University of Michigan and from the College of Physicians and Surgeons, New York, in 1887. He was for several years Professor of Nervous and Mental Diseases in the Woman's Medical College, and was President of the New York Medical Neurological Society in 1885-86. He was a member of several societies, and the author of several papers on nervous diseases.

PHILIP E. DONLON, M.D., died in New York, June 12th, aged forty-three years. He graduated from the University of New York in 1870. He was made coroner's physician in 1883, and has been re-appointed by each successive coroner.

THEODOR MEYNERT, M.D., Professor of Mental and Nervous Diseases in the University of Vienna, died May 30th, aged fifty-nine.

CHARLES FREDERICI, M.D., Professor of Clinical Medicine at Florence, died May 29th, aged fifty-four years.

BOOKS AND PAMPHLETS RECEIVED.

Medical Education and Legislation. By Geo. J. Engelmann, M.D., St. Louis. Reprint. 1892.

Myleitis in a Case of Incipient Posterior Spinal Sclerosis. By J. T. Bakridge, M.D. Reprint. 1892.

Original Articles.

CASE OF ALLEGED NAPHTHA POISONING IN A RUBBER FACTORY, WITH AN INQUIRY INTO THE EFFECTS OF THE INHALATION OF NAPHTHA VAPOR.¹

BY R. H. CHITTENDEN,
Professor of Physiological Chemistry in Yale University,
AND JOHN W. FARLOW, M.D., BOSTON.

MICHAEL KIRBY, about thirty years of age and weighing one hundred and sixty pounds, whose previous history is not well established, but who was considered healthy and not a drinker, while engaged in cleaning out a churn containing a mixture of rubber and naphtha was found dead in the churn at 2 P.M., although he was seen alive and apparently well about five or ten minutes before. He was removed from the churn and a doctor summoned, who pronounced it death from naphtha poisoning. No autopsy was held.

The churn, open at the top, was five feet one and one-half inches deep, and three and one-half feet in diameter, its capacity being about forty-eight cubic feet. In this receptacle was placed a mixture of rubber, whiting and very little sulphur with considerable naphtha, the whole being agitated by paddles which revolved in the churn. In the present case, the paddles for some reason stopped revolving, and it was decided to clean out the churn in order to learn the cause of the trouble. A trowel was found clogging the paddles, that Kirby had presumably let fall into the mixture. This was on September 4th, and Kirby was at once directed to clean the churn. As is customary in such cases, he drew off all that he could, namely, the more fluid portion, then got into the churn and baled out the rest. No trouble was experienced from this. The work was resumed the two following days, and on September 7th he was told to finish it. There was then about three-quarters of an inch of the compound in the bottom of the churn, although it was nearly dried out, that is, there was little or no naphtha in it; and it was while he was at work on this, after his dinner, that he was found dead. It was not necessary for him to have his head nearer than arm's length from the bottom of the churn.

Very soon after this, two men got into the churn and remained about the same length of time that Kirby did after he was last seen alive, and they felt no ill effects from it. A week later, a man got in and finished cleaning it, and he, likewise, experienced no ill effects. Later, a man got into it when it was half full of "rubber stock," and worked there for half an hour. He did not notice the naphtha any more than he did when he was in the covering-room, where most of the men work.

The churn-room is 24½ feet long, 15 feet 11 inches wide, and 12½ feet high, and contains 4,659 cubic feet. It has five large windows each 5 feet 5 inches wide and 7 feet 10½ inches high, two on the south side and three on the west. On the east is a door, 6 feet 9½ inches high and 2 feet 11½ inches wide, opening into a passage-way which leads to the outer air, the passage being 3 feet 10 inches wide and 13 feet 8 inches long. Huxley, in his "Elementary Physiology," page 100, says, "to be supplied with respiratory air in a fair state of purity, every man ought to have at least 800 cubic

feet of space to himself, and that space ought to be freely accessible by direct or indirect channels to the atmosphere." The churn-room contained nearly six times the space needed for one man.

The churn was on the east side of the room on a raised platform two feet three inches from the door-way. The top of the churn was five feet eleven inches below the ceiling and three inches below the top of the door-way, hence there was ample opportunity for circulation of air between the top of the churn and the ceiling, aided by the close proximity to the door-way.

At the time of Kirby's death, the door on the east side of the churn-room was wide open and also the outside door at the end of the passage; a south window was open six inches top and bottom, while another south window had a pane gone and one west window nearly opposite the door was down six inches from the top.

According to the weather report of that day, the wind averaged ten miles per hour from the north-east. The highest temperature was 77° F. in the afternoon. The humidity was high, 89 per cent. at 8 A.M., and 92 per cent. at 3 P.M. There was no rain.

In a room of the given size, with free access, by means of open doors and windows, to a wind blowing ten miles an hour, there could not have been any accumulation of vapor even if considerable naphtha had been exposed to evaporation. On the contrary, the evaporation of naphtha from the rubber stock in the churn at the time of the fatal accident must have been comparatively slow. First, because the amount of residual stock was small; secondly, because the residual stock could not have contained more than 20 to 30 per cent. of naphtha; and, thirdly, because the naphtha which remained in the stock was only slowly volatile.

The more fluid portion of the contents of the churn was drawn off on the afternoon of September 4th; on the 5th and 6th, more of the thick mixture was removed; and on the 7th, there was only a small layer of residual stock. During all this time evaporation was going on; that is, the dangerous element in the mixture was gradually diminishing during the three days in which Kirby worked without detriment, until finally a residue was left from which evaporation of naphtha took place very slowly.

This is plainly indicated by the following experiment: 128 grammes of rubber stock from the bottom of a churn, after standing three days, were placed in a suitable retort, and the naphtha distilled and collected. It was heated by contact with boiling water for five hours, and as a result 25.5 grammes or 22.2 per cent. of naphtha distilled over; on raising the temperature still higher, to above 200° C., 12.9 grammes or 10 per cent. more naphtha was obtained, making a total of 32.2 per cent. of naphtha.

Naphtha is a volatile fluid, but when in contact with rubber and other material making up the rubber stock it is apparently held tenaciously by this material, and its evaporation rendered a long and slow operation. In the experiment quoted above only a small quantity of material was taken and the mixture was heated for hours in boiling water, under conditions by which free naphtha would have been quickly evaporated off, yet it required over six hours continuous heating, a portion of the time at a temperature more than three times above the boiling point of naphtha before all of the latter could be removed from the rubber mixture.

¹ Read before the Boston Society for Medical Improvement, March 14, 1862.

Further, the evaporation of the naphtha was throughout the entire experiment a gradual process; at no time did a rapid distillation occur. Other experiments leading to the same result are as follows:

Two specimens of rubber stock, of the same thickness and consistency as that in the churn at the time of Kirby's death, were placed in sealed jars, and one labelled "No. 1, February 16th," the other, "No. 2, February 17th"; 524 grammes of the mixture from No. 1 yielded, by long-continued distillation, 144 grammes of naphtha or 27.4 per cent., while 641 grammes from No. 2 gave only 133 grammes of naphtha or 20.7 per cent. as a result of several hours' heating at a high temperature. These last two experiments confirm the preceding in showing that the naphtha held in the churn stock does not evaporate readily as free naphtha would, but is held tenaciously by the rubber mixture: further, the experiments show that there had evaporated 6.7 per cent. of naphtha as a result of one day's exposure of the rubber stock in the churn.

These results lead to the conclusion that on September 5th and 6th Kirby must have been exposed to a more dangerous atmosphere, or at least one more charged with naphtha, than on September 7th, when there was a much smaller amount of stock, and this contained a much smaller proportion of naphtha.

Let us now look at the nature of the naphtha in the churn. Naphtha is made up of a number of closely related hydrocarbons from the distillation of petroleum. These hydrocarbons are of low specific gravity, that is, are lighter than water and have a comparatively low boiling point, the naphtha representing the lighter and more volatile portions of petroleum, in distinction, for example, from kerosene and other higher boiling products. Commercially, naphtha and benzine are essentially the same, but naphtha, or as it is sometimes called, petroleum ether, is, strictly speaking, a lower boiling product and hence more volatile than benzine. But, as a matter of fact, the naphtha used so extensively for manufacturing purposes in this country is a mixture of naphtha No. 0, No. 1, No. 2 and benzine.

The naphtha used in the factory where Kirby was employed was examined, and it was found to have a specific gravity of 0.681, and contained about 37 per cent. by volume of hydrocarbons with a boiling point below 70° C.; in other words, 37 per cent. of the naphtha was volatile at a temperature of 70° C. The great difference in volatility between that portion of the naphtha distilling below 70° C. and that portion boiling or distilling above 70° C.—a point of considerable significance in this case—is made strikingly manifest by the following experiment: Two equal portions of naphtha, one the fraction distilling below 70° C., and the other the fraction distilling above 70° C., were exposed to the air, side by side in uncovered dishes at the ordinary room temperature, for six hours. As a result, it was found in measuring the naphtha remaining in the two dishes, that of the portion distilling below 70° C., 25 per cent. had evaporated, while of the portion distilling above 70° C., only 8.5 per cent. had evaporated. Now, the more volatile portions of naphtha are obviously the most dangerous. In all cases where persons are exposed to naphtha vapors the lower boiling hydrocarbons would be the first to volatilize, and their action would naturally be the most pronounced, and under ordinary circumstances the larger the proportion of

these more volatile products, the greater would be the danger from naphtha fumes. Dragendorff, Professor of Toxicology in Russia, says, "The higher boiling constituents of petroleum are hardly to be classed with poisons. There are cases where they have been borne in large quantities without harm."

A sample of rubber stock from the bottom of a churn of the same consistency and character as that in the churn at the time of Kirby's death, yielded only two per cent. of naphtha boiling below 70° C. In other words, the exposure of naphtha in an open churn for two or three days, is followed by a fairly rapid evaporation of the most volatile hydrocarbons, leaving a residue in which the heavier hydrocarbons predominate. Hence, it is obvious that the naphtha which remained in the residue of the churn stock Kirby was occupied in removing, must have been nearly or entirely free from those more volatile and dangerous portions of the naphtha which distil below 70° C.

Let us now consider the toxic action of naphtha as indicated by the result of experiments with animals. Over twenty distinct experiments were tried with rabbits and dogs, and where any toxic effect was produced the symptoms were essentially the same in every case. The animal was placed in a large can open at the top; on the bottom of the can was placed a quantity of naphtha, the animal sitting or standing on an inverted wire sieve, which raised him a few inches from the naphtha and kept him out of it, although allowing free passage of the vapors. At times, the top of the can was covered with wire netting to prevent the animal from jumping out. There was no rubber to retard the evaporation and the naphtha (76° Baume) contained the full amount of the more volatile hydrocarbons.

Restlessness was the first symptom noticeable and in no experiment did the action of the naphtha at first extend to such a point that the animal could not jump out of the can if allowed to do so. In fact, the animal always attempted to leap out. On being restrained, it gradually became weaker and ceased to attempt escape, the teeth grinding together and then, sooner or later, there invariably came a point when the animal fell over and was attacked by violent convulsions, the body being curved or arched, the legs rigid, the facial muscles drawn back, exposing the teeth and jaws, the mouth stretched open and the legs often quivering with convulsive tremors. On being removed from the can, after a minute or two, the animal always recovered after a short time, say thirty minutes. In no case were these attacks followed by death; weakness remained apparent for a short time, but the animal soon hopped about as usual. There was apparently no true anesthesia, no direct narcotic effect produced, no tendency to fall into a stupor and sink away into a quiet death, but always, at the end, there came the terrible convolution of marked opisthotonic character, shrill cries and effects which point plainly to spinal action, or to irritant action on the motor centres in the brain.

In Kirby's case there was no evidence of a violent, convulsive death, no clinched fingers, staring eyes, distorted features, and he made no outcry. With rabbits, when the fumes of the naphtha have nearly taken possession of the animal, he instinctively raises his head above the top of the can and by breathing a little of the purer air above obtains a new lease of life.

Animals do not quickly succumb to the action of naphtha fumes, even when they are exposed to com-

paratively large quantities of free naphtha for some time. This point is well illustrated by the following experiment: A large dog, weighing twenty-eight pounds, was confined in a wooden box or cage lined with galvanized iron, two feet wide, three feet four inches long and two feet eight inches high; the bottom on which the dog stood was of heavy wire netting; under this was a tightly fitting iron tray, the bottom of which was five inches below the netting. The top of the tray was of wire netting and during the experiment was partially closed by towels laid over it.

The dog was placed in the cage at 9.30 A. M., and a little more than a quart of naphtha (76° Baumé) poured into the tray. The vapor rose through the cage, and the atmosphere in the room was charged with it. The animal remained there five hours without being noticeably affected.

In order to see how quickly death would result from naphtha under circumstances most favorable for its action, the same dog was held by two assistants, and a sponge and cotton saturated with the same naphtha were continuously held to his nose. Within five minutes he began to tremble, the pupils widely dilated, quickly followed by a violent convulsion, the limbs rigid, the facial muscles contracted, showing the teeth and jaws, blood oozed from the nose, frothy mucus or slime from the nose and mouth, and shrill cries. Fresh naphtha was continuously applied to the nose. Involuntary discharges of urine and feces followed. The convulsions were so great that the two men could hardly hold him. It was a continual struggle, convulsion passing into convulsion, with occasional moments of comparative quiet with labored breathing. After twenty-five minutes, at the end of a violent convulsion, he sank down dead, without showing any tendency to sleep or stupor.

In order to note the different effects of the low and high boiling naphthas on animals, the following is instructive. Two rabbits of equal weight were taken. In the previously described can were placed 200 cubic centimetres of naphtha distilling below 70° C., that is, naphtha which was almost entirely wanting from the churn stock. The rabbit was placed on the sieve, and the top of the can covered by an inverted sieve. This was at 8.55. The rabbit became uneasy and restless at once. At 9.06 he was unsteady and swaying to and fro, head low down, jaws and teeth grating. At 9.07 he fell over in convulsions. At 9.08 he lay limp, breathing heavily. At 9.11, a slight convulsion, followed by a heavier one. At 9.12 he was taken out of the can and laid on the floor. At 9.14, recovering, but unable to use his legs, trembling on trying to walk. At 9.16, hopping about, apparently well.

In the same apparatus and under exactly the same conditions, the other rabbit was placed with 200 cubic centimetres of naphtha boiling above, instead of below, 70° C. This was at 9.27. At 10.15 he was unaffected. At 11.30, still all right, though apparently somewhat drowsy and weak. At 12.00, very quiet on the bottom of the sieve. Touched lightly he fell over, lay quietly for a moment, then fell over on his side without a convulsion. Finally, had a strong convulsion with shrill cries. Taken out and placed on the floor, he lay for some minutes scarcely breathing, then gradually recovered, though still weak in the legs. At 12.15 he was on his feet again, and hopping about as usual.

In this latter experiment, where the naphtha cor-

responds to that present in the residue of churn stock, we see that two and one-half hours elapsed before the animal was sensibly affected, while in the first experiment where the lower boiling naphtha was used the rabbit was in convulsions in twelve minutes. In both cases the mode of action was the same, the main difference being the rate of action. One other important point is brought out by the following: 200 cubic centimetres of naphtha distilling above 70° C. were poured into the can, a good-sized rabbit placed on the sieve, and an inverted sieve covered over the top of the can. This was at 9.55. At 10.58 the animal was quiet on the bottom of the can; at 11.18, ditto; at 12.00, fell over on his side; at 12.02, slight convulsion, then lay quietly on the bottom of can, eyelids and facial muscles twitching; at 12.05, heavy convulsion.

In most of the experiments, the rabbits were removed from the can at this point and an opportunity given for their recovery. In this case, however, the animal was allowed to remain in the can. At 12.07, there were convulsive tremblings continuously, most pronounced in the forelegs. The animal lay on its side, its head on the sieve, not more than three inches above the layer of naphtha, pupils contracted almost to a point. This condition continued till 12.35, when the convulsive tremblings were succeeded by a violent convulsion followed immediately by death, the head thrown well back, the mouth stretched wide open, and the lips drawn back. In the first part of this experiment we have simply a repetition of previous results; but after the heavy convulsion at 12.05, we see that death did not follow immediately, although the animal lay near the bottom of the cage with its head almost in the naphtha. Death was delayed half an hour, although the bottom of the can was covered with a layer of free naphtha.

In Kirby's case he was seen ten minutes before his death; the naphtha then in the churn must have been similar to that used in the last mentioned experiment with the rabbit. We are obliged to conclude that, if these experiments illustrate the way that naphtha acts, then Kirby could not have been killed by naphtha.

Naphtha is used very extensively throughout New England, but we have been unable to learn of a single fatal case of naphtha-poisoning that has come to the notice of the medical examiners and chemists. At a large rubber factory in the vicinity of Boston, we were told that in the cloth-covering room, where a great many times as much naphtha is used as in the churn-room, there were formerly among the working-girls, many instances of "naphtha-drunk" or silliness, sometimes followed by unconsciousness. When the girl was taken into the air, she soon recovered and went to work again. It was principally hysterical girls and those who ate no breakfasts who were thus affected. More ventilation in the room and obliging the girls to eat breakfast, put a stop to these unpleasant attacks.

In the *Revue des Sciences Médicales*, for 1888, Sury-Brienz publishes what he calls the first case of death from the vapor of benzine. A man, twenty-four years old, was working in a chemical factory. It was very cold out-of-doors. Against the rules, he went into a place where the toxic vapors were being formed, without opening doors and windows in advance. He fell dead immediately after coming out, but it is not stated how long he was there. The

autopsy showed some softening of the brain, old adhesions of the lungs and some thickening of the cardiac valves from former disease. The other lesions, probably due to the benzine, were fluid blood, great lividity, congestions and some haemorrhages. In this case, then, which is supposed to be the first fatal case in France, there is evidence of old disease of the brain, lungs and heart, and the benzine was inhaled in a fresh state, in a room where there was no ventilation.

Poincaré, a French authority, says there have been many cases of unconsciousness among workers in naphtha, but only one death. He gives no particulars of this one case, but it was before 1879. Lewin, a famous German writer on poisons, says that workers on rubber fabrics stand benzine without detriment to their health.

Felix, in the *Offentliches Gesundheitspflege*, for 1872, page 231, gives some experiments on healthy men. Into a paper cone, loosely filled with cotton wool, of which the point was cut off, pure benzine was poured, and held before the noses of several healthy men, as in giving chloroform. In the first eight minutes, the pulse rose and later fell. Five to fifteen grammes of benzine, inspired for from seven to twelve minutes produced dizziness, nausea, desire to vomit, cough, burning in the chest and sleepiness. Twenty to forty grammes inspired for eight to twenty minutes produced sleep and full anesthesia as by chloroform. The stupor lasted two to eight minutes, and after coming to, they complained of nausea, sleepiness, and headache. The very slow pulse returned to normal in ten to twenty minutes. Some persons bore the inspiration of fifty to fifty-five grammes without lasting disturbance.

Hirt, "Diseases of Occupation," 1875, Band 2, page 183, says he examined a great many workers in rubber, benzine and naphtha, and was astonished to find them exceptionally healthy. After a stay of several hours in benzine air, there was no trouble with pulse or respiration.

Poincaré, "Hygiène Industrielle," 1886, page 207, attributes the headache, pain, exhilaration followed by depression, to the bi-sulphide of carbon rather than to benzine. But bi-sulphide of carbon is very volatile, with a boiling point of 45° C., and cannot be present in the churn residue, which does not begin to boil until about 70° C.

In *L'Union Médicale*, Paris, 1861, page 92, is an article by M. Perrin. After some experiments on animals with benzine, he concludes that intoxication by benzine is very different from that by chloroform. In chloroform and ether the ultimate and deadly period of intoxication does not exceed three or four minutes, while with benzine it may last five times as long without the death of the animal following. Benzine seems incapable of producing that complete and remarkable inanition and insensibility of the whole body which is a characteristic of the anesthetic proper. The persistence of sensibility, which is only weakened, the *heavy convulsions* and the functional exaggeration of the circulation and the respiration, indicate that the nerve-centres are affected in a particular way, and that the physiological effects resemble closely those which result from animals breathing the essential oils, a toxic dose of which causes drunkenness, convulsions and death without the animal passing through the state of true anesthesia.

It would be possible to multiply experiments and

quotations; but, in our opinion, we are justified in concluding that Kirby's death was not due to naphtha, because—

(1) He was accustomed to it.

(2) He had worked in the churn for several days without bad effect, when the naphtha was much more abundant, more volatile, more dangerous, than when he was found dead.

(3) The churn room was well ventilated, and there was no possibility of accumulation of fumes.

(4) Experiments on animals, even with free, low-boiling naphtha, and continuously applied, show a mode of action and death entirely unlike the Kirby case.

(5) We are unable to find in medical literature any similar case to Kirby's, where it was known that death was due to naphtha.

(6) Cases of sudden death, particularly soon after dinner, in persons who were not known to have any cardiac or other serious disease, are sufficiently common to justify us in concluding that Kirby's death was due to some natural cause, and that it was not caused by naphtha.

ABDOMINAL AND PELVIC EMERGENCIES CAUSING SUDDEN DEATHS.¹

BY J. C. IRISH, M.D., LOWELL, MASS., AND A. R. STONE, M.D., BOSTON.

THE chief duty of the medical examiner, and what he especially owes to the State, is to make inquiries into each case to which he is called, why the State has lost its subject. When he can say that the State has lost its subject through nobody's fault, his investigation as medical examiner has ceased. The State is not interested to know of what one subject or another has died, only that there has been no foul play. It simply limits its inquiries by its desire to know whether it has lost its subject by the fault of another.

Now, in the number of cases in which a medical examiner is called during the year, there will be but a very small percentage of them in which the State has lost its subject by the fault of another; probably not one-tenth of them. Therefore in the remaining nine-tenths, when the medical examiner has established the fact that death was due to natural causes, one portion of his duty is fulfilled. In addition, however, he is not only to find that these subjects died from natural causes, but also to certify of what particular disease they died.

Hence, in connection with our office we are confronted oftentimes by simple, sudden deaths, with no preceding history of any illness in the few hours previous to death. For instance, the patient has gone to bed apparently well, and is found dead the next morning, and we are asked to decide what was the cause of death, or its most probable cause. This is one of the questions that we must answer to the best of our ability, and answer oftentimes with the aid of very little evidence.

So far as our absolute knowledge goes, we do not know the cause of death in many instances, and we have not data enough to make a reliable or probable conjecture as to its cause. Yet, there is no suspicion that the deceased came to his death by anything than by natural causes, so there is no reason for asking for

¹ Read before the Massachusetts Medico-Legal Society, February 3, 1892.

an autopsy. Fortunately, however, we often have the preceding history perhaps of one or two days' illness, which was not thought to be dangerous, to give us very considerable aid in forming our conclusions, and in those cases we are able to sign the certificate of burial intelligently, and probably correctly.

Still, as I have said before, there are very many of them in which the cause of death, is a matter of mere conjecture, which is entirely unsupported by any testimony. It therefore behoves us to investigate with all possible care the various causes of sudden death, and whatever investigation can throw any light on these various causes is of great assistance, and of great value in aiding us to arrive at correct conclusions in particular cases.

In the subject which has been assigned to me to-day, there are very many interesting inquiries to be made. The experience of any one man as to what causes sudden death due to any accident occurring in the pelvic abdominal cavity must be very slight. The ordinary practitioner, or medical examiner, who has seen two or three such cases, has had really a very large experience. Therefore in drawing any conclusions upon this subject relative to the frequency of those accidents, or, upon the occurrence of any given case, it is simply necessary to investigate as thoroughly and exhaustively as possible the combined experience of all our writers. I therefore avail myself of the recorded experience of others that has come readily within my reach.

It is not my purpose in this paper to touch upon the subject of hemorrhages into the pancreas, which has already been treated so ably and exhaustively by the President of this Society, Dr. F. W. Draper. Neither do I intend to consider abortion, for complicated as it is with questions of law and morality, it deserves a place entirely by itself in the transactions of this Society. I shall, however, call your attention to-day to those non-traumatic conditions in the abdominal cavity and pelvis which may cause death in such a manner as to demand our attention.

I shall run over briefly the cases which have come to my notice in glancing over the literature of the subject, and then add a few cases which have fallen under my own personal observation.

First of all I shall take up the cases which have occurred in the course of typhoid fever, where death has occurred in the so-called walking or ambulatory cases.

Dr. Fitz² in his recent investigations upon the subject of perforations has collected 4,680 cases with 5.58 per cent. of perforations, thereby agreeing with Holscher³ whose report of 2,000 cases observed by him showed perforation in 6 per cent. of the cases. Murchison⁴ gives a percentage of nearly double this, while Schulz⁵ and Liebermeister⁶ in the hospitals of Hamburg and Biele report a percentage of only 1.2 per cent. and 1.8 per cent. respectively.

All these taken together would make a trifle less than 5 per cent. in a total of 14,087 cases. What the exact data, from which Dr. Fitz obtained his 4,680 cases, is, we have no means of knowing, but it would seem from a number of other statistics that we have seen, that he made no attempt to tabulate all that has

been written on the subject, and that if all were collected, that the percentage would be on the whole less by one or two per cent. than the 6.58 per cent. which he is inclined to consider the true percentage of perforations. But whatever the real percentage may be, every one has the idea firmly fixed in his mind that a large number of these cases occur in the lighter cases of typhoid. Murchison⁷ states that this is due to the fact that this assertion was originally made by Louis and Chomel (1834), who found the disease latent, previous to the perforation, in 10 out of 12 cases examined by them. This statement was copied into all text-books, and it was only later after long investigation that perforations were found to be more common in severe cases of typhoid. Fitz's paper supports Murchison, for of the nearly 200 cases of perforation collected by him, only 14 cases occurred in walking typhoid.

Many of our instructors have taught what has been so strongly asserted, supported as it is by autopsies, and probably backed by unreported cases which have occurred in the course of their own consulting practice, that there is a prevailing sentiment through the medical profession that perforation is specially common in ambulatory typhoid. In spite of this general belief cases of sudden death often occur in persons who have had a mild form of the disease, and whose death has doubtless resulted from the carelessness of the physicians, who neglected to remember that perforation must always be borne in mind in the treatment of typhoid fever.

A case that will serve to illustrate this is one narrated by Louis,⁸ where a man with a mild case of typhoid was allowed to walk about the hospital garden each day. He was improving until the twenty-third day when perforation with the usual symptoms of collapse and peritonitis set in, and the patient died within thirty-six hours.

Two similar cases are reported to have occurred at Guy's.⁹

Many people have not known just what has been the matter with them, and have gone to the hospital only to die in a short time from perforation. Murchison¹⁰ relates a case of this kind where the patient walked three miles to the hospital in order to find out what was the matter with himself, and died within thirty-six hours of his entrance from collapse. And Louis is said to have seen a similar case. Such cases are always a great shock to the friends, but they do not specially interest us, for the cause of death in such cases is usually apparent. The same is true in those cases which occur late in the stage of convalescence. The history of the previous illness, together with the sudden onset of severe symptoms referable to the abdomen, leave little doubt as to the true cause of death.

The case of Tweedie¹¹ is in point. Here the patient had had an ordinary case of typhoid, and was up and about, apparently convalescent, and had been allowed to leave the house. The stools were well formed, and perfectly natural. Suddenly, symptoms of perforation occurred, and the patient quickly died.

Another similar case is recorded by Murchison. Here the patient, a laborer, had been convalescent for

¹¹ Recorded by Murchison.

two weeks, and had returned to his work. One day while working he was suddenly attacked, and died in a few hours. The intestine showed typhoid ulcers nearly cicatrized, one of which had perforated and caused the fatal peritonitis.

In spite of their rarity, cases do occur when the typhoid gives no signs, or such obscure signs that they are overlooked, and treatment meant to meet certain more manifest symptoms is inaugurated, which may work most disastrously upon the typhoid lesions.

Bennett¹² reports a case of this kind where a man who was supposed to have cardiac disease with dropsy was purged. He was allowed a liberal diet, as he had an extremely good appetite. After a fortnight the bowels became loose for a couple of days, then there was complaint of general distress with some abdominal tenderness, which was taken for peritonitis from inflammation of the kidneys. Sudden death took place the next day from perforation of the ileum.

Sestreville¹³ reports a case where there had been absolutely no symptoms till the sudden advent of peritonitis, and the patient died four days later.

A very interesting case is reported from the Hants County Insane Asylum,¹⁴ and one where the charge of neglect might give considerable trouble to the authorities. The patient, a woman, was confined in the asylum for mild mania and delusions, and having some dementia. She was up and about the wards, and was not considered sick until two days before her death. Till then made absolutely no complaint to the nurses.

July 17th she refused her breakfast, and complained of abdominal pain. By night she showed signs of peritonitis, and died the next day at noon. At the autopsy the ileum and large intestine were found to have numerous and undoubted typhoid ulcers, and one of the former had perforated.

Any one who has had experience with the difficulties of diagnosis in light cases of typhoid will readily see how much, on account of her mental condition, the difficulties would have been increased had she made complaint, as she did not.

A case reported by Kleinwachter¹⁵ shows how a really secondary matter can absorb the whole attention. A patient entered the hospital with an abortion well under way, and signs of peritonitis already present. A four months' fetus was delivered without any difficulty, but in spite of all treatment the patient died the next day. The general course of the case lead the physicians to think of induced abortion, and they were much surprised to find at the autopsy numerous typhoid ulcers, and a perforation from which the peritonitis had started. The abortion had started as secondary to the disease, or been induced at the time of the perforation.

November 21, 1891, I was called by a member of the Board of Health to investigate the cause of death in the case of Mrs. K., who had died suddenly, the preceding night. She was taken sick about five weeks before. The first physician who attended Mrs. K. pronounced the disease typhoid fever. A second medical attendant doubted this diagnosis. The fever was of very mild type. Her physician had not seen her for the ten days before her death and refused to sign the certificate for burial. Mrs. K. had for several days been about the house and in the street.

¹⁵ Wiener Med. Presse, 1880, xxi, 337.

In the night of November 20th, she was seized with extreme pain in the abdomen and great prostration, and died three hours later. Although no autopsy was made, there can be no doubt that this patient's death was caused by intestinal perforation.

Murchison¹⁶ gives some cases where sudden symptoms have followed exposure to foul air of vaults, etc., and as some of them have resulted in sudden death with symptoms which might have been attributed to poison, they are of value here.

In August, 1829, twenty out of twenty-two boys who were attending the same boarding-school were seized within three hours with fever, vomiting, purging and excessive prostration. One boy, three years old, had been attacked two days before, and had died comatose in twenty-three hours. Another, five years old, had died in twenty-five hours after being attacked. It was found on investigation that a choked-up drain had been opened two days before the first case of illness, and the contents spread on the boy's play-ground. At the autopsy the Peyer's patches and solitary glands were enlarged like "condylomatous elevations," and in one case the mucous membrane was slightly ulcerated. The mesenteric glands were enlarged and congested.

A little girl of nine had been playing over the grating of a choked-up cesspool, from whence such foul smells came that sometimes the horses had to be removed from the stable. She was shortly after attacked with febrile symptoms, vomiting, purging, and intense headache followed by acute delirium. She died forty-seven hours after the commencement of the attack. After death the characteristic lesions of early stage of enteric fever (typhoid) were found in the intestines.

Ulcerations in the stomach and upper intestine may give but little trouble, so much so that patients have no idea that anything serious is the matter, and think that they are only run down.

A case bearing on this point has been presented by Harman.¹⁷ A boy of ten years was playing in Central Park, New York, when he stumbled and rolled down the hill on which he was. Half an hour later he was brought to the hospital. He was slightly dazed, his temperature was 101.4°, and his pulse 110, the abdomen was slightly tympanic and tender on pressure. Four hours later he began to get pale, the pulse quickly became imperceptible, the tympany and tenderness increased, the respiration became weak and shallow, and vomiting set in, and the patient died within three hours after the onset of the collapse.

The autopsy disclosed an ulcer of the duodenum ten inches from the pyloric opening, which had perforated, and the peritoneal cavity was full of intestinal contents.

There had been no hemorrhage. No other ulcers were to be found. Investigation of his parents showed that the boy had made no complaint, and had no symptoms referable to the gastro-intestinal tract.

A class of cases will next present themselves for attention where there is usually sudden pain in the pelvis followed by severe collapse, blanching and general appearance of internal hemorrhage. These cases have been recognized as a source of danger for a long time, but their frequency has been understood only since the advent of abdominal and antiseptic surgery.

Since 1872 there has been a great mass of literature on the subject of ectopic gestation, yet but little of it

¹⁶ Murchison, p. 472.

¹⁷ Medical News, August 1, 1881.

is of value to us at the present time except that anything that will throw light upon the diagnosis of obscure pelvic symptoms of course aids us in establishing our opinion as to the cause of death. But the question of abdominal operation *vs.* electricity, etc., which have occupied so much space have no interest for us except as clinicians. Therefore we are obliged for the purposes of this paper to throw out the great mass of brilliant operations which have been accumulating in the last few years. The number of cases of ectopic gestation which are now seen and recognized make it probable that in the past there must have likewise been a great many. But the fact that there are so few lithopedia to be found in museums,¹² etc., make it probable that only a comparatively few cases pass to full term, and that from the small number of autopsies to be found that only a small per cent. die of either hemorrhage or shock. In by far the greatest number of fatal cases death seems to come from exhaustion, or from peritonitis, and follows some time after the first attack. Even in those cases that Barnes calls "cataclysmic," the patient usually survives long enough to allow of medical consultation.

A case reported by Dr. Trush gives a very fair idea of the usual course of an extra-uterine pregnancy. Dr. Trush's¹³ patient was attending to her ordinary household duties when she was suddenly seized with excruciating pain in the lower part of the abdomen, and almost immediately everything turned dark. When the syncope disappeared she vomited freely, and an intense sickening pain in the abdomen continued. This was the attack, and gradually, after a long tedious convalescence the patient recovered, an invalid.

In spite of the fact that death so sudden that it does not allow of diagnosis is extremely rare, yet enough cases do occur to make it necessary that the examiner should have the subject of extra-uterine pregnancy in his mind in cases where the history in any way points to the pelvic organs.

Dr. Draper¹⁴ has reported a case where an unmarried girl, of eighteen was brought to the City Hospital in a state bordering on collapse. She was greatly blanched, and complained of severe pain starting in the pelvis and extending down the thighs and to the back. The hypogastric region was extremely sensitive to palpation. In spite of all stimulation the patient died five hours after her admission to the hospital.

The clinical data were insufficient to establish a diagnosis, and an irritant poison and criminal procedure were thought of, the case became one for medico-legal examination. The abdominal cavity was found filled with three quarts of clotted blood. The left tube was distended at its outer end to the size and shape of a small olive, and in this distended portion was a rent, from whence the ovum had escaped, and the fatal hemorrhage had occurred. The gestation was probably in its second month.

A very similar case is recorded by Jordan,¹⁵ of Budapest. A mill-girl soon after beginning her day's work fell to the floor complaining of severe pain in her abdomen. She quickly became unconscious, and remained so until she died. At the hospital she was unconscious, very much blanched and lay slightly turned to the right side. The right leg was perfectly quiet

as if paralyzed. The left leg was drawn up flexed on the body. The patient moaned most of the time, and any attempts to examine the abdomen caused increased moaning, when the left leg was moved.

Physical examination showed the organs of the body normal excepting the presence of edema in the lungs was noted. In the pelvis a tumor was felt upon the right side. The breasts were slightly enlarged, and later it was learned from friends that there had been no menstruation for two months. After some delay diagnosis of extra-uterine pregnancy was made with rupture on the right side. As preparations were being made for operation the patient suddenly died. A medico-legal examination followed. The left tube was found ruptured, and a solid clot weighing about 1,000 grammes was found on the right side of the pelvis.

(The writer draws the conclusion from this case that the patient lay instinctively upon the unaffected side just as a person with acute pleurisy. The blood consequently gravitated to the right side making the tumor appear upon that side. Therefore Jordan thinks that the position of lying should always be taken into consideration in establishing a diagnosis as to which tube is affected.)

The following case of Zweifel,¹⁶ of Leipzig, though operated upon, illustrates very well the suddenness of the attack, and the difficulties in the way of making a diagnosis. The patient was taken with very sudden and severe symptoms of abdominal pain while she was in the garden. She fell to the ground, and from there was removed to the hospital. She had recently had her third child, and there had been no signs of pregnancy present. Colostrum was found in her breast, and a pelvic tumor was felt on vaginal examination. Laparotomy was performed, and a ruptured tube was found, but the patient only lived a short time after the operation.

In June, 1890, I was called to Meredith, N. H., to operate upon a patient who was suffering from hemorrhage into the abdominal cavity. I reached the patient about two o'clock in the morning five hours after the summons, when I found a woman apparently almost entirely exsanguinated with sighing respiration, and an almost imperceptible pulse. The history of the case is as follows:

This woman had been apparently well. Had missed one menstrual period, and a day or two before had commenced to menstruate. She was left in the morning alone in the house. When her husband returned at 5 o'clock in the afternoon, he found her lying upon the floor entirely unconscious. On examination an ill-defined solid mass was found in the abdominal cavity. There could be no doubt that this was a case of ruptured ectopic pregnancy. The patient had so much the appearance of being in *articulo mortis* that I regarded any surgical interference as absolutely hopeless. The patient, however, went on to a complete recovery, except that there has since remained in the pelvis a distinct solid mass. Although this patient did not die, and the diagnosis was not verified, either by operation or post-mortem examination, still there can be no question as to its correctness. When she fell to the floor, had she died instead of making a narrow escape, and had been found in this condition, the medical examiner who would have been called in, would probably never have suspected the real cause of death, and in no other

¹² Tabs, quoted by Cushing, Boston Medical and Surgical Journal, 1891, No. 2.

¹⁵ Allg. Zeit., November 14, 1891.

= Zweifel : Archiv. f. Gynäk., 1891.

way could this have been determined than by a post-mortem examination.

A case reported by Förster²² is very suggestive, as similar cases could easily occur among a class of patients where foul play might be suspected. The woman was twenty-nine years old, and had one child a year before. Menstruation was regular until one month before, when the duration was six instead of three days, but was very scanty throughout. The patient stated that she did not believe herself pregnant. With the approaching menstrual period she had had greatly increased sexual desire, which her husband had been gratifying to excess. During this procedure the patient felt a sharp pain in her right side, which she supposed to be due to indigestion, and various household remedies were used. Three hours later the physician was called. The patient was then in complete collapse, with pulse hardly to be felt, blanched, and with cold, clammy perspiration. The lower part of the abdomen was sensitive. The husband denied cohabitation for some months past, and refused an operation asked for on the diagnosis of extra-uterine pregnancy. The patient died in a few hours. After death two litres of blood were found in the abdominal cavity. The right tube was distended, and a rent was present large enough to allow of the escape of the head of the fetus. A right corpus luteum was present.

SUDDEN DEATH FROM AFFECTIONS OF THE NERVOUS SYSTEM.¹

BY PHILIP COOMBS KNAPP, A.M., M.D.,

Clinical Instructor in Diseases of the Nervous System, Harvard Medical School; Physician for Diseases of the Nervous System to Out-Patients, Boston City Hospital.

An inquiry into the causes arising within the nervous system which may give rise to sudden death is by no means easy. Registration reports and vital statistics seldom separate such cases from the total number of deaths attributable to any given cause, and a study of clinical records with autopsies would require an enormous expenditure of time before a sufficient amount of evidence could be accumulated. I can offer, therefore, only a few *a priori* considerations as to the possible occurrence of sudden death in affections of the nervous system, basing my statements rather upon the probable events in any given disease than upon statistics. In such a study I exclude traumatic affections of the nervous system, and poisons which cause death by their action upon the nervous system, whether they be taken into the system from without, as in the case of opium, or be generated within as in the case of the poison of uremia.

Before beginning the inquiry, however, a word of definition seems necessary. I shall limit the consideration to cases of death occurring within an hour from the onset of symptoms; only in such cases will I speak of sudden death, using the term speedy death for cases where death occurs within twenty-four hours.

I shall consider sudden death as occurring from affections of the peripheral nerves, the spinal cord, the brain, and in the neuroses.

I. PERIPHERAL NERVES.

Sudden death is not uncommon where there is in-

¹ Read before the Massachusetts Medical-Legal Society, February 3, 1892.

²² Förster: *Jour. Amer. Association*, 1890, p. 1304.

flammation of the vagus. It is due undoubtedly to paralysis of the heart. Such a vagus neuritis is not uncommon after the acute infectious diseases, especially diphtheria, and to it are now generally attributed the sudden deaths which are so common after these afflictions. In multiple neuritis arising from other causes such a sudden cardiac paralysis rarely, if ever, occurs. When death ensues as a result of vagus neuritis, as is not uncommon, it is of gradual onset, and is attended by various respiratory and circulatory symptoms. It would seem, therefore, that some other factor beside the vagus neuritis, is requisite; and this factor is probably the degeneration of the cardiac muscle, which is also not infrequent in such cases. Only in the last instance can these cases be attributed to affections of the nervous system, for the acute infectious disease has a large share in their causation. They may therefore be excluded from this inquiry, the more in that they seldom have any medico-legal interest.

II. SPINAL CORD.

Lesions of the spinal cord rarely, if ever, give rise to sudden death. Lesions of the medulla will be considered with lesions of the brain. It is, of course, obvious that lesions high up in the cord, close to the medulla, may act very like lesions of the medulla itself, but such lesions need no separate consideration.

Spinal meningeal hemorrhage.—Olivier long ago contended that meningeal hemorrhage, unlike cerebral hemorrhage, could not produce death by a "stroke." Leyden² later contested this statement, and Gowers³ thinks it very common for death to ensue in a few hours. Death, however, seems to be speedy rather than sudden; it usually takes place, at the soonest, after a period of three to six hours, with symptoms of spinal pain, paraplegia, etc. In a part, at least, of the fatal cases, especially those where death has come on the quickest, the hemorrhage was high up, involving the medulla, or there was co-existing cerebral hemorrhage, or the patient died of shock.

Spinal hemorrhage. Hemato-myelia.—This affection is extremely rare, and it seems to cause death rather less speedily than meningeal hemorrhage, unless the lesion be high up. The shortest time in which Leyden⁴ found that death occurred was thirteen hours.

Acute hemorrhagic myelitis.—Death in this affection is distinctly of slower onset than in hemorrhage. Strümpell⁵ thinks it not impossible that, in some cases where children die in a short time with fever, convulsions, etc., there may be an acute polio-myelitis; but that is purely an hypothesis. Unless the myelitis involve the upper part of the cord death seldom occurs until a week or more has elapsed.

III. BRAIN.

Meningitis.—Even in the fulminating forms of cerebro-spinal meningitis, and the rapid cases of tubercular meningitis and meningitis from ear disease, we rarely meet with cases of sudden death. Stillé⁶ finds the shortest duration of any case of cerebro-spinal meningitis (Gordon's) to be five hours. Meningitis of tubercular origin or from middle ear disease may come on suddenly, with paralysis, etc., as if from a "stroke," and the patient may rapidly become comatose, and die; but in such cases the period of coma is more or less

protracted and the patient usually lives several hours or even days.

Meningeal Hemorrhage. — Hemorrhage into the meninges of the brain, whether it be dural or pial, usually does not give rise to sudden death. In fourteen cases of surface hemorrhage Dana¹ found the limits within which death occurred to be from one to eight days. If, however, the hemorrhage be due to a rupture of a large vessel at the base (notably the basilar artery, the favorite seat of aneurisms), the resultant pressure upon the medulla will cause sudden death, sometimes within two or three minutes.

Cerebral Hemorrhage. — This may be regarded as the chief cause of sudden death in afflictions of the nervous system. Sudden death is, of course, most common in hemorrhages into the medulla, the pons, or the cerebellum; most sudden, of course, in hemorrhage into the medulla. In addition to these distinct focal hemorrhages, which may from their proximity to the vital centres in the medulla, give rise to sudden death, hemorrhages higher up may rupture into the ventricles. Dana found that out of thirty-two cerebral hemorrhages, twenty-six ruptured into the ventricles; Charcot and Bouchard² found this only in eighteen out of seventy-seven cases. In only a small proportion of these ruptures into the ventricle is death sudden, although it is usually speedy. Dana gives the average duration of life as from one to three days.

Cerebral Softening. — Cerebral softening is, as a rule, less dangerous to life than cerebral hemorrhage, and much less frequently can it give rise to sudden death. Hunt³ notes a case where embolism of the only large artery that supplied the brain did not cause death for several hours. As with hemorrhage, sudden death occurs chiefly from thrombosis in the arterial supply of the cerebellum, pons, and medulla, and thrombosis of these arteries is far less common than hemorrhage from them. Out of fifty fatal hemorrhages Dana found the average duration of life to be a week, if the hemorrhage were not ventricular, but with softening the duration was from one to ten weeks.

Abscess. — Cerebral abscess need be mentioned only to note the relatively rare occurrence of rupture of its contents into the ventricle, which may give rise to sudden or speedy death, as in hemorrhage.

Tumor. — It is not unusual in cases of cerebral tumor to see come set in, without any apparent cause, and death to ensue in a comparatively short time, twelve to forty-eight hours. The cause of such a condition is uncertain; but it is very likely due to vascular changes. Only in the rarest cases may some vascular change in a new growth close to the vital centres lead to sudden death.

Encephalitis. — The few cases of acute hemorrhagic inflammation of the medulla to which Wernicke has given the name of acute polioencephalitis are the form of encephalitis in which we should most naturally look for sudden death, but even here death has occurred only after an illness of several days.

Sclerosis. — In disseminated sclerosis and in general paralysis of the insane, pseudo-apoplectic seizures and convulsions are not infrequent, and they may bring about death. Sudden death, however, is in all probability extremely rare from such a cause.

Insanity. — Sudden death is occasionally seen in

cases of acute mania, but it is due to conditions outside of the nervous system, and need not be considered here.

IV. NEUROSES.

Convulsions. — Beside accidental causes, such as asphyxia and injury, death may occur suddenly, in very rare instances, in the epileptic fit. The precise cause is unknown, but there is probably some profound vascular disturbance. It is not, however, solely in the true epileptic fit that sudden death may occur, but also in the fit due to gross cerebral lesions, tumor, general paralysis, or multiple sclerosis; and Raynaud⁴ reports a case of death from spasm of the larynx and pharynx in what was probably an hysterical convolution.

Exophthalmic Goitre. — In this affection death is occasionally sudden, and the cause is obscure. Recent hypotheses as to the nature of this disorder tend, however, to remove it entirely from the diseases of the nervous system; and, considering the profound cardiac disturbance, it is most probable that sudden death is due to some affection of the heart.

Shock. — Finally, we must speak of those cases of sudden death from emotional disturbance, from slight injury, etc., which are usually ascribed to "shock." The nature of the process is far from understood, but it is usually ascribed to inhibition of the vagus centre from cortical or reflex stimulation, and in some unknown way the nervous system plays a part.

From this very imperfect review we see, therefore, that sudden death may ensue from certain disturbances of the nervous system, — vagus neuritis, hemorrhage, convulsions and shock. Excluding the first of these, for reasons already given, we find that the chief and by far the most frequent cause is hemorrhage, and that when hemorrhage into the central nervous system causes sudden death, its seat is almost always in the brain, involving the important centres in the brain-stem. Speedy death may arise from various other conditions, — spinal hemorrhage, softening, new growths or sclerotic processes.

In the ultimate analysis, therefore, we find that sudden death in so-called affections of the nervous system, is to be referred not to changes in the nervous system itself, but to changes in the vascular system — the system primarily responsible for the majority of cases of sudden death.

At the beginning of this century apparently many of the cases of sudden death were attributed to apoplexy. As a matter of fact the nervous system is apparently responsible for only a few of the cases. Such few statistics as I have been able to gather are of old date, but they may be of interest.

Granville,⁵ found in the English reports from 1847 to 1851, 17,478 cases of sudden death, out of a total of 2,028,145, nine-tenths of one per cent. or one in one hundred and sixteen. Francis⁶ out of 733 deaths of persons over ten in the Manchester work-house found nineteen, or one in 38.57 which were sudden, within a quarter of an hour. Of these three died of apoplexy, and two of epilepsy. Derville,⁷ in forty cases of sudden death at the Paris morgue found one from hemorrhage into the pons, three from meningeal hemorrhage, two from "serous apoplexy with pulmonary

congestion," and three from "cerebro-spinal congestion." Only four of these can certainly be assigned to the nervous system. Out of seventy-four cases of apoplexy collected by Dana only one involved the pons and three the cerebellum, and sudden death was not noted.

It is probable, from these figures, that not one death in a hundred is sudden, and only about one-tenth of these are to be attributed to affections of the nervous system.

Clinical Department.

SOME ANOMALOUS CASES OF SCARLATINA.¹

BY J. RICHMOND BARSS, M.D., MALDEN, MASS.

I OFFER the following cases of scarlatina as interesting from a diagnostic point of view, important from a sanitary standpoint, and possibly of value to the younger members of the profession. Every gentleman present, of course, claims to be able to diagnose a case of scarlet fever, yet each one probably has had at times grave doubts as to the lesion, or even failed to make a correct diagnosis through lack of symptoms or sufficient data of local conditions to fill in the missing link. While two of the cases I am about to report are records of my own blunders, fortunately harmless both to patients and myself, I trust they may be a reminder to you, if caught under circumstances which might be more deleterious to your reputations; bearing in mind two medical friends—both capable men—who suffered more or less professional injury from false diagnoses in somewhat similar cases. To those who have made these errors, certainly to myself, comes like balm to the wounded pride, the statement of a German author who says, "one of the most remarkable peculiarities of this disease is the great variety of symptoms which it presents; a variety so great, in fact, that in consequence of the lack of sufficient evidence, there is still some doubt whether some of its forms should be included under the general designation of scarlet fever."

These reasons, and the fact that these different forms occurred in one family at the same time, seem to me to make them worthy of report. On August 16, 1891, Annie C., aged fifteen, with very fair sanitary surroundings, was taken with sore throat, which grew worse, and on the 18th, I was sent for.

I found her with temperature 102° F., and a follicular inflammation of both tonsils, no symptoms other than those of an ordinary case of tonsillitis, no eruption, no enlargement of lymphatics; ordered a gargle and phenacetin to relieve fever. Next day, 19th, found temperature nearly normal, about 99.5° F., and throat so much improved that parents thought it unnecessary for me to call again. On the second day, namely, the 21st, was sent for to see a younger child, Mary, aged seven, who had had attacks of vomiting during the day, and found temperature of 103° F., with an eruption over different parts of body, photophobia, and sneezing a good deal, no sore throat; made a diagnosis of measles; the next day I felt confirmed in my diagnosis, in spite of the fact that I now learned that there had been several cases of scarlet fever in the neighborhood, and that a child had been visiting at the house, said to be convalescing from

measles, but with anasarca, peeling and other symptoms to forcibly remind me of scarlatina. Still, I believed my case to be measles, and reported it as such. On the 26th, while still attending Case II, I was asked to see the brother, Tim, aged fifteen years, who had been purging and vomiting for several days and whom I found so thoroughly jaundiced, that he looked as dark as an Indian. The 27th he began to complain of fever and sore throat, and on examination, I found, in spite of the hue of the skin, a well-marked scarlatinal eruption. I then began to reinvestigate Mary, Case II, and found her eruption had gone, but that her temperature had kept up pretty well, averaging 101.5° F., with very rapid pulse, no swelling, no albumen, but quite sick with acute articular rheumatism, affecting wrists, knees and ankles. At this time, Annie, Case No. I, had recovered from her sore throat and was feeling well, her urine was found free from albumen, but some of the lymphatics of neck were slightly enlarged and the skin on ends of the fingers began to peel in very large flakes, so that they were very tender, no desquamation on other parts of the body. On the 28th, namely, seven days after first visit to Case II, she also began to peel, and on left half of back and belly had a liberal crop of varicella-like vesicles or pustules.

This, in brief, is the history of these cases which were all undoubtedly cases of scarlatina. No. I was probably a case of scarlatina without eruptions, the enlarged lymphatics and marked desquamation pointing to this conclusion; No. II was probably what Thomas means, when he says: "The exanthem may be very unlike the normal eruption of scarlatina, as, for instance, when it consists in discrete large roseola," this was probably the condition that I mistook for measles. The pustular eruption can be accounted for by the fact that "now and then the scarlatina eruption is followed by other forms of cutaneous disease, as herpes labialis, acne, urticaria, pemphigus, ecthyma, varicella-like and pustular eruptions, etc.; there is no connection, however, between them and the scarlatina exanthem; they belong to the domain of complications and sequelae"; as also the slight apparent rheumatism in Case No. II, which passed away in about a week. These cases all finally recovered.

Medical Progress.

RECENT PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

(Continued from No. 21, page 531.)

GASTROSTOMIE A LA HAHN.

V. HACKER reports two cases in which he followed the technique recommended by Hahn, of Berlin,² and placed his opening in the left eighth intercostal space. He found that the gastric fistula in this position was always above the level of the stomach contents, whether the patient was sitting, standing or lying, and that it also formed practically a diverticulum from the anterior wall of the stomach. He would choose this site for operation for those patients who would require the permanent use of a gastric fistula. The action of the ribs in closing the opening when

¹ Read before the Malden Society for Medical Improvement.

² Boston Medical and Surgical Journal, 1890, vol. xxii, 320.

not in use was effective only when the intercostal space was narrow and the fistula small. This required the introduction of a Nélaton catheter at each feeding. There was found difficulty in preventing pressure necrosis of the ninth costal cartilage. This was noticed in both v. Hacker's cases, and is exceedingly liable to occur if a tube is allowed to remain in the intercostal space for any length of time.²⁹ V. Hacker also reports the results of twelve cases of gastrostomy³⁰ where the operation was performed according to his plan for forming an external sphincter to the gastric fistula by making the external opening through the fibres of the rectus muscle.³¹ He prefers the "delayed" opening of the stomach, also a small fistulous opening, and says that primary union is necessary since suppuration destroys the sphincter position and action of the muscular fibres. All of v. Hacker's cases bore the operation well. It is also shown that a suitable apparatus for closing the opening, notwithstanding its continual dilating effect, can be permanently worn in the fistula without dilating the opening and without leaking of gastric contents or causing eczema. Girard has also operated through the rectus.³²

THE SURGICAL TREATMENT OF PYLORIC STENOSIS, WITH A REPORT OF FIFTEEN OPERATIONS FOR THIS CONDITION.

N. Senn,³³ after a careful record of these cases, submits the following propositions for consideration and discussion:

(1) Pyloroplasty, as devised by Heineke-Mikulicz, is the safest and most efficient operation for cicatricial stenosis of the pylorus.

(2) Pyloreotomy in the treatment of carcinoma of the pylorus is a justifiable procedure when the disease is limited to the organ primarily affected and the patient's general condition furnishes no contra-indication.

(3) Gastro-enterostomy by the aid of large, moist, perforated plates of decalcified bone should be resorted to in the treatment of malignant stenosis of the pylorus as soon as a positive diagnosis can be made; and a radical operation is contra-indicated by local or general conditions of the patient.

In this connection the article entitled "Contribution to the Surgery of the Stomach," of Navarro, a valuable abstract of which has been written by Pick,³⁴ is of interest.

OPERATIVE TREATMENT OF INTESTINAL STRICTURE AND STENOSIS.

König (Göttingen) reports a group of 14 laparotomies done during the past ten years for intestinal stenosis due to intestinal tumors.³⁵ The cases are classified as follows:

Constriction from a band, 1. Diseases of the intestine, 13 (cancer 10 — colon descendens 4, cæcum transversum 3, colon transversum 2, colon ascendens 1); sarcoma small intestine 2; tuberculosi 1. There were 13 operations: 3 exploratory only; 3 artificial anus, 3 deaths; 7 intestinal resection. Of these seven cases, immediate suture was performed on four, with

²⁹ Wien. Klin. Wehnschr., 1890, III, 43.

³⁰ Wien. Klin. Wehnschr., 1890, III, 38-37.

³¹ Surgical Reports: Boston Medical and Surgical Journal, 1887, vol. cxvi, 257.

³² Surgical Reports: Boston Medical and Surgical Journal, 1888, vol. cxix, 200.

³³ New York Medical Record, November 7 and 14, 1891.

³⁵ Centbl. f. Chir., Beilage, 1890, No. 25.

two deaths; the gut could not be united and an artificial anus was made in three instances, all of which resulted fatally (two died immediately and one from recurrence one year after operation).

The cancerous tumors being in the colon were next to the abdominal wall and movable; if adherent, could be mistaken for tumor of abdominal wall. The symptoms are varied; sometimes increasing constipation, colic-like pains from accumulation of fluid above stenosis or by invagination in vicinity of growth. Hemorrhage only in one-half the cases. Operation is the only effective treatment, and in resection with immediate union by suture, or an artificial anus, or an artificial anus without resection. König prefers to open the abdomen over the tumor. The tumor is exposed, freed, brought outside the abdomen, and operated there. Mesenteric glands should be removed if possible. In uniting the resection wound he sutures the mucous membrane, then superimposes the usual suture of the muscle and serous coats.

INTESTINAL ANASTOMOSIS BY MEANS OF VEGETABLE PLATES.

Dawbarn³⁶ has brought forward a serviceable emergency plate.

A pair of the potato plates can be made, he states, by his method in ten minutes. The material can always be procured. It has no tendency to swell; it is rigid, and remains so longer than the majority of other materials devised for this purpose. For use upon the human gut the plate should be made about one-third of an inch in thickness, and should be cut so long that the opening is about twice the normal diameter of the gut to be operated upon. To prevent the threads from cutting through, they should be very coarse, and the needle before passing through the plate should transfix a scrap of rubber drainage-tube or a minute bit of cloth, which, by its broad surface, prevents the large knot tied on the end of the thread from pulling through. Instead of first making the incisions into the gut, which subsequently serve as the artificial opening, the plate is inserted into the lumen of the bowel, through its divided end and the needles are made to traverse the gut-wall at their proper positions. When the two plates are thus placed in the two extremities of the bowel, at least two inches from the cut extremity, the corresponding threads of the two plates are tied together, thus apposing the two peritoneal surfaces covering the plates. These surfaces previously should be well scraped with a knife, so that prompt adhesions may take place. After the plate-threads are tied, at least one line of sutures should be run around the plates, great care being taken not to pass the needle into the lumen of the bowel. The author prefers a basting-stitch, since it is easier to apply, employing three stitches to the inch. When these stitches are placed, a strip of wood is passed into one open gut-end; this is for the purpose of cutting against; the opening is then made through the apposed gut-walls enclosed by the rings. To do this a scalpel is inserted into the unoccupied open end of the gut, and as long an anastomotic opening is made as the plates will allow. The strip of wood prevents cutting too deeply. After this incision is made, water should run freely into one end and out the other. Under gentle hydrostatic pressure for a few minutes, the outlet end closed with the finger and thumb, the

³⁶ New York Medical Record, vol. xxxix, No. 26; American Journal of the Medical Sciences, September, 1891, vol. ci, No. 3.

line of suture will not leak if properly made. The free ends of the bowel are next scraped, inverted, and secured in this position by a double line of running sutures. Finally a stitch or two fastens together the blind ends and the gut against which each rests, first scraping the opposed peritoneal surfaces. This prevents the possibility of another loop forcing its way into this angle with the result of undue tension of the stitches at the plate-ends.

LAPAROTOMY FOR INTESTINAL PERFORATION IN TYPHOID FEVER.

Still another case is recorded of recovery following this operation. Dr. Weller Van Hook²² answers the question, "Shall laparotomy be performed for intestinal perforation in typhoid fever?" by recording a successful case. Besides this, he records two unsuccessful cases, making to date, 19 recorded laparotomies with four recoveries. Van Hook's conclusions with those of Dr. R. H. Fitz in a thorough *résumé* of the subject read at the 1891 meeting of the Association of American Physicians are already published.²³

CIRCULAR ENTERORRHAPY.

Paul,²⁴ in cases in which end-to-end apposition is indicated, employs a decalcified bone-tube from an inch to an inch and a half long, from one-half to three-fourths of an inch in diameter, and from one-sixteenth to one-eighth of an inch thick, the lower end of which is perforated for suturing the proximal end of the bowel to it. A double thread, carrying a needle, is fastened to the tube to facilitate invagination. The tube is entirely introduced into the proximal portion of the bowel, the free margin of which is sutured to the tube through the perforations by means of fine chromicized catgut. Care should be taken to include in the suture the severed edges of the mesentery. Next, the needle armed with the double thread is introduced on a director into the distal segment of bowel, and, at a distance of three inches, made to emerge through the wall of the intestine. Then the distal end is sutured all around to the proximal end through the muscular and serous coats by means of chromicized catgut, special attention being again given to the mesentery. An assistant now makes traction on the double thread and resists the operator as he draws the distal end of the bowel back over the tube, thus invaginating the proximal end. The parts are retained in position by a few Lembert sutures, one on either side of the mesentery, and others as needed. The double thread is finally drawn tight and cut off short.

LAPAROTOMY FOR ACUTE INTUSSUSCEPTION.

Dr. D. Farquhar Curtis²⁵ records a case of operation for this condition, and adds to his former statistics as follows:

He states that in the series of cases which he reported in the Transactions of the New York State Medical Society, 1888, there were 70 cases operated upon from 1873 to 1887 inclusive, in which the mortality was seventy-six per cent. I find that there are now on record 105 cases, with a mortality of seventy per cent, — a very encouraging improvement. It also appears that out of 65 cases in which the intussusception could

be reduced only 38 died, a mortality of fifty-eight per cent. — among the children the mortality was sixty-six; among the adults forty-seven per cent. Of 17 cases in which the affected bowel was resected and sutured, only two recovered, both adults. Of 16 cases in which an artificial anus was made (with or without reduction or resection of the intussusception), two cases recovered, also both adults.

These figures show that prolonged operations are almost invariably fatal, and furnish another argument against delay, for that is the usual cause of the conditions which render operations difficult. Delay is also responsible for the high mortality in these cases, for nearly all the patients are recorded as being in very bad condition, or even in collapse, at the time of operation. Laparotomy, to give good results, must be performed as soon as systematic efforts to reduce the intussusception with rectal injections have been made without success. We must constantly bear in mind both sides of the shield; there is danger in performing laparotomy for intestinal obstruction, but there is also danger in postponing it until it must be undertaken as a last resort.

RESECTION OF THE APPENDIX VERMIFORMIS DURING THE QUIESCENT STAGE OF CHRONIC RELAPSING APPENDICITIS.

After a careful study of reported cases of operation on the appendix vermicularis,²⁶ Weir summarizes the subject as follows:

(1) That the final outcome of the review of these cases has been that the large majority of current attacks are due to catarrhal appendicitis, which, though to an unknown degree capable of producing explosive and serious peritoneal inflammation, yet generally, from the lumen of the tube being previously shut off from the cecum, limits correspondingly the chances of fecal or severe infection of the peritoneum.

(2) That the simple catarrhal appendicitis can be suspected when the recurrences are frequent, that is to say, more than four or five times, as in the acute processes this is seldom exceeded — and when such attacks are not of a severe type, nor of greater duration than a week, and particularly so if there be no appearance of a distinct tumor.

(3) In such cases delay in operating may be encouraged to a reasonable extent, at least until it is indubitably proven that the invalidism is a confirmed one. Out of five cases seen by Weir in the last year for recurrent attacks of appendicitis, in three, of the above described simple form, it was advised to wait until the next acute attack presented itself as a further justification of surgical interference; but this did not occur in any of these. In the two others, from the persistent invalidism or the severity of some of the attacks, an operation was advised.

(4) Where a tumor is present in the quiescent stage, or has been decidedly felt after the acuteness of the attack has passed off, more urgency is present, as it indicates, it is believed, either an accumulation of noxious contents or of ulceration within the appendix, or an already present small perforation. It is in such cases that Mackenzie says that we can expect, if an acute process is subsequently set up, that it will be a circumscribed rather than a general suppurative peritonitis. The frequent conjunction, in the collected cases, of adhesions with the severer forms of the catarr-

rhal appendicitis with retained secretions or with minute perforations, seems to corroborate this view.

(5) That as the diagnosis of the separate condition of simple catarrhal appendicitis and its complications of distention from retained fluids and of ulceration, are not at present to be differentially diagnosed, and as it has been shown that each case can give rise to dangerous conditions, recurrences of severity and frequency should hereafter mean that an exploratory laparotomy should be resorted to, on the general principle of this being of less risk than the disease itself.

FIRST DAY.—AFTERNOON SESSION (CONTINUED).

MID-SYSTOLIC AND LATE SYSTOLIC MITRAL MURMURS,

by J. P. CROZIER GRIFFITH, Philadelphia.

By mid-systolic and late systolic mitral murmurs are designated those which have the area of diffusion of the ordinary mitral regurgitant murmur with the symptoms of the disease, but which occupy only the middle or latter portion of the systolic period. I report three cases. The first, that of a woman of twenty years, who had suffered from rheumatism and had the ordinary symptoms of mitral regurgitation. Auscultation showed a loud and very musical murmur which occupied only the middle portion of the period between the time of the apex beat and the first sound. It was sharply separated from both the first and second sounds. The area of diffusion was purely that of mitral regurgitation; the pulmonary second sound was accentuated and there was enlargement of the right ventricle. The second case was that of a man of seventy-two, who had for some years suffered from the symptoms of regurgitation through the mitral orifice. Auscultation showed a murmur which did not begin until the latter portion (rather less than one-half) of the systolic period. It ran up to the second sound but did not supplant it. It possessed purely the area of diffusion of mitral regurgitation. The right side of the heart was enlarged. On certain occasions, when examined, the murmur was very short and very close to the second sound. The third case was that of a woman of forty-seven years who had had severe muscular rheumatism but no subjective cardiac symptoms. Auscultation showed a high pitched, systolic, slightly musical murmur which occupied the latter half or two-thirds of the systolic period and ran up to but did not replace the second sound. The murmur occupied the area of the murmur of mitral regurgitation and the second sound was accentuated. The right side of the heart was enlarged. The form of murmur just described is certainly very unusual, and the literature shows but occasional and indefinite references to it, generally under the title of post-systolic murmur, which involves a misconception of its nature and cause. The term post-systolic could apply only

on the theory that the systolic of the ventricle lasted only to the beginning of the short silence and that this silence corresponded to the relaxation of the ventricles and the time supposed to be required for the aortic valve to close. This would place the second sound not at the beginning of the diastolic period but at an appreciable time after the beginning. Several observers from the study of cardiographic tracings have indeed maintained that such was the case. This, however, involves the assumption of the existence of a physiological aortic regurgitation produced by the blood in its recoil upon the aortic leaflets passing backwards through the orifice in the process of rapidly closing. Such an assumption as this seems contrary to the perfection which we have learned to expect in Nature's apparatuses. I have long believed that there existed no appreciable time during which a murmur could occur between the relaxation of the ventricle and the occurrence of the second sound.

The recent studies of Martius with the cardiograph and the interesting investigations of Ceradini made years ago prove that such a physiological regurgitation does not exist. Ceradini showed that as the blood ceased streaming out of the ventricle, a reverse whirl of that in the aorta brought the semi-lunar leaflets into closer approximation so that the recoil when it did come with the first relaxation of the ventricle found them in perfect apposition and simply put them on the stretch, thus producing the second sound. The existence of this "persistence time," as it is named by Martius, that is, the time during which the ventricle simply remains contracted after the blood is expelled is rather short to permit of closure without regurgitation. This theory renders impossible the existence of a murmur just before the second sound, due, as Skoda and others maintain to the friction of blood on the roughened aortic walls during this recoil upon a competent aortic valve.

Adopting the view that the second sound marks the beginning of diastole, murmurs heard before it must of course be systolic and the cases which I report, all having murmurs heard in the mitral area, can with good reason be regarded as cases of mitral regurgitation. The first case is an interesting example of mid-systolic mitral murmur analogous to the mid-diastolic mitral murmur of Bristowe. The last two cases, and especially case second, are interesting in that they offer clinical proof of the view that the systole lasts quite up to the second sound. They prove too that the "persistence time" must be of exceedingly short duration as indeed Martius admits.

The production of these mid- and late-systolic murmurs admits of different explanation, depending upon the area of diffusion. In the cases reported they must, I think, have been due to regurgitation through the mitral orifice. It is possible that such regurgitation might have taken place only at the middle or latter portion of the systolic period. It seems probable, however, from the symptoms of the cases and the variation in the murmurs heard at different times that a much greater degree of regurgitation occurred than the murmur alone would indicate. This murmur is probably analogous to the potential pre-systolic murmur described by Bristowe and it is likely, I think, that the regurgitation lasted through all or nearly all of the systolic period but usually became audible, for unknown reasons, only toward the middle or latter portions of it.

SECOND DAY, WEDNESDAY.—MORNING SESSION.
DISCUSSION ON DYSENTERY: ETIOLOGY AND PATHOLOGY.¹

by Dr. W. T. COUNCILMAN, Baltimore, Referee.

We can divide dysentery into three forms: (1) Diphtheritic, (2) Catarrhal, (3) Amœbic.

The diphtheritic dysentery is characterized by necrosis of the epithelium and a fibrinous exudation. It is the form usually met with in acute epidemics. It may also appear in the course of a number of diseases, and may be produced by a number of causes. There is nothing in the anatomical lesions by which we may distinguish the action of a definite pathogenetic agent.

The catarrhal dysentery is characterized by an inflammation of the mucous surface of the intestine, leading to the production of shallow ulcers. Affections of the lymph follicles are more common in the catarrhal than in the other forms. What is said of the croupous is also the case in the catarrhal.

In both these forms, abscess of the liver may appear, but it is very rare.

The amœbic dysentery is characterized by definite lesions in the large intestine and elsewhere. The lesions have always the same character, and we can recognize in them the action of a common agent. There are extensive ulcerations of the intestines, which, contrary to those of the other two forms, appear to be produced, not by extension downward, from the surface, but by a primary infiltration of the submucosa, with subsequent destruction of the overlying mucous membrane. Clinically, the disease is characterized by remissions and great chronicity.

Abscess of the liver and lung is more frequent in amœbic dysentery.

The disease is caused by the amœba dysenteriae. It forms the most of the cases of tropical dysentery.

DISCUSSION ON DYSENTERY: SYMPTOMS, COMPLICATIONS AND TREATMENT,

by Dr. A. BRATTON BALL, New York, Co-Referee.

Differential symptomatology of (1) Catarrhal colitis, (2) Diphtheritic colitis, (3) Amœbic colitis, (4) Secondary colitis.

Absence of "dysenteric" symptoms in certain cases.

The marked tendency to anæmia and its causes.

(The symptoms and treatment of dysenteric, hepatic and hepato-abscess will be omitted, as they are to be fully treated by Dr. Dabney in his paper on "Hepatic-Abscess.")

Malarial complication, its frequency, symptoms and diagnosis.

The arthropathies of dysentery, their symptoms and pathology.

Dysenteric paralyses, their symptoms and pathology. The *Ipecac Treatment*.—Of late years physicians in India have become less enthusiastic about the advantages of large doses, and more comprehensive of their depressing effect. They have not lost faith in the ipecac treatment, but advocate its use in smaller doses. In this country the treatment has never secured a firm foothold, partly on account of the frequency with which depressing effects have been met with, and partly because the superiority of this over less objectionable methods has not been demonstrated

for the dysenteries of this country. Many recent writers who discard the large doses recommend the drug in amounts sufficient only to excite slight nausea (two or three grains), or in still smaller doses, (one-fourth of a grain every half-hour), as suggested by Loomis. The author's preference is for this method.

Opium Treatment.—After citing various authorities for and against opium, the author says the use of opium in dysentery as an antiphlogistic, is not based on known properties of the drug, and the mere fact that patients survive even large doses does not counteract the strong objections to such an employment of it. It destroys the appetite, impairs digestion, favors the retention of decomposing and fermenting products, and can be justified only by a clear demonstration of its superiority over other less hazardous methods. Such proof we certainly do not possess.

Purgatives.—Probably most, if not all, of the good effects from purgatives come from the cleansing of the intestinal canal. For this purpose it probably matters but little, which of the milder purgatives is used. Some prefer the salines, others castor oil. The latter is disagreeable to sensitive stomachs, and has no special advantages. Purgation in acute cases every second or third day is all that is required. It is objectionable in adynamic cases and unnecessary in the not infrequent cases with diarrhoeal rather than dysenteric dejections.

Calomel.—This drug has of late years fallen into general disfavor. Dr. H. C. Wood, however, says that in his hands it has yielded better results in acute stenotic dysentery than any other remedy.

Corrosive Sublimate.—The best results are obtained from this in acute cases, especially in those in which the stools are bloody and slimy. It should be given in small doses (one hundred and twentieth to one sixtieth of a grain hourly), with or without one or two drops of laudanum.

Bismuth Subnitrate is probably useless for arresting the morbid process in its early stage, but when the stools have become diarrhoeal in character, this remedy has a certain value from its sedative, astringent and possibly its antisепtic effects.

Salol.—Very favorable reports from its use have been made in recent years.

Nitrate of Silver, solution of the pernitrate of iron, tannic and gallic acids, catechu, krameria, and haematoxylon are useless, and may be even injurious in acute dysenteric affections, but are often valuable in chronic forms.

The local treatment by topical applications to the rectum, or by flushing the entire canal below the ileocecal valve, has grown rapidly in favor in late years. The favorable reports with medicated solution have been due in large measure to the sedative action of the heat or cold, and to the mere removal of the irritating material from the surface of the mucous membrane. In the author's hands, no topical application has proved so efficacious in chronic dysentery as large enemas of nitrate of silver, one or two grains to the ounce.

Dietetic Treatment.—Although no article of food agrees so generally with these patients as milk, yet this diet needs careful watching. The stools should be examined habitually for undigested curds; and when these are present, the milk must be reduced in quantity, or given in another form, or abandoned entirely, at least for a time.

Meat.—In cases of long standing the patients are

¹ Dr. Councilman's paper will appear in full in an early issue of the Journal.

always anaemic, and full nutrition is essential. In no way can this indication be met so well as by meat, in an easily assimilable form, such as scraped meat, raw or partly cooked, salted and peppered to the taste of the patient; or, when bread can be digested in small quantities, scraped-meat sandwiches with the thinnest possible layers of bread, or even tender cooked meats in the usual form, when the patient can be relied upon to masticate them perfectly.

TREATMENT OF ACUTE DYSENTERY BY ANTISEPTIC COLON AND RECTAL IRRIGATION,

by Dr. W. W. JOHNSTON, Washington.

The adoption of a rational and successful plan of treatment in dysentery must be based upon a consideration of

(1) The localization of the disease in the colon and rectum.

(2) The intensity of inflammatory process, and rapid infiltration of tissues.

(3) The tendency to early ulceration, and to necrosis and extensive destruction of tissue; the decomposition and retention of decomposing solids and fluids in the bowels, with the resulting danger of auto-infection.

(4) And lastly, the probable dependence of all these conditions upon the introduction of a parasite, which finds its most favorable field for growth and multiplication with the resulting production of a chemical poison in the colon and rectum.

The condition of the colon and rectum in dysentery:

Retention of decomposing fluids within the rectum, from imperfect emptying of the cavity and spasmodic contraction of the sphincter; rectum is never completely emptied.

Advantages of the irrigation treatment in this connection.

Reference to the history of the treatment of dysentery by (a) cold and warm water irrigation; (b) by antiseptic irrigation. Reference to recent successful reports on this method of treatment.

Methods of irrigation and antisepsis of the colon and rectum. Injection, not irrigation.

DR. DABNEY's paper on

HEPATIC ABSCESS

was based chiefly on a study of 108 cases of this disease, which had been collected from various sources. When considering the causes of this affection, however, he called attention to the great rarity of any connection between diseases or injuries of the head or of the bones and abscess in the liver.

It would appear also, from the cases which he has collected, that while a large proportion of hepatic abscesses are due to diseased organs connected with the portal system of vessels, there is also a large proportion in which no evidence of disease or injury of any of those organs was forthcoming.

So far as any light can be obtained from an analysis of these cases, it would seem that the abscesses due to dysentery may be either large or small, single or multiple, and that very little information can be obtained as to the number and size of the abscesses in a given case from a knowledge of its cause. He states also that abscesses due to injury are not as apt to be adherent to the abdominal walls as would naturally be supposed, nor are there any definite symptoms or signs which will show whether such adhesions exist in a

given case. Pain and tenderness and œdema of the skin over the liver, which have been thought to show the presence of adhesions to the abdominal wall, were absent in some of the cases which he collected in which adhesions existed; and, on the other hand, they were present sometimes when there were no adhesions.

In considering the symptoms and signs of hepatic abscesses, he calls attention to the fact that large abscesses may exist without giving rise to any symptoms or signs during life; and he shows by reference to cases occurring in his own practice and to others reported by Councilman and Laffleur that aspiration sometimes fails to reveal the presence of pus even when a large needle is used and the abscess cavity is entered by it. He refers also to the influence of the number of abscesses which may be present or the propriety and result of operative measures of treatment, and considers free incision and drainage indicated in all cases where pus is present, unless it is being freely discharged, and there are no evidences of absorption, or unless the patient's general condition is such that no operative treatment even of the simplest character, would be safe.

He compares the results of aspiration on the one hand, and incision and drainage on the other, and shows that the latter is by far the best mode of treatment.

SECOND DAY, WEDNESDAY. — AFTERNOON SESSION.

A CASE PRESENTING THE SYMPTOMS OF LANDRY'S PARALYSIS, WITH RECOVERY,

by DR. F. T. MILES, of Baltimore.

A man aged thirty-three, well built, rather corpulent than muscular, temperate in all his habits, and accustomed to lead a quiet life; previously in good health. On November 26, 1891, he took cold. On November 28th, he got wet by rain. During this time he had at intervals pain in the calf of the leg. About December 1st he observed "a cold feeling across his toes, also the same cool feeling in the left upper lip." December 6th, on attempting to go up-stairs, found he had not power to raise the left leg from one step to the other without serious exertion in the way of dragging it. In a few days took to his bed, being unable to "hobble around any longer." The feeling of coolness and numbness continued to get worse and to extend upwards on his legs to the knees and also invaded the hands and arms to the elbows, the muscular power steadily failing from the lower extremities upwards.

On December 17th his condition was as follows: The lower limbs completely paralyzed, but not emaciated or flabby. The muscles of the trunk and belly were greatly weakened. Hands and arms quite weak, with a tendency to the position of wrist-drop. Shoulder movements good. The face was not affected. Sensation was apparently normal except that the sense of tickling in the sole of the foot was nearly or quite lost.

Power of localizing correctly any point of the foot touched was retained. Farado-cutaneous sensibility apparently normal. Could distinguish hot and cold objects. No pain elicited on pressing the muscles. Reflexes, both superficial and deep, completely lost. To the faradic current the muscles responded normally. To the galvanic current the muscles responded normally, contracting quickly without a sign of degenerative reaction, with no quantitative or qualitative al-

teration. The muscles also contracted from nerve stimulation. The sphincters absolutely intact.

After this, for three or four days, paralysis increased in the upper extremities until he could no longer use his hands. The abdominal muscles became so weak that he could not cough. The facial nerves now became involved in all their branches, most markedly on the left side. He could not frown, could not close the left eye, could not whistle. His breathing became oppressed and he had several attacks of threatened suffocation. The heart was not affected either in frequency or force.

At this point the progress of the disease seemed to be arrested; and then improvement, especially of the respiratory symptoms began, and proceeded somewhat rapidly, the face and arms recovering first. On the first of January, 1892, he could raise himself in bed; on the 7th, sat up on the side of the bed; next day, dressed himself; on the 14th, was able to walk alone; and on the 20th, was able to leave the house. About a month later his limbs were not thinner than natural, though still a little weak. The patella reflex was still absent.

A CASE SHOWING THE SYMPTOMS OF LANDRY'S PARALYSIS, RECOVERING,

by ALEXANDER MCPHEDRAN, Toronto.

George E. W., a clerk, aged twenty-six. With the exception of malarial fever fifteen years ago, has always been healthy.

His present illness began December 2, 1891. For three or four days before this, he noticed some uncomfortable sensations in the feet, which he supposed due to his boots. On the evening of December 2d, after stooping to close the safe, he found it difficult to rise again to the erect position. Next morning, on rising he found his legs very weak; was able to dress and walk down-stairs, but had immediately to lie down on a sofa. While dressing, he first found trouble in his hands; some muscular pains in forearms and shoulders. Electrical reaction normal.

December 4th. Paralysis of all the extremities complete; those of trunk and neck also involved, so that the head could scarcely be raised from the pillow. Speech, swallowing and breathing unaffected; sensation normal; bladder and rectum acted normally; knee-jerk absent.

December 10th. No change noted in symptoms until to-day, when speech became somewhat thick.

December 12th. Swallowing slightly affected, so that there was considerable difficulty in taking soft food. This difficulty soon improved and disappeared in a few days.

December 13th. Some pain in lumbar region; relieved by heat. It recurred frequently for a week.

December 20th. Reflexes still absent; no wasting; no tendency to bed-sores; able to move the hands and forearms slightly.

January 1, 1892. Power of motion has returned in all the extremities to a slight degree, being most advanced in the upper. He is able to maintain the sitting posture in an arm-chair, and can hold the head erect for a few minutes without support. Knee-jerk quite distinct in right and very slightly developed in left knee.

February 3d. Able to walk a few steps unsupported; uses his hands freely, though the muscular power is still very weak.

He continued to improve and was soon able to walk freely; knee-jerk became somewhat exaggerated; no ankle-clonus. Sitting with his elbows resting on the arms of his chair and fingers extended, there was marked tremor of forearms and hands while the position was maintained.

April 20th. Looks vigorous and walks well, but if he allows the knees to bend much they give way under him; knee-jerk increased. Electrical reaction continued normal throughout. The spleen could not be felt at any time, although the area of dulness was slightly increased.

DR. CHARLES CAREY reported a case presenting the same line of symptoms as the other cases reported, except that there was involvement of the sphincters, and the pulse ran up to 130 beats per minute. The paralysis began in the lower extremities, below the knee, and crept up gradually, the abdominal muscles and both upper extremities becoming involved. There was much respiratory difficulty; deglutition as well as articulation became absolutely lost; she was able to whisper, but there was no phonation. There was no loss of sensation. This patient has made a complete recovery, improvement beginning above and gradually extending down the entire body. The case was seen by several eminent specialists, who all agreed that it was a case of so-called Landry's paralysis, or acute ascending paralysis.

DR. W. H. THOMPSON: It seems to me that the involvement of the sphincters rather excludes this case from Landry's paralysis. I have had one case in which the usual course of rapidly-developing ascending symptoms, ending in death, occurred, and in which nothing in the shape of peripheral neuritis nor any centric lesion was found by Professor Delafield, who made the post-mortem. A case now in Bellevue Hospital has an interesting history. He was paralyzed first in the left leg, then in the right, then in the lower part of his body, then in both arms; then difficult respiration occurred, and there was entire paralysis of the lower jaw. No trouble with micturition or bowels. These symptoms all passed off, except some weakness in mastication and moderate weakness in the upper extremities, the right being more affected, and permanent weakness in the lower extremities. His gait is neither ataxic nor paraplegic.

A STUDY OF ANESTHESIA AS A GUIDE TO THE LOCALIZATION OF LESIONS IN THE LOWER SPINAL CORD AND CAUDA_EQUINA,

by DR. M. A. STARR, New York.

Necessity of careful examination for small areas of anesthesia in lesions of the lower spinal cord.

Collection of eighteen cases (six original), in which small, peculiarly shaped areas of anesthesia were present, and in which the situation of the lesion could be determined either by autopsy, or at operation, or by other symptoms.

From these cases an attempt is made to assign to each segment of the sacral and lumbar segments of the cord, the area of body surface from which it receives tactile impressions. Diagrams were distributed.

A STUDY OF THE SEASONAL RELATIONS OF CHOREA AND RHEUMATISM FOR A PERIOD OF FIFTEEN YEARS (1876-1890),

by DR. MORRIS J. LEWIS, Philadelphia, Pa.

(1) Study based upon the months of onset of 1,383

separate attacks of chorea and 673 separate attacks of acute inflammatory rheumatism; 666 of the attacks of chorea occurred in Boston, the rest in Philadelphia.

(2) Comparison made with the meteorological records of Boston and Philadelphia during the same period of time.

(3) Chorea and rheumatism evidently seasonal diseases.

(4) Fewest attacks of chorea occur in October and November, and the greatest number in March and April.

(5) The greatest number of attacks of rheumatism occur in April, and the fewest in the autumn months.

(6) Considerable resemblance, in general form, of the tracings for the diseases in question to the tracings showing the number of "storm centres" passing within 400 miles of the two localities mentioned; also marked resemblance to tracings showing mean actual barometer and mean relative humidity.

(7) Close resemblance of chorea and rheumatism tracings to the record showing the monthly variation in the amount of general sickness in the community; relation probably not one of cause and effect, but both conditions due to same cause.

(8) Over-study considered a predisposing, not an exciting, cause of chorea, acting in conjunction with meteorological conditions, probably the most active etiological factor.

DR. M. A. STARR: The points that have been brought up by Dr. Lewis are pretty fully covered by statistics which I have kept for the past four years at the Vanderbilt Clinic, New York. The tables that the doctor has presented coincide quite closely with the chart that I have prepared from these cases of my own. The doctor's highest month is March; my highest month is April; his lowest months are October and November; my lowest month is December.

Regarding etiology, it seems to me that over-study is not a very decided cause of chorea. I see very few cases amongst the classes who do the most studying. I find that 65 cases are decidedly assignable to fright. We cannot trace all causes of this disease to weather nor to mental work, but must look for a number of etiological factors.

As regards rheumatism, eighteen per cent. of my cases had a distinct history of rheumatism preceding the attack of chorea. The heart was found to be normal in 199 out of 356 cases. An organic murmur was found in 64, a functional murmur, subsequently disappearing, in 56, and the heart was not examined in 37.

It seems to me that the reason why chorea occurs mostly in the lower classes and in the spring of the year is to be found in the fact that in spring those elements which are likely to produce disturbances of nutrition then culminate, — the confinement, more or less physical and mental strain, etc.

DR. S. WEIR MITCHELL: The class of cases that we deal with at the clinic of the Infirmary for Nervous Diseases is so much above the tenement-house class that the conditions that apply to one would hardly apply to the other. It is the mechanic class and those a little above them with which we have to deal, and they live in Philadelphia in an atmosphere of comfort not enjoyed by that class in any other city. I am still in doubt as to the complete etiology of the disease, but think Dr. Lewis's paper a great advance upon any knowledge we have had hitherto. I hardly believe that mental strain has much to do with the

matter. The conditions stated by Dr. Starr ought to apply more strongly to the class of blacks, and yet chorea amongst the blacks is practically unknown.

DR. HENRY: In studying the relations between chorea and rheumatism, it must be remembered that there are other manifestations of rheumatism than the articular. It is universally admitted that tonsillitis is a manifestation of rheumatism. It is believed by some that certain skin eruptions, especially erythema nodosum, is a manifestation of rheumatism. If these things are borne in mind, I think the relation between chorea and rheumatism will be found to be more intimate than at present appears.

DR. JACOBI: I believe Dr. Starr to be correct in attributing the predisposition to chorea not so much to over-study alone as to the results of over-study and similar causes. As a rule, we find that choreic patients are either underfed or are hydramic or in a condition of ill-nutrition. In the spring time the system of every one is run down, not so much by over-work but because during the winter windows are not opened and people are less exposed to fresh air.

For many years I have been of the opinion that chorea minor is to be attributed largely to acute rheumatism. Many cases of rheumatism in childhood are not diagnosed. Many of these cases have no articular symptoms. I have seen many cases in which chorea was the first symptom to appear. I have seen three or four cases in which there was an alternation between choreic and rheumatic symptoms. The so-called "growing pains" that come on every few months are often the results of rheumatism.

DR. H. M. LYMAN: In my own clinic my experience coincides with that of Dr. Starr, namely, that while the majority of cases are sickly, they are not of a class who are worrying their brains with study. In almost all cases there is a history of consumption or rheumatism or of some other cause of debility preceding the outbreak of chorea; not necessarily in the child itself, but a hereditary precession of such causes.

DR. M. J. LEWIS: The children coming to the Infirmary with chorea belong to an unusually intelligent class, and are themselves, as a rule, very intelligent.

In my experience with chorea I have seen only four colored children affected with the disease.

The rheumatism records are taken from the Pennsylvania Hospital and are all from adults. They are not taken from the same cases as chorea.

I do not see why, if the disease is due to under-nutrition it should develop just at the time in the spring when the windows are opened and the children allowed to breathe the fresh air.

DR. W. H. THOMPSON: If fright, as Dr. Starr intimates, is an element in etiology, then the statistics given us would go to show that there are more people frightened in April than in any other time of the year.

DR. MUSSER: It has occurred to me that the difference in the number of cases of chorea in different seasons of the year might partly be accounted for by the diet of the patients; thus, as winter comes on, the diet of this class of people changes almost entirely, and they live on starchy foods and meats. As a culmination of this starchy diet, the confinement of the winter and bad hygienic conditions we have the development of a large number of these cases in the early spring. As they begin to use fresh succulent vegetables and take more fluids the curve for these diseases falls.

AMERICAN MEDICAL ASSOCIATION.
SECTION IN THE PRACTICE OF MEDICINE.

FIRST DAY, TUESDAY, JUNE 7TH.

THE RELATIONS OF BACTERIO-CHEMICAL RESULTS
TO PROPHYLAXIS AND THERAPEUTICS,

was the title of a paper by DR. ROBERT T. EDES, of Boston, Mass.

The great progress of the year has been along the line of investigating the poisons which are the result of germ activity, their nature, and their effects. It has been shown that many germs produce an alkaloid, and as well a poisonous albumin or albumose. Fever itself was undoubtedly the result of some such substance, which acted by its influence on the heat-centres.

Researches also had recently been carried on regarding the absorption of nitrogen by plants from the air. It had always been supposed that this element was derived from the soil in plant formation; but certain plants, especially the bean family, can grow in a soil entirely devoid of nitrogen and yet form nitrogenous compounds. This property seemed to depend on the presence on the plant, or rather on its surface, of a certain bacillus.

Another most important topic which had received attention during the year had been that of immunity. We had come to believe that much depended on the condition of the blood, either its fluid elements (possibly blood-germs) or the leucocytes, more probably the latter. Furthermore, the products of germ action (toxine) seem, after reaching a certain degree of strength, to inhibit their own activity. An analogous illustration was seen in the power of a certain percentage of alcohol to check fermentation, though it was a product of the latter. Such a method was as yet unavailable in the human system. Koch's tuberculin was not to be condemned as a failure. It was an attempt along a line which is likely soon to witness a great and fruitful development. Closely allied to the doctrine of immunity is that of resistance to disease. We do not know why some persons can meet with impunity an exposure to which others would succumb. Animals, if starved, will be overcome by an amount of bacterial poison without effect if they were properly nourished; and, furthermore, over-feeding will enable them to withstand a much greater dose of the disease-poison. There is in each system a certain protective element which comes in contact with the product of our usual contagious diseases and destroys the toxines of the latter, thereby protecting the system from the further inroads of the same kind of poison, but rendering it more liable to succumb to other kinds. So far as treatment was concerned, emphasis was to be laid on two special points. There was great danger from the flesh and milk of tubercular animals. There was not, in the writer's opinion, much risk from mere association with phthisical patients. The latter should be cautioned against scattering their sputa around. Special attention should be paid to nutrition and climate. So far as the latter had reference to lung cases, a lofty, dry place was preferable, because the air was relatively free from germs. It also acted as a general tonic, and the increased pulmonary activity it occasioned was in itself a favoring circumstance.

All of these questions had to be looked at from a different stand-point so far as the scientific worker was to be compared with the chemical student. The pro-

blems of the sick-room were not those of the laboratory. It was difficult to free clinical work from personal errors, but we should faithfully report our results, good or bad.

IMMUNITY.

DR. KINSMAN, of Ohio, gave an account of some experiments which had been made in that State with reference to hog cholera. Immunity is, he thought, only a relative term. Our ideal should be absolute protection. Our present trouble is that our doses of remedies strong enough to kill the germ or inhibit the products of its life activity are also strong enough to harm the patient. In several of the Western States attenuated cultures of the hog cholera-germs were given to animals, with good results. They could then be pastured in fields and thrive where uninoculated animals speedily died. The culture medium used in the experiments detailed by the speaker was sterilized human urine. The fluid inoculated was diluted to about one-sixth of its original strength, the cultures being kept at blood temperature, and the sterilization of the urine being accomplished by the customary methods.

The fact was that in many of our investigations we did not know exactly what the cause of the disease was, and hence, while we approximated toward perfect immunity, we could not quite reach it.

DR. W. J. SCOTT, of Cleveland, O., thought there was some doubt as to whether in our dilution by attenuated virus we are not also altering the nature of the poison, so that we have to deal with a morbid principle different from the one which is the result of the first generation of germs. As regards the effect on the body temperature, anything which disturbs the relations of the system and the products of nutrition and waste will cause increased chemical activity, and that we know is always a source of heat.

DR. DENISON, of Colorado, had recently received a letter from Koch, of Berlin, in which the latter disclaimed ever having admitted that tuberculin was a failure. The speaker himself had unbounded faith in its future. He also alluded to recent experiments made with a piece of the thymus gland as a culture fluid. Tetanus germs had in fourteen days been rendered from three to five thousand times less powerful than the original cultures.

DR. GREENWOOD, of Kentucky, did not believe that hog cholera was altogether a contagious disease. It would skip about from one farm to another in a given locality, while animals on intervening farms were not affected. In one instance live hogs ate the bodies of their kind who had died of the cholera, and the disease was soon checked in the entire drove.

DR. S. P. KRAMER, of Cincinnati, reviewed the work which had been done by German observers during the past year with reference to immunity, laying special stress on the "anti-toxines" developed by adding to the blood of an animal one of the peculiar albumoses produced by bacterial action. If we could isolate the latter by injecting it, we could with the aid of the union with the blood cause immunity. In these experiments on animals there was always the danger that the attenuation product may revert to its original type, and so offer no stay to the ravages of the disease. It was interesting to know that if goats were thus rendered immune to tetanus, the immunizing principle appeared in the animal's milk.

ETOLOGY OF SPECIFIC DISEASE.

A paper with this title was read by DR. R. FRENCH STONE, of Indianapolis, Ind. It was a historical review of the various theories which have prevailed in times past with reference to the exact nature of specific disease. He took strong ground against the wholesale acceptance of the present products on the germ theory of disease.

RECENT INVESTIGATIONS OF THE ETOLOGY OF DIABETES MELLITUS,

was the title of a paper by DR. S. P. KRAMER, of Cincinnati.

No less than twenty-seven theories had been put forth with reference to the cause of diabetes; it had been found that the pancreas was at fault in fully one-half of all the cases. The removal of the organ in animals was always followed by the malady. If it was partially removed, the disease remained absent, providing one-tenth of the original bulk of the organ was left *in situ*. Ligation of the duct gave negative results. These results, seen in dogs, were duplicated in cats and swine, but not in birds. In dogs in whom the malady supervened after the removal of the organ, if they were fed on pancreas no relief ensued, but the latter did follow if bits of the organ were transplanted back into the interior of the abdominal wall; if they were fed on glucose it was used up in the system and none excreted, but not so with codose. As the result of a long series of experiments, Dr. Kramer expressed the belief that the organ supplied to the blood a glycolitic ferment by which the sugar in the blood was destroyed, but if the viscous was removed the absence of the ferment, which resided chiefly in the white cells of the blood, caused the glycosuria. He did not offer this as an exclusive view, the ferment was found in the blood at its maximum four or five hours after removal from the animal. Normally, the sugar of the blood combines with some albuminous principle therein for the general benefit of the system. In diabetes this does not take place.

HEPATIC ABSCESS.

DR. GEORGE E. FELL, of Buffalo, related a case of hepatic abscess in diabetes. The pus eventually opened into the gut and the diabetes disappeared. This was evidence, in his opinion, the lesions of the pancreas were not the only factor in etiology.

DR. S. SOLIS-COHEN, of Philadelphia, quoted the division of diabetes by a recent French writer into thin cases and fat cases. The pancreatic cases were in thin people, but not in the fat people. There was still another form, related in some way to the uric acid diathesis. Moreover, nowadays, the polydipsia and polyuria were more dreaded than the glycosuria. There was a malignant combination of the two former causing a fatal result even with no sugar. There was probably a group of cases here alike clinically, but differing in their etiology.

INFLUENZA.

DR. JOHN E. LINK, of Terre Haute, Ind., read a paper on "la Grippe," in which he took the ground that the disease was not a germ disease, but one spending itself principally on the pneumo-gastric centre in the medulla. He thought that all the various aspects of the malady could be explained by this view. He had noted many cases with a peculiar paleness of the

face, a milky whiteness of the tongue, and great prostration, with occipital pain, even before any active grippal manifestations came on. They had all yielded promptly to quinine and opium, but after recovery, if the former drug was stopped too quickly, they suffered severe relapses. Dr. Link doubted whether there were any real inflammatory or congestive properties belonging to true grippe. He believed we might have an inflammatory neurosis, say of the lung and bronchial tissue, with abundant serum, but it was not pneumonia. In many cases the out-pouring of the serum into the air-cells led to the death of the tissue and abscess formation. The physical signs were not like those of pure pneumonia. There was a loud moist râle in addition to the crepitus of pneumonia.

A MODIFIED FORM OF CONTINUED FEVER FOLLOWING THE EPIDEMIC GRIPPE,

was the title of a paper read by DR. JOHN H. HOLLISTER, of Chicago, Ill.

This disease had seemed to increase the severity of all our endemic maladies. He had observed following the epidemic, many cases of continued fever which had been admitted to hospital classified as typhoid. He soon began to doubt the correctness of the diagnosis. A study of fifty cases had afforded the following data: No common cause could be assigned. Previous history was negative. Some had had grippe, but the majority not. The prodroma lasted four days, with extreme muscular soreness. The onset was gradual, no chill being noticed, but the fever was continuous without intermission. The average duration was twenty-three days. Relapses were common, but could be attributed in many cases to dietetic errors. There were no head symptoms or coma, and no subsultus. In four cases there was profuse sweating, lasting over ten days. The stomach was not troublesome. Secretions were all diminished, and there were no cutical discharges. The mouth was rarely dry, tongue not fissured, and no sordes. The dorsum was milk white. There was no tympanites or abdominal tenderness; no peritonitis, while the bowels were bound up. In only three cases did the stools suggest typhoid. No bacteria were found in the stools. The urine did not respond to the Ehrlich test, nor were any albumen, sugar or casts found. There was no rash. Dr. Hollister did not believe that the disease was typhoid. In treating the cases main reliance was placed on sponging and packs. Three cases died, one from pneumonia and two from exhaustion. No intestinal lesions were found at any of the autopsies.

The paper was also discussed by DRs. DIDAMA, of Syracuse; CRONYX, of Buffalo; HERMENWAY, of Illinois; DAVIS, JR., of Chicago, and WILSON, of Michigan.

(To be continued.)

MASSACHUSETTS MEDICAL SOCIETY.

COUNCILLORS MEETING.

THE Annual Meeting of the Councillors was held at the Medical Library, Boston, on Tuesday, June 7, 1892, at 11 o'clock, A. M., the President, Dr. Amos H. Johnson, in the chair.

One hundred and twenty-two Councillors were present.

The Secretary read the names of 119 new, and of 47 deceased Fellows.

The Treasurer, Dr. Forster, reported the receipts for the year ending April 15th including the balance on hand at the beginning of the year to have been \$12,318.63; and the expenditures, \$10,456.98; leaving a balance of \$1,861.65. The report was accepted.

The Committee on Membership and Finances recommended, and it was voted, that \$1,400 of the surplus in the treasury be distributed among the District Societies.

On recommendation of the same committee, Fellows were allowed to resign, to become retired members, and to have dues remitted. Others were dropped from the roll for non-payment of dues.

The Committee on Publications presented their report. They announced Dr. William Osler of the Johns Hopkins Hospital, Baltimore, Md., as the Shattuck Lecturer at the annual meeting of the Society in 1893.

The Committee on Medical Diplomas recommended, and it was voted, that the following be added to the list of colleges whose diplomas are recognized for admission to the Society: Berkshire Medical College (prior to its closure), Medical Department of the University of Minnesota.

The Committee on the By-Laws of the District Societies recommended, and it was voted, that any proposed alteration or amendment of the By-Laws of any District Society be referred to the committee before such alteration or amendment is adopted.

The committee appointed to consider the petition of the Massachusetts Society for the Prevention of Cruelty to Animals, regarding vivisection, reported through Dr. H. P. Bowditch, as follows:

Whereas, the Massachusetts Society for the Prevention of Cruelty to Animals has asked for some official action on the part of the Massachusetts Medical Society, in the form of a resolution, or otherwise, as to whether in their judgment any law, and, if so, what law, should be enacted by our legislature to restrain or limit the practice of vivisection by physicians, medical or other students, or pupils in medical or other colleges or schools, therefore,

Resolved, That the Councillors are not aware that vivisections are practised in this State in an unnecessary or cruel manner.

That the existing statutes furnish sufficient security against cruelty in vivisection, as well as against cruelty in general.

That experience has shown it to be very undesirable to impose restrictions of any kind upon the advancement of medical science by the researches of properly qualified persons.

That, in view of the above facts, it is, in the opinion of the Councillors, inexpedient to legislate upon this subject."

(These resolutions were passed in concurrence by the Society, on June 8th.)

The Librarian, Dr. Brigham, presented his annual report.

The following, as presented by the Committee on Nominations, were elected to the offices of the Society for the ensuing year: President, Dr. James C. White, of Boston; Vice-President, Dr. Francis A. Howe, of Newburyport; Treasurer, Dr. Edward J. Forster, of Boston; Corresponding Secretary, Dr. Charles W. Swan, of Boston; Recording Secretary, Dr. Francis W. Goss, of Roxbury; Librarian, Dr. Edwin H. Brigham, of Boston; Orator, Dr. J. T. G. Nichols, of

Cambridge; Anniversary Chairman, Dr. George W. Gay, of Boston.

Voted, That the next annual meeting of the Society be held in Boston, on the second Wednesday in June, 1893.

The following Standing Committees were appointed: Of Arrangements: Dr. J. T. Bowen, Dr. H. Jackson, Dr. J. Homans, 2nd, Dr. F. M. Briggs, Dr. J. C. Munro, Dr. A. Thorndike.

On Publications: Dr. G. C. Shattuck, Dr. B. E. Cutting, Dr. O. F. Wadsworth.

On Membership and Finances: Dr. F. Minot, Dr. F. W. Draper, Dr. J. Stedman, Dr. E. G. Cutler, Dr. L. R. Stowe.

To Procure Scientific Papers: Dr. H. P. Walcott, Dr. H. L. Burrell, Dr. L. Wheeler, Dr. F. H. Zabriskie, Dr. S. B. Woodward, Dr. C. W. Townsend.

On Ethics and Discipline: Dr. G. J. Townsend, Dr. G. E. Francis, Dr. F. C. Shattuck, Dr. C. G. Carlton, Dr. E. Cowles.

On Medical Diplomas: Dr. E. J. Forster, Dr. F. H. Hooper, Dr. H. E. Marion.

A petition from Dr. M. E. Webb and others for a change in the boundary line between Norfolk and Suffolk Districts was referred to the Presidents of the Middlesex South, Norfolk and Suffolk District Medical Societies, to report at the next meeting.

A communication from the Bristol North District Medical Society concerning the inadequacy of fees for the commitment of the insane was referred to Drs. C. F. Folsom, F. A. Hubbard and F. B. Harrington, as a committee to report at a future meeting.

A communication regarding the bill to create a Cabinet Officer of Public Health was referred to Drs. H. P. Walcott, S. W. Abbott and Henry Jackson as a committee to report at a future meeting.

Drs. E. N. Whittier, J. O. Marble and F. W. Chapin, were appointed a committee to report at the next meeting regarding the Pan-American Medical Congress.

Dr. Williams presented an account of the life and labor of the late Sir William Bowman, an honorary member of the Society. It was voted, that Dr. Williams be empowered to prepare and send to the family of the deceased resolutions of condolence.

The Council adjourned at 12.20 p. m.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. O. SEARS, M.D., SECRETARY.

MEETING of March 14, 1892, the President, DR. FREDERICK I. KNIGHT, in the chair.

DR. J. W. FARLOW reported

A CASE OF SUDDEN DEATH IN A RUBBER FACTORY: INQUIRY INTO THE EFFECTS OF THE INHALATION OF NAPHTHA.¹

DR. E. S. WOOD: Within the past year a case of this kind came under my observation, a legal case, in which a boy employed in the rubber works in South Boston, it was claimed, had not been warned in regard to any unfavorable effect which the naphtha vapor might have upon him. His work was to regulate some part of the machinery intended for pressing the

¹ See page 621 of the Journal.

rubber. The rubber was placed in the tank in which were forty gallons of naphtha, and allowed to remain until it had become of suitable consistency, that is, it was largely dissolved; no bisulphide of carbon was used. Then this solution was allowed to flow slowly from the tank between a couple of rollers, and there rolled into sheet rubber. When the rubber was rolled out into sheets and as it was poured between the rollers there was a large surface exposed to the air, and a great deal of naphtha vapor escaped. This boy was directed to insert a wedge in some portion of the machinery near the cog-wheels, and his statement is that the room was not very well ventilated; at any rate, he was exposed to the action of an unduly large quantity of naphtha vapor. When he went to insert the wedge, where he was instructed to insert it, he became dizzy. To prevent himself from falling, he grasped at the first thing he could, and got his hand caught in the cogs, and received such an injury that it necessitated his being carried to the City Hospital and his arm amputated. This case went to trial and the jury disagreed. There did not seem to be any doubt in my mind but what the boy was made dizzy by the effect of the naphtha vapor, and the inquiries made at the refining works at Atlantic City have shown that the workmen employed at those departments of the work where there are large quantities of vapor are liable frequently to be made dizzy and have a species of intoxication, which may go so far as to produce complete unconsciousness. I have never seen any record of convulsions having been produced, but there are records of cases of unconsciousness, although the patients, as a rule, recover as soon as carried into the fresh air. There are some records which have been given showing that there may be even such an amount of cerebral disturbance as to produce a sort of acute delirium, from which the patient recovers as soon as carried into the fresh air; there is also the record that one of the superintendents at Point Breeze, although accustomed to inhale naphtha vapor, went to investigate a leak in one of the naphtha canals and was made unconscious in two minutes; and there are some statements recorded to the effect that an adult may be made unconscious in from two to seven minutes after the inhalation of a few grammes of naphtha vapor. The workmen employed in handling the light naphthas, gasoline, rhigolene, etc., in pouring by means of pails from the tanks into casks or barrels may inhale a sufficient quantity to be made dizzy, to have ringing in the ears, and more or less of the first symptoms of intoxication, and unconsciousness has been produced in those cases in workmen. I have seen a statement that death has occurred, although in the vast majority of cases recovery takes place immediately upon the patient being taken to the open air. Death has resulted from the unconsciousness produced in those engaged in cleaning the tanks in these refining works and working in confined spaces where there has not been proper ventilation.

DR. STURGIS: I have been rather interested in the workers in rubber factories for the last three or four years. All the cases have been chronic. I have not been able to deduce much from the cases I have seen. They generally occurred in the women engaged in making up gossamer cloth. The effect seemed to be cumulative. Girls would work some months or years before they were affected. The heart seemed to be most affected. There was a tendency to syncope and

a good deal of praecordial distress and palpitation on the least exertion. The pulse in most cases was very feeble, and the first sound of the heart sharp and short. Generally there was a hæmico murmur, and there may or may not have been a venous hum in the neck. Menstruation was generally scanty. A good many of the patients complained of dizziness. I found that the cases were all rather difficult to treat, did not yield to the treatment of ordinary anemia. Iron did not seem to do much good although the stomach was generally in good condition. I generally used Fowler's solution and manganese.

DR. KNAPP: I have seen quite a number of women working in the various rubber factories, but I have not seen any who presented any symptoms which I was disposed to ascribe definitely to naphtha. The majority of the cases have been cases such as we see very commonly in working women who do not work in rubber factories. They were anaemic and debilitated, neurasthenic, and complained of the ordinary run of rather indefinite symptoms. As a general thing, they seem to be underfed, living in rather poor hygienic surroundings, and most of them seemed to improve with considerable rapidity when properly fed and their supply of tea was cut off. Their trouble seemed clearly due to ordinary causes and not to naphtha. They were given an ordinary tonic. I recall now but one case where I thought the symptoms were due definitely to the work in the rubber factory. That was a man who had been working in a factory for some time and had been using in addition to the naphtha, bisulphide of carbon. He had some slight symptoms of pain and weakness and paraesthesia in the arms. It seemed to me a very slight multiple neuritis which I supposed was due to the bisulphide of carbon; it was more likely to be due to that than to the naphtha. He had a still slighter neuritis in the legs.

DR. G. B. SHATTUCK: I remember two patients at the City Hospital, girls who had worked in a rubber factory. They had marked anaemia and debility and a slight neuritis. They had not had to do with the bisulphide of carbon, and they did not respond to the treatment for anaemia.

DR. W. D. HODGES: I should like to mention the case of a man who was engaged in filling a receiver with gasoline, and after having almost emptied the barrel a leak was discovered in the receiver. He entered the gas-pit, which was six feet square, to stop it, and was immediately rendered unconscious. Upon removing him from the gas-pit consciousness soon returned.

DR. FARLOW: It is important to bear in mind when inquiring into the complaints of workers in rubber factories, that in some parts of the work considerable naphtha is used, for instance, in the room where cloth is covered with liquid rubber, while in other parts very little or no naphtha is used and the symptoms must be due to something beside naphtha.

SPECIMENS.

Dr. Farlow showed a myxo-sarcoma which he had removed from the left nostril of a patient thirty-two years of age. A year ago there was evidence of ethmoid disease, but no tumor. The growth was removed with the cold snare and hemorrhage was profuse. He also showed a very large piece of adenoid growth which he had removed by forceps from the vault of a child four years old.

Recent Literature.

Treatise on Gynecology, Medical and Surgical. By T. POZZI, M.D. Translated, and with additions, by BROOKS H. WELLS, M.D. Vol. II. William Wood & Co. 1892.

When the first volume of this work appeared about three months ago, we reviewed it, and expressed our high opinion of its value, as the best exponent of the best teaching of the French school. This second volume completes the book, comprising four chapters on Inflammation of the Uterine Adnexa, five on Neoplasms of the Uterine Adnexa and Ligaments, three on Genital Tuberculosis, Intra- and Extra-Peritoneal Pelvic Haematocele and Extra-Uterine Pregnancy, four on Diseases of the Vagina, seven on Diseases of the Vulva, three on Malformations of the Genital Organs, and two on Diseases of the Urinary Tract, Rectum and Pelvis.

Diagnosis and Treatment of Hemorrhoids and other Non-Malignant Rectal Diseases. By W. P. AGNEW, M.D. Second edition. San Francisco, Cal.: R. R. Patterson, publisher. 1891. 148 pages. Illustrated.

This book is concisely, attractively written, and is intended by its author to present in plain, comprehensive language methods of treatment of the affections designated in its title, which are of actual value and can be depended upon to accomplish what is claimed for them by their advocates. It is an interesting work. Its chief feature is the importance and value assigned by its writer to the use of carbolic acid for the radical cure of hemorrhoids and fistule. The book is well written, the facts and details clearly, very accurately stated, so that the reader will have no difficulty in understanding or testing the methods recommended. It seems worthy of a careful perusal.

A Treatise on Diseases of the Lungs and Pleura. By the late WILSON FOX, M.D., F.R.S. Edited by SIDNEY COUPLAND, M.D., F.R.C.P. Philadelphia: P. Blakiston, Son & Co. 1892.

It is difficult to estimate the amount of labor which Dr. Fox has expended in preparing this volume. Not only is each article written in fulness and attention to detail which makes the book practically unique in its field, but the text is enriched by such copious references to other works and to periodical literature as to give a very complete bibliography of each subject. In fact, such references are so frequent from the author's evident desire to do justice to others as to suggest a compilation, but to quote the preface "his reputation as a clinical observer and a profound pathologist is too well established to be affected by any mistaken inference from this characteristic of all his writings." As was to be expected from Dr. Fox's special interest in the subject, the article on Pulmonary Tuberculosis would be particularly thorough, and it occupies over a third of 1,200 pages, but those on pneumonia and pleurisy are also very complete, and the same care is seen in the preparation of the shorter chapters. Dr. Fox speaks with the authority of a large clinical experience and wide reading, and his book deserves to become a classic. Whatever additions have been rendered necessary by investigation and discoveries since the author's death, to bring the text up to date, have been made by the editor.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JUNE 23, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the *Boston Medical and Surgical Journal*, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DANIELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

URINARY INFECTIONS.

The urine contained in the bladder and kidneys of a man in perfect health is aseptic. The urethra is normally inhabited by germs, which may contaminate the urine in its passage outwards. The microbes of the urethra are bacilli and micrococci, inoffensive under some circumstances, pathogenic in others. The *staphylococcus pyogenes aureus* is one of these micro-organisms of the urethra. Purulent urine, from an inflamed urethra, bladder or kidney always abounds in micro-organisms: among these are especially to be mentioned the *staphylococcus aureus*, *albus* and *citreus*, the *streptococcus pyogenes*, the *uro-bacillus liquefaciens septicus*, and the *bacillus non-liquefaciens*. The latter, says Guyon, has a preponderant rôle in urinary infections. Halle and Albaran describe it under the name of *pyogenic bacterium*, Guyon thinks it identical with the *bacterium coli commune*.

These microbes may exist in morbid urine either singly or associated; two, three, or more species infecting the same bladder. The gonococcus of blennorrhagia and the bacillus tuberculosis are also met with in the urinary passages under circumstances of specific infection.

The micro-organisms found in purulent urine are to be regarded as the agents of the suppuration which they accompany. This appears to be a fair inference from all the facts which have been accumulated by a multitude of observers the past thirteen years. All these pyogenic bacteria have the property of producing pus in the subcutaneous cellular tissue; all are capable of causing cystitis; the injection of their pure cultures into the bladder under circumstances of temporary retention, or traumatism of the mucosa, provokes suppurative cystitis.

The micro-organisms may find access to the urinary apparatus in two ways: they may come from the outside environment and penetrate the urethra, ascending to the bladder and kidneys. This is direct primary infection, and is the rule. In other cases, the organism is first infected, and the kidneys are secondarily infected through the blood.

Spontaneous infection of the bladder in man does not exist (Guyon). In woman this is often observed, owing to shortness of the urethra and feeble occlusion.

In the pathological state, spontaneous infection is frequent in both sexes. Septic inflammation of the urethra propagates itself to the bladder. Oftener still, the infection is provoked. The bladder is contaminated by a urethral injection, by the introduction of a septic sound or catheter.

Whether the bladder may be infected by an aseptic catheter introduced through a normal ureter may, practically, be answered in the negative. The accidents of catheterism have, in fact, virtually disappeared, since sterilized instruments have been used.

Secondary infection of the urinary apparatus belongs to the pathological history of general infectious diseases. It begins with the kidney by one of those infectious nephritis described by Bouchard, and generally remains limited to this organ. Rarely it causes secondary cystitis by taking a descending course.

The penetration of the microbes into the bladder is one condition, but not the only condition of its infection. There must first be receptivity. Receptivity is created by divers causes. The most active are distension of the bladder, stagnation of the urine, traumasms of the mucosa, neoplasms. In order that the bladder may be contaminated some lesion, or at least stagnation of the urine, seems necessary. Microbes are often introduced into a normal bladder without, thereby, infection taking place; the first flow of urine sweeps them all away before they have time to begin their pathogenic action.

According to experiments of Guyon and Albarran, the injection of microbes into the bladder of a healthy animal is generally unattended with any morbid effect; but if you add retention from any cause, or if you wound and inflame the mucous membrane, infectious cystitis sets in.

As to how the microbes produce suppuration in the bladder — this is probably brought about directly by virtue of the pathogenic properties of the microbes (Guyon).

When suppuration is established in the bladder, it may long remain localized in this organ; this may be said to be the rule with cystitis. But cases are only too numerous where the pathogenic agent ascends along the ureter to the kidney, infecting that organ, producing a radiating nephritis, suppuration, and all the lesions of the surgical kidney.

The experimental demonstration of the pathogenic action of the microbes of the urine on the kidney, has been fully given. The injection of a pure culture of these organisms into the ureter followed by ligature of that duct constantly produces in the animal all the lesions of ascending suppurative nephritis. One of the most interesting portions of the little treatise of Albarran (*Etude sur le rein des urinaires*) is the chapter where he details these experiments. The microbes whose culture was made the material of experimentation were the *bacterium pyogenes*, the *staphylococcus*

aureus and *streptococcus pyogenes*. The animal selected was the hare; the left ureter was chosen, as being more accessible than the right.

By the side of suppurative pyelo-nephritis, of infectious origin, we must mention certain sclerous nephrites without suppurations whose microbial origin has been demonstrated by the histo-bacteriological study of the kidney in man. In certain cases, these sclerous inflammations follow experimentally simple ligation of the ureter practised without antiseptic precautions. The principal feature of pathological histology is the enormous proliferation of connective tissue, the nodulated, shrunken condition of the kidney in advanced stages. In the human subject, renal sclerosis is a frequent result of obliteration of the corresponding ureter by a calculus or tumor; it has been witnessed in connection with prostatic disease (Albarran).

Guyon affirms that it is of the first importance to remember that it is the stagnation of septic urine in the bladder that favors the ascension of microbes to the kidney, and that on the regular and repeated evacuation of the bladder depends, before all, the fate of the kidney. Suppuration of the bladder is of little consequence as compared with renal suppuration; the latter is always accompanied by serious disturbances of the general health, while the former may long exist without serious constitutional damage.

With regard to the pathogeny of the general accidents of infection, and of urinary fever in particular, the necessary condition for the appearance of these accidents is the infection of the urine joined to the existence of a solution of continuity pathological or traumatic.

These accidents may appear spontaneously without any provocation; generally, however, they come on as the sequel of a surgical operation, catheterism simple or traumatic, urethrotomy, etc.

It is to the absorption of the septic urine (microbes and the toxic products which they elaborate) that we must refer the urinous fever. The presence of urinary microbes (the pyogenic bacterium alone or associated with the suppurative staphylococci and streptococci) has been noted both during life and after death in the blood of patients suffering from urinous fever. Albarran has found both the *bacterium pyogenes* and the *bacillus liquefaciens* in the blood at the onset of a chill.

Experimentation has proved the infectious nature of the urinary accidents. The injection of a pure culture of the microbes habitual to morbid urine (*bacterium pyogenes*, *uro-bacillus liquefaciens*) into the serous cavities, pleura and peritoneum, generally causes the speedy death of the animal; at the autopsy the micro-organism is found diffused in the blood and all the organs. Injection into the blood produces the same general infection, and often, also, infectious nephritis.

Nothing can be more interesting than the chapters in Albarran's monograph¹ in which he details the numerous experiments which he has made on animals,

¹ *Etude sur le rein des urinaires*, Paris, 1891.

producing in them the entire symptomatology and lesions of urinary fever and infectious nephritis; experiments which an antivivisectionist sentiment would doubtless denounce, but which are fruitful in the addition of positive data to our knowledge. These results have been also admirably summed up in the exhaustive paper read by Professor Guyon to the recent French Congress of Surgery: "On the Pathogenesis of the Infectious Accidents in Urinous Diseases," a paper from which we have freely borrowed.

This secondary localization in the kidney of the infectious agent which has entered the blood under circumstances above mentioned, plays an important rôle in human pathology. There is no more formidable complication and termination of urinary diseases than this secondary infectious nephritis with its cortical miliary abscesses; it is called by Albaran and Guyon "descending nephritis" to distinguish it from the ordinary form where the infection is caused by ascent of the microbes from the bladder and ureter.

"We must," says Guyon, "admit along with the direct action of the microbe that of the toxic products which it elaborates in the urine of the bladder. These soluble products becoming absorbed are capable of giving rise to fever and the general constitutional symptoms, even where the microbe is not absorbed and diffused. The acute, grave form of urinary fever is due, assuredly, to true microbial infection of the blood. It is in these acute, fulminant, rapidly fatal forms that the presence of the micro-organism has been most often noted in the blood. At the same time, the appearance, so rapid and almost instantaneous, in some cases, of febrile accidents following repeated micturitions through a urethra which is the seat of lesion, their very short duration, their complete disappearance, justify the belief that a part of the symptomatology is due to soluble products. In these cases, the victory of the organism when it is complete, is, among other conditions, due to the healthy state of the kidneys. In those rare cases where death supervenes quite suddenly and with symptoms of great intensity, it is to the massive dose of the microbes absorbed and to their great virulence that we must attribute the fatality. Acute, prolonged urinary fever, with repeated attacks, indicates that the infection of the blood has been followed by secondary renal lesions. This is the theory which I maintained before the demonstration of the microbial nature of urinary poisoning, and which has always seemed to me to result from the interpretation of the facts. The renal lesions may get well in a considerable number of cases. It is, at the same time, the persistence and the profoundness of these lesions which cause death when it supervenes in the course of this grave form of urinous fever."²

THERE were 26 graduates at the annual Commencement of the Blackwell's Training School for Nurses, New York, which was held at Charity Hospital on June 15th.

² La Médecine Moderne, April 28, 1892.

MEDICAL NOTES.

TYPHUS FEVER IN RUSSIA.—Typhus fever is increasing in those districts of Russia which are suffering from the famine. This is especially true of Kasan, Astrakahn and many of the cities on the Volga.

INTERNATIONAL CONGRESSES IN RUSSIA.—With the sanction of the Emperor of Russia, there will be held at Moscow, during the current year, two international congresses: a congress on anthropology and prehistoric archaeology, to be held from the 13th to the 22d of August, and a congress on zoölogy from the 22d to the 30th of August.

CHOLERA IN PERSIA.—The mortality from cholera at Meshed, Persia, has reached 400 daily. The Persian government has placed a military cordon around Teheran. The Russian government is taking rigorous and extensive measures to prevent the spread of cholera into Russia.

SUNSHINE IN ENGLAND.—The lack of sunshine in the United Kingdom can be appreciated by reading an article by Mr. R. H. Scott, in *Longman's Magazine (Lancet)*, June 4th), in which he says, that in the matter of sunshine the Channel Islands bear pre-eminently the palm, being "the only region which records, on the average of ten years, sunshine for one-half the time the sun is above the horizon in any month, and this it does in May, with 52 per cent., and in August, with 55 per cent."

COGHILL VS. BONAPARTE.—This case, which has recently been tried in England, has received a good deal of attention from the daily press, even in this country. Dr. S. Coghill sued M. Clovis Bonaparte for attendance on himself for alcoholism, and on a lady who passed for his wife for what was described as "grave specific disorder of a highly contagious nature." The bill had been sent in, but not paid. The defendant was impudent, and conceived the idea not only of not paying the doctor's bill, but of making the doctor pay large damages by threatening an action for divorce against the woman who he maintained was not his wife, in which the plaintiff was to be made co-respondent. He drew such a picture to his so-called wife of an imaginary action that was to be commenced by Dr. Coghill, and that was only to be averted by money, that he got her to make what purported to be a confession of disgusting actions involving the plaintiff, and to part with all her jewels. She finally acknowledged in court that the documents were mendacious from beginning to end. The jury in their verdict declared that Dr. Coghill left court without the slightest imputation on his character.

NEW ENGLAND.

THE AMERICAN LARYNGOLOGICAL ASSOCIATION held its fourteenth annual congress in Boston during the first three days of this week. About twenty members were present. An interesting programme, consisting of eighteen papers, had been prepared. On

Monday and Tuesday a lunch was provided at the Athletic Club. On Monday evening, the annual dinner was held at the Parker House, and on Tuesday afternoon the Association went on an excursion to Plymouth.

THE LYMAN PRIZE.—The late Dr. George Hinckley Lyman was for twenty years a visiting physician to the City Hospital of Boston. Mrs. Lyman, in her wish to commemorate Dr. Lyman's great interest in the growth and development of the institution and his sympathy with the young men who leave it every year to practice the profession to which his life was devoted, has offered an annual prize of \$150 for an essay on any subject relating to medicine or surgery which the writer may select.

This prize will be open for competition to graduates of the City Hospital of *not more than three years' standing*, in January of every year, beginning with January, 1893. The senior members of the medical, surgical and gynecological staffs of the City Hospital, with the President and Secretary of the City Hospital Club, will act as a committee of award. Essays must be type-written, and must be sent to the Secretary of the City Hospital Club before January 1st. Each essay must bear upon the title-page an assumed name or a device, and must be accompanied by a sealed envelope containing the name and address of the writer. If no essay worthy of the full prize be received in any year or years, the committee shall be at liberty to award a smaller prize or prizes of \$50, \$75, or \$100. The amount which may remain will be added to the prize for the following year.

NEW YORK.

A PROLIFIC NEGRESS.—During the past week a negro woman now living in New York, gave birth to her twenty-fifth living child. She is about forty-two years of age, and when sixteen was married to the husband with whom she is still living. She was born in Richmond, and resided in Virginia until seven years ago. Among the twenty-five children there have been no twins or triplets.

PUBLIC SCHOOL BUILDINGS.—For some time past Dr. Moreau Morris, of the Health Department, acting under orders from the Sanitary Superintendent, Dr. Cyrus Edson, has been making a careful examination of the public school buildings in the city in order to make an exhaustive report on their sanitary condition, particularly as regards the effectiveness of the system of ventilation in use in each school, and to commend the adoption of such means as in his judgment would adequately ventilate the buildings. In nearly every instance Dr. Morris found a most unsatisfactory condition of affairs, and Dr. Edson has now laid the results of his investigations before the Board of Health, accompanied by a report of his own. In the latter he says: "In other cities and States, more especially in Massachusetts, excellent work has been performed by the authorities in effecting proper ventilation of school

buildings. The outcome of this work has demonstrated that the only adequate means of ventilating school buildings is by fans so arranged and operated as to force into the rooms a supply of fresh air equal per minute to about 30 cubic feet per capita, and by outlet ducts so constructed as to permit egress of partially respired air. . . . In the cases of the buildings upon which the reports of Dr. Morris have been made, it has needed no chemical analysis of the air to demonstrate that the means of ventilation were insufficient. . . . It is unnecessary to describe the unhealthy effects of vitiated air upon the systems of human beings in order to show the necessity for the work in hand. Aside from the well-known direct effects of bad air, slight physical ailments of children, wholly unnoticed, are often developed by the impurities of the air in our school-rooms into serious disease. The only objection that can be made to the recommendations of Dr. Morris is that their compliance will entail the expenditure of a large sum of money. This objection should not weigh for a moment against the health of the school children. Pure air is absolutely essential to their well being. The air of our school buildings should be made pure, regardless of cost.

Miscellany.

THE BACILLUS OF INFLUENZA.

PFEIFFER and Beck¹ have published a report of their further investigations of the bacillus of influenza, an account of which was given in the JOURNAL of February 11th. The pathological appearance found in the lung in cases of typical influenza-pneumonia are characteristic. There is no general hepatization, but foci of bronchopneumonia of different sizes, which occasionally coalesce, and are found mostly in the lower lobes. In the centre of such patches, on section, a yellowish green, purulent secretion may be pressed out from the smaller bronchi. This secretion consists of pus-cells and mucus, and in it can be found the typical bacillus, sometimes free, sometimes inside the cells. They occur often in enormous quantities and generally in pure culture. The bacilli appear to grow in the smaller bronchi and also in the parenchyma of the lung. The authors have failed to find the bacillus in the blood and come to the conclusion that the growth of the specific micro-organism takes place entirely in the bronchi or in the lung. The bacillus is very similar in appearance to several others, and the authors appear to believe that most, if not all of those described by others, have not been true influenza bacillus. The bacilli are aerobic bacteria and are soon destroyed by drying. The authors have not yet found spores, or a condition in which the bacilli may live for any length of time. They are killed by a temperature of 60° C. in five minutes. A description of their appearance and peculiarities of growth are given. The authors have never failed to find this bacteria in cases of influenza, nor found it in persons not suffering from the disease. They have succeeded

¹ Deutsche med. Woeh., May 26th.

in producing a condition in apes similar to human influenza by placing a little of the pure culture upon the mucous membrane of the nose.

EFFECT OF BITTERS ON GASTRIC MOVEMENTS.

TERRAY has published an account of some investigations to determine the effect of various bitters on the movements of the stomach.¹ The experiments were made with dogs. The animal was kept on a restricted diet for two days, and a quarter of an hour before being killed a dose was introduced into the stomach of some bitter which acts on the peripheral automatic centres of the stomach. The most powerful drug was gentian, and after that cetrarin and condurangin; then taraxacum, quinine and lastly quassia. The irritability of the stomach to mechanical stimuli was increased by gentian, taraxacum, quassia, strychnine and columbine. Small doses of absinthium diminished the irritability, and large doses arrested it altogether. Columbine and strychnine increased the irritability until persistent general contractions were induced. Picrotoxin produced no effect on the contractions, while cetrarin not only set up increased movements in the stomach, but produced a similar effect upon the intestinal movements. From a therapeutic point of view, therefore, it appears that in tonic conditions and moderate dilatation bitters may be given with advantage. Cetrarin acts as an aperient in addition to its effect upon the stomach.

THE GROWTH OF MEMORY IN SCHOOL CHILDREN.

MR. THADDEUS L. BOLTON² has tested the growth of memory in school children, using as a basis, tests made upon about 1,500 pupils in the public schools of Worcester. The experiments were made by reading aloud a series of numbers in which the digits were so arranged that they did not stand in their accustomed order and no digit was repeated. At a given signal after the dictation of each number, the pupils wrote the digits as they remembered them, from five to nine digits were given at a time. From the large amount of material thus collected the following conclusions are reached: The limit to the memory-span for the pupils in public schools is six. The memory-span increases with age rather than with the growth of intelligence. Experience in this matter is a better school than books. The memory-span measures the power of concentrated and prolonged attention. Intellectual acuteness, while more often accompanied by a good memory-span and great power of concentrated and prolonged attention, is not necessarily accompanied by them. Girls have better memories than boys. With practice pupils increase in their ability to remember groups of digits. They unconsciously remember digits which they heard the day before. The tests did not show that the pupils suffered fatigue from the day's work, a fact which shows that the work in the schools is probably not excessive. Memory images pass through three stages in leaving the mind, first

they suffer a confusion of order; second, loss of certain elements and the substitution of associated elements; and third, a complete loss of some elements and no recovery. Ideas previously in the mind, association and forms of ideas are factors in causing confusion of the memory image and its final loss. There is an apparent tendency to over-estimate the number of ideas presented to the mind when the number of ideas is slightly greater than the memory-span, but the general rule is to under-estimate the number. Ideas except the last two or three in the series are lasting in an inverse order as they are removed from the beginning of the series in which they occur. The last two or three are lasting, but in a decreasing degree, as they are removed from the end of the series.

THE CURE OF A CASE OF HYDROPHOBIA.

PROFESSOR MURRI, of Bologna, reports a case of a man twenty-two years of age who was bitten by a rabid dog. A few days afterwards he commenced a course of treatment by Pasteur's method which lasted twenty days. He was then seized with undoubted symptoms of hydrophobia of a paralytic form. The lower extremities were completely paralyzed. Two days after the first symptoms intravenous injections of anti-rabic virus were begun. The emulsions used contained medulla of six, five, four and three days. These injections were continued for nine days, one or two being made daily. In commenting upon this case Dr. T. W. Hine³ says, that no method of treatment, known up to the present time, has ever saved a man seized with marked symptoms of hydrophobia. The good result in this case lies in the novel and bold modifications of the method originated by Pasteur. A subcutaneous method is too slow to be of practical use in the presence of a well marked case of rabies.

THERAPEUTIC NOTES.

A NEW KIND OF CIRCUMCISION.—During the discussion of an address by Dr. Joseph Hoffman (on treatment of lesions at and about the head of the colon) before the Alumni Association of the Medical Department of the Niagara University at Buffalo, N. Y., it was suggested by Dr. Wilder, of Ithaca,⁴ that, in view of the dangers to which human beings are exposed from inflammation of the veriform appendix, it be extirpated by aseptic laparotomy soon after the birth of the child.

BETOL⁵ (salinaphthol) is a compound of salicylic acid and naphthol, very similar to salol, and applicable to the same uses. It was expected theoretically that this new compound would be superior in action to salol; but clinical experience has not been generally favorable, although good results are reported from its use so far as an intestinal antiseptic. It comes as small, colorless and odorless broken crystals insoluble in water. Its taste is not disagreeable, and its toxic effects are not noticeable in moderate doses. It is, therefore, a reasonably safe remedy in children's bowel complaints.

¹ Lancet, May 28th.

² New York Medical Record, xxxvii., p. 738, June 28, 1890.

³ Squibb's Ephemera.

BROMOFORM⁸ still continues to give satisfaction in the treatment of whooping-cough, although its use has apparently been confined to only a few observers. Care must be taken to see that it is in normal condition, that of a colorless liquid, for by exposure to the light bromine is set free and colors the liquid. Foreign observers are most pronounced in its favor, and more practitioners in our own country should put investigations on record.

BROMOL⁸ (tribromophenol) is not new, but has been known as the product of the action of bromine in acetone on carbolic acid. As it has been found now to have marked antiseptic properties, this short name has been given it, both for convenience in use and to be in harmony with the already too many new compounds being pushed forth, most of which have names less indicative of their true composition. It has been applied with vaseline to open wounds with success. Its internal uses have been in cases of typhoid fever and cholera infantum. Little has been written yet on its therapeutic uses.

Correspondence.

A BIOGRAPHY OF DR. D. HAYES AGNEW.

UNIVERSITY MEDICAL MAGAZINE, EDITORIAL OFFICES,
PHILADELPHIA, June 17, 1892.

MR. EDITOR:—At the request of Mrs. D. Hayes Agnew, I am preparing a biography of her late distinguished husband; in consequence, I am looking for data on this subject. Will you please state in the columns of the *Boston Medical and Surgical Journal* the fact that I am desirous of obtaining from all of Dr. Agnew's former friends, colleagues, associates, students and acquaintances all such authentic data as relate in any way to his career or character. Dr. Agnew's acquaintance was so vast and his life was so actively spent among his friends, while his own modesty was so marked, that undoubtedly a great many incidents, anecdotes, characteristic stories, etc., are unknown to his family. All material, however insignificant or small will be welcomed, and credit will be given to all data which are used.

Yours faithfully,
J. HOWE ADAMS.

TOXIC RETRO-BULBAR NEURITIS.

SALEM, June 13, 1892.

MR. EDITOR:—The appearance of two new patients, one day last week, both the victims of loss of sight owing to the abuse of alcohol and tobacco, lead me to look over my records, where I found that the ratio of such cases is apparently greater than it was ten years ago.

The late Mr. Crittenden once remarked, somewhat tersely, at Moorfields, "Rum, shag, and W——(women) are frequently the causes of serious eye-troubles."

Three cases are recalled within a few years where the vision was affected in tobacco-chewers. On abstaining, the sight in two was greatly improved. All were teetotalers, so far as the use of spirits was concerned. The smoking alone of cigars and pipes has not infrequently been the apparent cause of amblyopia. No cases of this eye-trouble, owing to the smoking of cigarettes, have yet come under my observation. It is somewhat remarkable that no females having this affection have yet been seen, when we consider how largely snuff is used, ostensibly as a dentifrice, by mill operatives in our factory towns—a more elegant procedure, perhaps, than the dipping that prevails in our Southern States.

And strong beer, at least, is partaken of somewhat freely

⁸ Squibb's Ephemeris.

by such females, but no case of the old *amblyopia exabusa* has yet been seen by the writer in the gentler sex.

Most patients who suffer from this form of neuritis are both smokers and drinkers. Ordinarily they live in cities or large towns—or such has been my experience—yet some of my tobacco cases lived far from the madding crowd, as did two old smokers in a Florida village.

Soldiers of the late war appear each year, with fishermen, an occasional master-mariner, saloon-keepers more frequently, and sometimes men of our calling and (tell it not in Gath), more rarely, a disciple of a calling akin to ours who has followed too literally the advice of Timothy as to the use of a little wine.

This disease is more common in this country and in Great Britain, where the tobacco is strong, than it is in Germany and Turkey. Then, too, in the latter countries spirits are less consumed.

An excellent London ophthalmic surgeon in his first treatise on the eye, in 1875, expressed some doubt as to the action of these agents on the sight, but in a later volume (1887), he evidently ascribes to them this form of toxic neuritis.

Patients having this trouble are apt to be unsatisfactory ones to treat.

They ordinarily promise to abstain with gratifying alacrity but they by no means invariably carry out their good intentions. They take potassium iodide or strichnina with "acid phosphate," and at night, perhaps, a bromide draught. The subsequent gain in vision is sometimes found to have been considerable (in the rare instances when the patient consents to return) while if he does not reform his habits the reverse is pretty sure to follow.

Yours truly, DAVID COGGIN, M.D.

RECORD OF MORTALITY FOR THE WEEK ENDING SATURDAY, JUNE 11, 1892.

Cities.	Estimated population for 1890.	Reported deaths in week.		Deaths under five years.	Infectious diseases.	Acute lung disease.	Diarrhoeal disease.	Diphtheria and croup.	Measles.

Deaths reported 2,291; under five years of age 801; principal infectious diseases (small-pox, measles, diphtheria and croup,

diarrhoeal diseases, whooping-cough, erysipelas and fevers) 406; acute lung diseases 310; consumption 284; diarrhoeal diseases 104; diphtheria and croup 62; measles 75; scarlet fever 48; typhoid fever 29; whooping-cough 20; cerebro-spinal meningitis 17; erysipelas 11; malarial fever 9; small-pox 1.

From scarlet fever New York 21, Philadelphia 10, Brooklyn 7, Boston 6, Cincinnati, Lowell, Lawrence and Pittsfield 1 each. From typhoid fever New York 7, Cleveland 5, Philadelphia 4, Cincinnati 3, Washington 2, Milwaukee, Lowell, Holyoke, Haverhill and Everett 1 each. From whooping-cough New York 4, Philadelphia 3, Brooklyn, Boston and Washington 2 each, Cincinnati, Milwaukee, Nashville, Charleston, Worcester and Lawrence 1 each. From cerebro-spinal meningitis New York 6, Washington 4, Brooklyn 2, Nashville, Haverhill, Malden, Quincy and Everett 1 each. From erysipelas New York 4, Boston and Cleveland 2 each, Washington and Springfield 1 each. From malarial fever Brooklyn 3, New York 2, Philadelphia, New Bedford and Charleston 1 each. From small-pox New Bedford 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,188,449, for the week ending June 4th, the death-rate was 17.9. Deaths reported 3,006: acute diseases of the respiratory organs (London) 240, measles 189, whooping-cough 106, diarrhoea 51, diphtheria 27, scarlet fever 32, fever 26, small-pox (London) 3.

The death-rates ranged from 10.8 in Portsmouth to 25.9 in Burnley; Birmingham 20.0, Bradford 14.7, Hull 16.0, Leeds 18.9, Leicester 20.6, Liverpool 21.9, London 17.4, Manchester 24.2, Newcastle-on-Tyne 15.7, Nottingham 18.4, Plymouth 12.8, Sheffield 18.4, Sunderland 19.2, Wolverhampton 18.1.

METEOROLOGICAL RECORD.

For the week ending June 11, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:-

Date.	Baro-meter	Thermometer.	Relative humidity.	Direction of wind.	Velocity of wind.	Weath'r.	Rainfall in inches.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 11, 1892, TO JUNE 17, 1892.

The leave of absence granted CAPTAIN WILLIAM C. GORGAS, assistant surgeon, U. S. A., is extended one month.

The leave of absence for seven days granted CAPTAIN HENRY S. T. HARRIS, assistant surgeon, U. S. A., is extended twenty-three days.

FIRST-LIEUT. MERRITTE W. IRELAND, assistant surgeon, is relieved from temporary duty at Fort Yates, N. D., and will rejoin his proper station, Fort Riley, Kansas.

FIRST-LIEUT. HENRY C. FISHER, assistant surgeon, is relieved from duty at Fort Riley, Kansas, and will report in person to the commanding officer, Fort Yates, N. D., for duty at that station.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 18, 1892.

W. F. ARNOLD, passed assistant surgeon, detached from U. S. Training-ship "Richmond" and placed on waiting orders.

M. W. BARNUM, assistant surgeon, detached from Naval Hospital, Washington, D. C., and to the U. S. Training-ship "Richmond."

H. T. PERCY, passed assistant surgeon, ordered to the Naval Hospital, Washington, D. C.

GEORGE M. C. PICKRELL, passed assistant surgeon, detached from Naval Hospital, Norfolk, Va., and to the U. S. S. "Newark."

HARVARD MEDICAL SCHOOL ASSOCIATION.

The annual meeting of the Harvard Medical School Association will be held in Boston, at the Medical School Building on Boylston Street, at 12 o'clock on Tuesday, June 28, 1892.

The second annual dinner will be given at Hotel Vendome, Boston, at one o'clock of the same day (Tuesday, June 28th). Among the speakers at the dinner will be President Elliot, Dr. Wm. Pepper, Provost of the University of Pennsylvania, Dr. Wm. H. Welch, Professor of Pathology at Johns Hopkins University, and Dr. James C. White, President of the Massachusetts Medical Society.

Dinner tickets will be two dollars each, and can be obtained by members either at the Medical School or at Hotel Vendome between the hours of 11 and 1 on the day of the dinner.

ROBERT W. LOVETT, Secretary.

CORRECTION.

In our report of the meeting of the Massachusetts Medical Society on page 512, a few mistakes in the Treasurer's report will be found corrected on page 640.

RECENT DEATHS.

CLARENCE WHITFIELD PRYTON, M.D., M.M.S.S., died in Dedham, Mass., June 14, 1892, aged twenty-six years.

ERZA BARTLETT, M.D. (Dart. 1832), died in Brooklyn, N. Y., June 16th, aged eighty-one. He had practised in different cities in New England, and during the war served as surgeon in the United States Army.

HENRY F. FORMAD, M.D., Demonstrator of Pathology and Lecturer on Morbid Anatomy at the University of Pennsylvania and Pathologist to the Philadelphia Hospital, died June 5th, at the age of forty-five years.

DAVID N. SKINNER, M.D. (Bowd. 1867), died in Auburn, Me., June 18th, aged fifty years. He was the author of several papers on diseases of the eye.

BOOKS AND PAMPHLETS RECEIVED.

Proceedings of the New York Pathological Society for the Year 1891.

Address.**ADDRESS AT THE ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION.¹**BY S. W. LANOMAID, M.D., *President.*

It is my honorable and pleasing duty to announce the opening of the Fourteenth Annual Congress of our Society. Estimating the value of the Association as I do, I can conceive of no greater honor than to be its presiding officer. The enjoyment which I always have in our annual meetings is enhanced by the evident desire which was shown that we should meet in Boston and because you are our guests.

The present membership of the Association consists of forty-five active, one honorary, and ten corresponding Fellows. The council recommends the enlargement of the Society by the reinstatement of a former member, and by the election of eight active Fellows. It will recommend for corresponding fellowship three well-known European laryngologists.

During the past year the Association has lost by death one active Fellow. Dr. Frank Donaldson, of Baltimore, emeritus clinical professor of diseases of the throat and chest in the University of Maryland, died December 8, 1891. The loss to our Association by the death of Dr. Donaldson is real. We have lost his genial companionship, his sympathy, his manly sweetness of character, his active interest in the Society, and his fair-minded judgment. We have lost a learned friend and most valuable member, and the Association mourns to-day and will continue to regret his untimely death.

Another loss to the Society and to the world is already in your minds before I can utter it. The death of Sir Morell Mackenzie removed not only the personal friend of many of us but an interested friend and member of our Association. Any words of mine would be sadly incompetent to convey an idea of what the loss to laryngology is by Mackenzie's death. Fortunately, the most sympathetic and comprehensive utterances have already been made by his associates and friends all over the world, and although we cannot add to them we can make these utterances our own through our sincere endorsement of their truth.

A remarkable man has departed, a teacher and arbitrator in all laryngological matters, and in our grief at our loss we selfishly murmur that we cannot longer avail ourselves of his skill, his knowledge and his judgment. The office of the teacher has no superior, and in that office Mackenzie was pre-eminent.

The programme of the present meeting consists in the reading and discussion of no less than eighteen papers. The subject of each paper is of vital interest, and the time for discussion will be far too short for our satisfaction and instruction. Under these circumstances the preliminary address, which is expected at the opening of the Congress, must necessarily be short.

I cannot refrain, however, from giving utterance to a few thoughts which have presented themselves in anticipation of this occasion. When I think of the present status of this Association; of what it is, and what it has done; when I consider the wealth of laryngological knowledge of which the world is possessed, to which this Association has been a not small contributor, I cannot forget the small beginning, the tiny

rivulet from which this quiet stream of knowledge had its rise, and that some of us began our voyage of professional life almost at its source. I hold in my hand the rare but interesting works of Beunati.² So rare, that our lamented Elsberg, whose bibliographical knowledge was second to none, had never seen them until a few years before his decease.

To me they are intensely interesting because of the original investigation which they record, and because they are the last worthy publications of the old dispensation — the dispensation of darkness and guess — worse before the new dispensation of light and certainty were ushered in by the discovery of the laryngoscope. No special student was ever more in earnest, and no one has given a better account of what could be seen in the singer's throat than Beunati. The reader cannot help a sigh of pity that the means by which that wonderful mechanism, the living larynx, can be seen, had not then been discovered. Beunati's investigations were of necessity confined to parts which were then visible, namely, those which constitute the buccal pharynx. All below and all above were *terra incognita*. Throughout Beunati's works one can read between the lines his burning desire to be able to see the living glottis.

When I began the study of throat disease as determined by the laryngoscope, almost the only works upon the subject were the well-known paper of Czermak, a small treatise by Elsberg, and the volume by Sir Duucan Gibb. The original paper of Garcia was inaccessible. Since then, as we know to our cost, the literature of laryngology has increased by standard publications and ephemeral magazine articles until no one without assistance can hope to keep quite abreast of discoveries and clinical observations. Such industry in observation and study, and such rapid discoveries evince the greatest activity in the laryngological specialty. To this multitudinous literature this Association has contributed largely and valuably.

In the address of welcome which I had the pleasure of making ten years ago on the occasion of the former meeting under the presidency of Dr. Knight, I said in effect that I believed the coming years would show as good work from the members of this Association as had already been done by them. My belief was not unfounded. During the last ten years I find in our archives, among others, most valuable papers and discussions upon the following subjects: Upon the respiratory function of the human larynx, upon the special senses of smell and taste, tension of the vocal bands, the nervous origin of diseases, the physiology of the voice, the paralysis of the larynx, morbid growths in nose and throat, new operations for deformities, descriptions of many new instruments, new remedies, climatology in connection with laryngeal phthisis, photography of the larynx, correction of the faults of the voice, investigations with regard to brain centres, etc. These papers are the result of *original* thought, invention and discovery, and we have reason to be proud of them.

Ten years ago I said that in no special branch of medicine were such advances being made as in our own. I am pleased to say that within these ten years there has been an advance all along the line of medicine and surgery, perhaps more marked in the special departments of brain and abdominal surgery. The

¹ Boston, June 20, 1892.² Recherches sur le mécanisme de la voix humaine. Recherches sur les maladies de la voix humaine. Par F. Beunati. Paris, 1832.

methods used and the results obtained are largely due to the discoveries which have been made in the biological laboratories. Let us hope that the future will not find us behind in the rapid march of improvement and discovery.

I believe that our advance will be greatly helped by faithful adherence to this Association. A man's education does not consist entirely of what he can acquire by his own effort. Companionship with fellow-workers is necessary to complete his growth. The kindly but severe criticism of those who are engaged in similar pursuits, and who are, therefore, best fitted to estimate the value of any theory or invention is of incalculable use. Membership is not only a means of information, but it is a stimulus to work and production as well.

Let us hope that the next ten years will show such a record of work performed, of knowledge gained, that the American Laryngological will not occupy any other position than that which has always been accorded it, namely, the first in merit as well as in priority of establishment.

THE VERTIGO OF ARTERIO-SCлерOSIS.¹

BY ARCHIBALD CHURCH, M.D.,

Professor of Neurology, Chicago Polyclinic; Lecturer on Insanity, Chicago Medical College.

The discussion of a pathologically subjective state is in itself practically impossible, and the difficulty is not lessened when that state is a symptom of many widely differing conditions, some functional and some grossly organic. To use the term vertigo is therefore undesirable, but for lack of one more definite its employment a necessity, and in this connection is not open, perhaps, to the emphatic objection that elsewhere obtains. It is in its generic sense that I wish to make use of it.

In a very recent and comprehensive article Suckling² takes up the subject of vertigo and in a way describes it as the consciousness of disordered equilibration, showing that it may exist from want of harmony in the impressions received from any of the senses, and possibly from the sensibility of the viscera as well, but it is not the present purpose to direct attention to the physiology of equilibration nor to take up the interesting topic of co-ordination, which is closely associated therewith. He clinically classifies the forms of vertigo as aural, ocular, vascular, dyspeptic, nervous, epileptic, toxic, of organic brain disease, and from reflex irritation, but says specifically nothing of the vertigo of arterio-sclerosis. Most other writers either on the topic of vertigo or that of arterio-sclerosis are equally silent; yet vertigo may be and often is, as will be urged farther on, a signal symptom of this arterial state, the proper recognition of which may lead to such treatment as will obviate organic diseases of the brain, kidneys, liver, and other important structures, and many times definitively prolong life.

It is only of late years that arterial changes have been given the importance in pathology and in clinical medicine that they deserve. The degeneration of senility, the modifications found in gout, rheumatism,

chronic metallic poisoning, syphilis, and which are associated with alcoholism, Bright's disease, and many other serious maladies, makes it imperative that we recognize at the earliest moment the presence of a change in the artery which may in many instances be amenable, in the early stage, to treatment but which soon otherwise passes beyond the possibility of medical control. Atheroma is not here synonymous by any means. It is the pre-atheromatous condition with which we have to deal, and it is the vertigo symptomatic of that arterial fibrosis to which your attention is directed. As a matter of demonstrable fact this arterial state is widely and generally disseminated in these cases, but the complexion of the disease varies with its local intensity. In some instances a contracted kidney, in others angina pectoris, in others the cerebral symptoms are the prominent features, and of the brain symptoms the earliest is vertigo, and the last cerebræ hemorrhage or dementia.

When a man past the prime of life, without any previous serious illness, becomes suddenly faint, has a swimming in the head, a feeling of giddiness, of distinct gyration, of darkness and impending death, one or several of these sensations, he usually at once seeks advice in grave apprehension, sometimes well founded, of approaching cerebral apoplexy, and usually gets a chalagogue cathartic, or is told that his stomach is wrong, and sometimes is told rightly. But cases are constantly presenting themselves in which such vertiginous attacks are happening at shortening intervals, the patient gives up his tobacco, his spirits, if he is a drinker, cuts down his meat, takes to some of the many waters recommended, has Turkish baths, and gains only moderate relief—or none at all. If he is carefully examined he will probably present a well defined tortuous frontal artery, a distinct arcus senilis, a strong, even a clanging, second sound of the heart, sometimes reduplicated, and give a sphygmogram indicative of increased arterial tension. The pulse may be abnormally slow or arrhythmic, the urine scant and a trace of albumen is not rare. He finds that exertion of a moderate amount precipitates the attack, that he cannot endure a temperature at all above the usual, and often a change of position from recumbency to the upright is the occasion of a "blurr" or of giddiness.

The attack itself is, as already indicated, widely variable in different patients, but usually consists with itself for the given individual. A fullness and throbbing in the head, a feeling of heat in the scalp, and a blur before the eyes are usually mentioned, and at such times marked paleness is noticed, followed, as a rule, by considerable redness of the face. There is a tendency to get into the open air, and badly-ventilated or close apartments are unendurable. An habitual smoker will sometimes find tobacco smoke repugnant. In more severe forms the patient may stagger, fall, or gradually sink to the ground; he cannot speak for a few seconds though consciousness is rarely completely lost. The recumbent position is usually sought, or the patient clings to some object, and after a period of from five to twenty minutes the feeling passes away leaving him rather languid, with an inclination to sleep, and usually mentally depressed and apprehensive. At first he attributes the attack to anything and everything that in his estimation can cause a departure from health, and usually establishes a close watch upon his diet, habits and mode of life, is inclined to avoid exercise or exertion of any sort, fearing to precipitate an

¹ Read before the American Medical Association, June 8, 1892.

² Birmingham Med. Rev., Nov. 1891.

attack, or to go by himself on the streets, and in short becomes an invalid with hypochondriacal tendencies.

In a remarkable monograph on this subject Professor J. Grasset,⁴ of Montpellier, divides the vertigos of arterio-sclerosis into three forms: (1) Simple vertigo, (2) Vertigo with epileptiform crises, and (3) Vertigo with slow pulse and syncopic, or epileptiform attacks. Some of the features of the slighter attacks, as already roughly sketched, undoubtedly suggest a similarity to mild epileptic seizures, for instance, the paleness of the face, the oppression and the final confusion, depression and tendency to sleep, but personally I have never encountered well marked convulsive phenomena reasonably attributable to this cause.

With Huchard,⁵ this writer is inclined in some cases to attribute acquired habitual extreme slowness of the pulse, which in numerous reported instances has ranged from twenty to forty per minute, or even less, to the effect upon the medulla of an arterio-sclerosis acting mechanically to lessen the blood-supply to the cardiac centres. As yet this hypothesis has received, as far as I have been able to ascertain, no positive anatomical or experimental support, though it is seductively reasonable. This bradycardia is almost always marked by syncopal and vertiginous features and arises in individuals predisposed to or actually the subjects of marked arterio-fibrosis.

The diagnosis is often one of extreme difficulty, in spite of a hasty contrary statement by a recent American writer, and I have known this symptomatic vertigo confused with Meniere's disease by a very competent specialist in nervous diseases, for it may, as in that particular instance, be of a systematized character, that is to say, marked by a sensation of falling in a given direction, or of being rotated in a constant manner to the right or left, and even associated with a suggestive stagger. If to this a little middle ear catarrh is added, a diagnosis of aural vertigo might be easily reached, but a closer and somewhat wider examination will detect the integrity of the auditory nerve and the presence of the arterial fibrosis with the underlying predisposition of alcoholic excess, syphilis, gout, rheumatism, chronic lead infection, or other constitutional state of etiological significance.

In the treatment the basic element is the object of attack, and whatever this may be, the iodide of potash will find an indication in the arterial change, which if recognized in its incipiency can be practically controlled, providing the patient is manageable. It is the sheet anchor, and given in moderate doses of from thirty to ninety grains a day for a number of months, much benefit and often a substantial cure can be expected.

I am lead to emphasize the importance of this vertigo because it is a very early symptom of a condition which neglected leads to distressing and even fatal results, and which unrecognized is the source of endless anxiety and misery to the patient and of chagrin and disappointment to his medical attendant. If it were desirable numerous case records could be cited, but it is hoped that attention once having been called to a proper interpretation of the symptom it may be less frequently mistaken, and I would urge that the condition of the arteries and the heart be made an object of early and thorough investigation in every instance where obscure vertiginous attacks, or a persistent giddiness is present.

⁵ Traité des Maladies du cœur et des vaisseaux.

MALARIAL EPILEPSY.¹

BY EUGENE W. HILL, M.D., WEST BOSTON, MASS.

TWENTY-ONE years ago Echeverria, in the preface of his work, stated "It does not claim to offer any new discovery . . . still less is it designed to be an English treatise on epilepsy." I have attempted to meet a deficiency in my own knowledge by comparing the cases I have carefully noted. How far these notes may meet the wants of others remains to be seen. The foregoing expresses the object of this paper.

I have selected from my notes two cases of malarial epilepsy, with some observations as to the prognosis of epilepsy in general as modified by treatment, which I submit for your approval.

CASE I. M. F., a boy, eighteen years of age. Parents dead; father from alcoholism, mother from phthisis. Patient was never mentally at par, and for a year after birth had periods of dulness lasting several days during which he was morose and sleepy. At school, he was not apt, and was withdrawn early; being of slender physique and in indigent circumstances, he remained at home without education, employment or medical assistance. Under this routine, he gradually became morbid and melancholic. Two years ago he was attacked by the tertian form of intermittent fever, responding readily to treatment. Hygienic measures and anti-malarial treatment were instituted for two or three months. Under this stimulus he improved mentally and physically, and for a year suffered from no ailment of any kind until he was seized by malarial fever of the same form, beginning with a twenty-five-minute chill; the second day he remained in bed, with normal temperature but irregular pulse; at time of expected chill on the following day a convolution occurred, followed by others. Medical assistance for this seizure was not until then summoned. I found him unconscious, convulsions occurring every five or six minutes, beginning locally by twitchings in the right hand extending up the muscles of the arm, followed by rotation of the eyes and head over the left shoulder, with a general epileptic paroxysm. The face during the quiet interval was flushed and hot, but became livid during the spasm. The temperature was difficult to follow from the rapidity of the convulsions, but rose to about 104° in the interval, and from 104.5° to 105° during latter part of the paroxysm; the usual depression seen before a normal epileptic explosion I was unable to obtain; the pulse was irregular, weak, bounding from 80 to 140 and over. Gradually perspiration appeared on the forehead and upper extremities of a cadaveric odor, the temperature fell gradually to 100° between, and 101° during the paroxysm, the urine was passed involuntarily, nearly colorless in character. The epileptic status still continued showing no change or diminution of vigor with falling temperature and profuse perspiration as compared with the previous condition of high temperature, flushed face and dry skin. For five hours they averaged four to eight per hour. Chloroform and nitrate of amyl controlled them slightly, but one-fiftieth of a grain of nitro-glycerine (two drops, one per cent.), dropped on the tongue every twenty minutes caused a gradual cessation in course of an hour, during which bromides were administered with quinine hypodermatically. Nevertheless, the paroxysms again returned and continued until death in the morning.

¹ Read before the Norfolk District Medical Society, January 29, 1892.

CASE II. F. K., a boy, aged nine, strong and hardy. Parents living; no hereditary history of any disease; three sisters all in good health. In April, 1890, he suffered from intermittent fever, beginning with a chill at 4 A. M. Forty-eight hours later had an attack commencing at midnight, ceasing at 7 A. M., about twelve paroxysms, but did not bite his tongue.

In May, 1891, one year later, suffered from malarial intermittent fever as before. On third day, at time of expectant chill, was seized with convulsions to the number of fifteen. Bromide amyl pearls and chloroform failed to give results which followed use of nitro-glycerine as in previous case. The paroxysms recurred in spite of treatment every other day for ten days, but diminishing in number and severity. The temperature gave the same rise and fall as in Case I, but never ascended above 103°. The scalp remained very tender for several days. The patient was still subject during the autumn, about once a month, to nocturnal attacks preceding twenty-four to thirty-six hours by malaise, nausea and vomiting. The attacks are readily aborted by quinine, bromides and calomel.

These cases are the result of malarial fever in New England; during the years 1880 and 1884 forms of malarial fever appeared in Massachusetts of sufficient frequency to claim the attention of the State Board of Health. In the latter part of 1885 and beginning of 1886, they were epidemic in character at South Framingham, disappearing from its previous localities, spreading along the course of a small stream (Beaver-dam Brook) to Natick. Since 1886, it has disappeared entirely from South Framingham, and became prevalent along the Charles River through South Natick, Wellesley, Dover, Watertown, and the Newtons. In South Natick and Dover, the location of the cases reported, malarial fever prevails with greater severity than in any portion of the valley, scarcely any resident escaping during the summer and fall seasons.

Malarial epilepsy has been recognized from early times of medicine. Hippocrates clearly refers to epileptic fevers (*febro comitales*) and their greater frequency during the spring and autumn months (*Echeverria*). According to modern authors, it is rare. The literature examined shows reports only by

Lowe and Paine: Indian Annals of Medical Science, Calcutta, 1860-61, vol. vii, p. 267, et seq.

Hansfield Jones: Clinical Observations of Functional Nervous Disorders, 1868, p. 139.

Echeverria: Epilepsy, 1870. Two cases.

Mackay: Edinburgh, Eng. One case in detail.

Jacobi: Hospital Gazette, New York, 1879, pp. 41-43. One case.

Hamilton: Pepper's System, vol. v, p. 472. Three cases.

Hammond: Nervous Diseases, 1891, 7th edition. Seven cases as a cause (?).

Ferreira: Archivo Italiano di Pediat., 1889.

Ferreira finds four varieties of cerebral form of malaria seen in children during the heated season: (1) the eclamptic, (2) the comatose, (3) the delirious, (4) meningitic. The last two were observed in older children.

Meigs,² Pepper² and Lewis Smith⁴ hold that it is not unusual for malarial fever to be ushered in by a convolution taking the place of a chill; and in 1882 the *North Carolina Medical Journal* stated, editorially, "there is no more fatal disease in children in the malarial districts of the South than malarial eclampsia."

Dr. Smith, however, says he is surprised at the immunity of epileptics from infantile convulsions.

Dr. Morris J. Lewis,⁴ with ten years' experience at the Dispensary of the Children's Hospital, Philadelphia, has failed at that parallel to note such fatal results from malarial poison as seen in North Carolina; and in New England, malarial fever, I believe, does not show any such convulsive substitution.

It is interesting to note — already mentioned — that the convulsions continued unchanged with unrelenting energy under three entirely different conditions, namely, the three stages of an intermittent fever; (2) the temperature rose with the close of each paroxysm, but fell in the quiet interval to the fever level, and did not show the abrupt, rapid and successive rise which occurs in eclampsia;⁵ (3) the success of nitro-glycerine, as an epileptic status, over bromides, chloroform and nitrate of amyl, especially in those cases characterized with a large flow of pale urine, and which is in accord with the observations of others.

Clinical Department.

A CASE OF INFLUENZA WITH ERUPTION.¹

BY CAPT. S. G. ROBINSON,

Medical Department United States Army, Fort du Chesne, Utah.

LOUIS SCHEAR, white, age nineteen, laborer, was admitted to the post hospital at Fort Du Chesne, Utah, on March 28th, with the following history: With the exception of measles fifteen years ago, and typhoid fever one year ago, has always been strong and well. Has worked in the Park City mines, but has never had any symptoms indicating lead poisoning. Was taken sick seven days before admission with headache, severe pains in the calves of the legs, slight chilly sensations, fever, slight cough, marked muscular weakness and loss of appetite, two days after which an eruption appeared which even when first noticed was universal. Has taken no medicine.

When admitted, he had a temperature of 101.5° (which rose that afternoon to 103°), a pulse of 120, a slight cough, no corza or conjunctivitis. Over the whole body, but most abundant on the legs, where it was deeper in shade, was an eruption of reddish spots from one-half to two millimetres in diameter, irregularly circular, coalescing in a few instances, elevated just enough to be perceptible to the touch, not exclusively associated with hair follicles, without special arrangement, not itching, and which fourteen days after its appearance—gradually faded without desquamation. On the hard and soft palate, were similar spots, with such modifications in appearance as might be expected from their seat. It was also visible on the palms of the hands. Epitrochlear and inguinal glands to be felt. On the knuckle of the right ring-finger was a slight abrasion surrounded by a parchment-like induration. This came, the patient said, from a burn received the day before he was taken ill. It disappeared without treatment. No oedema of legs or swelling of joints. Some sub-sternal soreness on coughing, but no tenderness on percussion. Tongue coated, bowels constipated, urine scanty and depositing urates, but otherwise

normal. Auscultation of heart and lungs gave negative results. The temperature, which gradually declined, was usually one-half to one degree higher in the morning, and became normal on the eighth day after admission. He complained once of a sore throat, which was speedily relieved by a chlorate of potash gargle. No trace of sores or induration on penis or in rectum. He was discharged from hospital April 7th, complaining only of a weakness that was rapidly passing away.

The treatment was limited to rest in bed, regulation of the diet and the administration of a few doses of quinine, Dover's powder and phenacetin.

The interest in this case centres on the diagnosis. Without the eruption and during the prevalence of influenza, one would not hesitate to give the disorder that name. Cases of influenza accompanied by an eruption have recently been reported. Was this one?

A CASE OF RECURRENT APPENDICITIS; OPERATION; RECOVERY.

BY JOHN C. MUNRO, M.D.

The following is reported as a contribution to those cases of removal of the appendix for recurrent, severe attacks of pain, in which the pathological lesions are not commensurate with the suffering endured.

N. M., seventeen years old, servant, rather fat and undersized, with a marked phthisical family history, and of a nervous temperament, came to me first in November, 1889. In the previous year she had had a short attack of colic, but none since, until a few weeks before I saw her when she had had several attacks of cramps in the bowels, coming on generally at night, and, so far as could be determined, without any reference to the catamenia, diet, etc.

There were no evidences of heart, lung, renal or hepatic trouble; the menses were normal, and the bowels, though constipated, were regular. Improvement followed the administration of iron and laxatives.

In the latter part of December, however, without any warning, she had a severe colic lasting eight hours, and not relieved by hot applications or mild opiates. She could lie partly on the right side and located the pain in the cecal region. The next morning, feeling better, she worked; but in the afternoon the pain returned, and she came to my office, when I found marked tenderness over the cecal region, but a normal pulse and temperature. She complained that the jolting of the horse-car caused pain in the same locality.

That night she had a severe attack; Dr. Vaughan, of Cambridge, was called in, and found her suffering acutely, with a weak, rapid pulse, but normal temperature. Pain was controlled only by large doses of morphia. The following morning I saw her with Dr. Vaughan, and he kindly admitted her to his wards in the Cambridge Hospital, where she remained about two weeks and made an uninterrupted recovery under rest, diet and opium.

For a few weeks she did well; but a mild attack coming on, she went at my advice to St. Luke's Home. No gain was made, so she was admitted to the gynecological ward at the Carney Hospital, and carefully examined for pelvic trouble, with negative result, a diagnosis of inflammation of the appendix being made. While there she had some slight attacks, but being

anxious to work, she returned to her former place in Cambridge. Shortly afterwards, while reaching upwards, she felt a sharp stinging pain in the abdomen; and this was followed, in a few hours, by one of the old attacks, and then for the next two months by repeated sharp, short attacks, together with a constant dull aching and tenderness over the cecum, always made worse by fatigue or jolting.

In the summer of 1890 I proposed excision to her, or absolute rest for four months. She chose the latter and went into the country; but, even with the most careful diet and rest, she had one acute attack that kept her in bed for a week.

I did not see her again until January, 1891, when she reported that she had been trying to do light work, but that the cramps were induced at the slightest provocation. She looked badly: was thin, discouraged, and showed in her face that she had suffered a great deal. She asked that some operation be done; and a few days later Dr. R. W. Lovett kindly saw her in consultation. No satisfactory examination could be made on account of the extreme sensitiveness over the lower right abdomen.

On February 20th, at St. Margaret's Infirmary, with the kind assistance of Drs. Mixer, Lovett and Paul Thorndike the abdomen was opened in the right linea semilunaria. The uterine appendages on the right, as examined by my finger, were apparently normal. On the cecum were a few strands of fresh lymph. The appendix appeared to be normal, though perhaps slightly rigid and thickened. It seemed best, however, to remove it, and after ligating its mesentery, it was amputated about one-third of an inch from the cecum, the peritoneum being invaginated and secured over the stump with silk. The abdominal wound, including the peritoneum, was closed with silk and dressed with iodoform gauze and a swathe.

During the day she had some pain, controlled by morphia; and that night the temperature rose to 101°, but rapidly fell to normal and remained so throughout.

Convalescence progressed steadily, twice during the first week pain from gas in the intestine being immediately relieved by a turpentine enema; and on the fifth day the bowels were thoroughly moved by a Seiditz powder. At the first dressing on the sixth day there was primary union, and by the thirteenth day all the stitches were out. She sat up on the seventeenth day, and as soon as able was moved to St. Luke's Home, wearing an abdominal supporter.

At no time since the operation — over a year now — has she had any return of the original attacks.

The portion of the appendix removed was kindly examined by Dr. H. F. Sears, at the Pathological Laboratory of the Harvard Medical School, and pronounced normal so far as could be determined microscopically.

M. BROUARDÉL, M. Ogier, and M. Du Mesnil have reported to the Academy of Medicine concerning the sanitation of cemeteries. Their investigation has demonstrated that the speedy or slow destruction of the corpse is in direct proportion to the quantity of air which reaches it; in chalky soil, dead bodies become transformed into a fatty substance, which lasts five or ten years; but if air freely circulates they are completely destroyed at the end of a year.

Medical Progress.

RECENT PROGRESS IN ANATOMY.

BY THOMAS DWIGHT, M.D.

THE RELATIONS OF THE BRONCHI TO THE POSTERIOR WALL OF THE THORAX.¹

BIANCHI and Cocchi examined twenty-one bodies, with the following results: They find that the trachea divides opposite the body of the fifth dorsal vertebra, and that its lower end is somewhat to the right of the middle line. They state that the right primary bronchus, which descends more obliquely than the left one, corresponds to the fifth intercostal space. The left primary one runs parallel to the sixth rib. (We report this without explaining it.) The area occupied by the great and medium bronchial tubes extends vertically from the fourth intercostal space or the third rib, to the eighth space, and laterally to four or five centimetres from the line of the spinous processes.

SOME ANOMALIES OF THE CRANIA OF THE INSANE.

Bianchi and Marimò have examined over a thousand skulls of insane persons. Among their conclusions are the following. They believe that cranial anomalies are, perhaps, more dependent on the locality from which the persons came than on the disease or the degree of intelligence of the individuals. In so-called degenerative forms, purely bony anomalies related to cerebral development are more rare than in psychoneurotics. There is no direct relation between insanity and cranial anomalies, but yet these are much more common in the skulls of the insane.

THE NUMBER OF PIECES IN THE COCCYX.

F. Marimò has studied the number of pieces in this fusion of vertebral elements on 66 skeletons of male criminals. There were no vertebral anomalies in 56 of these spines. Of these 21 had five pieces, 15 had four pieces only, and 11 had four pieces with a suspicion of a fifth. Of the other ten spines, six had five pieces and four had four pieces. Marimò looks on this as evidence that perhaps it is more usual to have five pieces than four in the coccyx, and especially as these are all male skeletons, believing that coccyges of five pieces are more commonly found in women. He does not seem to be acquainted with E. Steinbach's researches,² who found that five is the more usual number in men and that coccyges of four and five pieces occur about evenly in women.

THE WEIGHT OF THE TWO SIDES OF THE BRAIN.³

It is very generally held that the left half of the brain is heavier than the right, and this alleged fact has been frequently brought forward as a physical cause for right-handedness. Professor Braune has done a very important work by weighing, and having weighed by other competent men, one hundred human brains. These were divided in the median line and the cerebella with the medulla and pons cut off and bisected. Thus the table shows the comparative weights of the two sides of the whole encephalon and also of the cerebral hemispheres and the halves of the

cerebellum (with medulla and pons). The two sides of the whole were equal once. The left side was the heavier in 52, and the right in 47.

It is curious to find that if the excess of weights of the two sides is added up the right shows a preponderance. It is further to be remarked, as Braune points out, that in most cases the difference between the two sides was so slight as to deserve no consideration. In five cases in which the right side considerably outweighed the left the bodies were examined for signs of left-handedness, but none were found. Other curious results were obtained from the results of the weighing of the separate parts, which, however, was not always done. Once the cerebral hemispheres were equal. Of 91 other brains the right hemisphere was the heavier in 54 and the left in 37. Of the cerebellae five had the two sides equal. In 54 cases the left side was the heavier, in 38 the right. Thus in the number of cases we find that the hemisphere of one side is the larger about as often as the cerebellum of the other. But in this connection it must be very carefully noticed that we do not say that the larger half of the cerebellum is to be found on the opposite side from the larger hemisphere. Braune does not feel justified in drawing conclusions from the observations on the cerebellum. For our own satisfaction we have gone through his tables to see whether the larger hemisphere and the larger lobe of the cerebellum are on opposite sides. We find that the larger halves are on the same side about twice as often as on different sides.

THE PHRENIC NERVE.

Dr. John Fergusson, in *Brain*, 1891, gives evidence in support of the view, which had been previously advanced, that the phrenic contains sensory as well as motor fibres. In the autopsy of a case of progressive muscular atrophy in which the diaphragm was involved, certain fibres in the phrenics were found uninjured. Some vivisections on cats gave confirmatory results. One observation may be given in his own words: "About nine months ago I had a patient who died of an abscess in the liver. There was decided inflammation of the serous membrane covering the diaphragm in contact with the liver. In this case the pain in the back of the neck and out on the shoulder was very intense. The pain was always made worse by movements, coughing, or vomiting. These acts disturbed the diaphragm and at once started or intensified the pain in the shoulders and neck." We would suggest that this may be the long-sought cause of the pain in the acromion sometimes found in disease of the liver. The skin over the acromion and clavicle is supplied by the descending superficial branches of the cervical plexus, coming chiefly from the third and fourth nerves and practically wholly sensory. If sensory fibres from the same nerves go into the phrenic, which is derived chiefly from the fourth, the connection is evident.

THE HORIZONTAL LEVEL OF THE HUMAN SKULL.

Professor Braune⁴ has written a long paper on this subject. It is clear that such a basis for craniological observations is very desirable. What has been called the Frankfort level was one adopted by a meeting of anthropologists in that city in 1882. It is the plane bounded laterally by two lines passing from the highest point of the external auditory meatus to the lowest of the inferior border of the orbit. In many skulls

¹ This and the two following titles are accounts of papers read at the Congress of the Italian Medical Association held at Siena in August, 1891. They are taken from reports in *Arch. Italiennes de Biologie*, tome xvi, fasc. 1, 1891.

⁴ Festschrift zu Rudolf Virchow, Band I, 1891.

this is practically the same as a plane bounded by the upper border of the zygomatica. It has been objected to the Frankfort level that it is situated by the frequent want of symmetry of the two sides of the head and face. Braune made many observations on this point. He found that there is an error; indeed it is evident that there must be one, but he does not consider it serious. He finds that, as Ecker has already shown, this plane does not correspond with a physiological horizontal. Such a horizontal in fact does not exist. One can speak only of a mean position of the head in standing. He finds further that the carriage of the head varies considerably according to the position of its centre of gravity, according to the curves of the spine and the state of the muscles. He concludes very justly from all this that craniological measurements must be quite independent of the position in which the head is carried and suggests that the line in question should no longer be called horizontal.

THE OBTURATOR ARTERY.⁵

Dr. Zastschinski discusses the variations of the obturator artery in a very able paper of, however, a somewhat bewildering minuteness. The following are his conclusions:

(1) Of the irregular origins of the obturator artery the most common is that from the internal epigastric (in about 28 per cent. of all cases, normal and abnormal). That from the external iliac occurs in about 1.2 per cent., and that from the femoral in about .4 per cent. The irregular origin is most common in childhood, in the female, and probably on the right side of the body.

(2) The author renewes an old and just charge that anatomists, while discussing at length variations in the origin of this artery, are silent on the point of greatest practical interest to the surgeon, namely, the relation of the irregular branch to the crural ring, and consequently to femoral hernia. He finds that this relation varies with the origin of the artery. If it springs from the external iliac, it has no relation to the hernia; if from the femoral, the artery runs behind it. If the obturator arises from the internal epigastric, its relation varies with its point of origin. If from the first part of the artery, between the internal iliac and Poupart's ligament, it runs outside of the ring; if it arises above Poupart's ligament, it runs inside the ring.

(3) *The course external to the hernia is the rule, that internal to it a rare exception. In women the internal course is rarer than in men.*

(4) At the height of the ilio-pectineal line the obturator artery is not in contact with the posterior surface of Gimbernat's ligament, but is from 1.5 to 1.7 centimetres distant from it. There is, therefore, less danger in an operation for femoral hernia at this point than at Poupart's ligament, close to which the abnormal artery runs.

(5) Anomalies of this artery arise either during foetal life or directly after birth.

(6) New variations do not occur in adult life.

(7) The anomaly requires for its production, first, a system of anastomoses between the internal epigastric and the normal obturator, in which the blood current is directed towards the obturator foramen; and, secondly, some interference with the growth of the normal vessel.

⁵ Internationale Monatschrift für Anatomie und Physiologie, 1891.

THE CIRCUMFLEX ILIAC ARTERY.

In a recent Report we referred to a paper by Trzebicki, in which he described a case of serious bleeding from an artery in the abdominal wall which was hit by tapping at the point said to have been recommended by Munro, namely, at the middle of a line from the navel to the anterior superior spine of the ilium. Trzebicki came to the conclusion that this is not a safe place, owing to the proximity of branches of the internal epigastric, and advises either to tap in the median line or in the outer half of the above-mentioned line. Now comes Dr. Hermann Stieda⁶ to prove that the danger comes from another artery, namely, a branch of the circumflex iliac. The branch in question is thus described in Quain's anatomy: "One considerable branch, sometimes replaced, however, by two or three smaller ones, arises near the anterior superior spine, and ascends between the internal oblique and transversalis muscles, supplying the abdominal wall and anastomosing with the epigastric and lumbar arteries." According to Stieda this branch, which, following Führer, he calls the external epigastric, arises usually from four to six centimetres from the anterior superior spine measured along Poupart's ligament. It sometimes extends to above the umbilicus. At the level of the anterior superior spine it is usually from four to five and a half centimetres internal to it. This writer, therefore, protests against Trzebicki's advice to tap in the outer half of the so-called line of Munro.

THE LOBULE OF THE LUNG AND ITS BLOOD-VESSELS.

Dr. W. S. Miller, of Clark University,⁷ has done some very excellent work on this subject which he has studied by injections, corrossions, and reconstructions. Some of our readers may be glad of a description of the last named method, which we give in Dr. Miller's own words: "For the more complex lungs the reconstruction method of Born was resorted to, by which after the devotion of nearly two years to a single specimen, the desired light was obtained. The lung was first prepared by making a triple injection by which the capillaries were filled with Prussian blue, the arteries with vermillion, and the veins with ultramarine-blue gelatine. A single lobule was then removed, imbedded in paraffine and cut into sections twenty μ ⁸ thick. The magnifying power employed in reconstruction was one hundred, and each section was drawn on a wax plate two millimetres thick. As long as the terminal bronchus is in the section, it is quite easy to locate all the air-cells from section to section. Beyond the terminal bronchus the location of the blood-vessels and the shape of the air-sacs served as guides. In this way all the air-cells communicating with one bronchus were drawn on wax plates, and the sections carefully cut out. The framework left, when piled up, gave an exact model of the air-sacs, and the pieces piled gave a 'corrosion' of the same. The models were now cut in various directions in order to study the relation of the air-sacs to the terminal bronchus."

These studies, which were made on the dog's lung, gave the following result: A terminal bronchus gives off a number of passages called *vestibules*, each opening into an expansion called the *atrium*. From this three or more *air-sac passages* run to as many *air-sacs*,

⁶ Anatomisches Anzeiger, Nos. 7 and 8, April, 1892.

⁷ Ibid., 1892, No. 6.

⁸ This is twenty micro-millimetres.

which are much larger than the atria. Around the air-sacs lie the *air-cells*. To be accurate, we should say some of the air-cells, for there are others arising from the bronchi and from the atria. The air-cells do not communicate directly, one with another. Dr. Miller states that the walls of the atria are thin like those of the air-sacs, having a network of capillaries enclosed in them. We infer from this that these parts as well as the air-cells serve for respiration.

The branches of the pulmonary artery follow the bronchi. Somewhat beyond the terminal bronchus the vessel divides into as many terminal branches as there are atria. Their ramifications cover the central side of the air-sacs, the capillary-network which arises from them enveloping the whole system, and emptying into veins which lie on the peripheral side. In the lobule each air-sac has a vein running at right angles to the direction of the artery. For the most part the veins keep on the periphery of the lobule. Each air-sac has an artery on its central and a vein on its peripheral side with a rich capillary system between them.

Reports of Societies.

ASSOCIATION OF AMERICAN PHYSICIANS.

THE Seventh Annual Meeting, held in the Army Medical Museum, Washington, D. C., May 24, 25, and 26, 1892.

SECOND DAY, AFTERNOON SESSION (CONTINUED). THE SIGNIFICANCE OF INTERMISSION ON FUNCTIONAL NERVOUS DISEASES,

by DR. W. H. THOMSON, New York.

The term functional has been applied in general to the nervous diseases in which no characteristic organic changes have yet been demonstrated. Most writers, however, regard the term as only provisional, on the assumption that some kind of structural change in nervous matter must underlie every definite nervous disorder and that such change will in time be found. It has long seemed to the author that there are intermittent nervous disorders which cannot be explained by any hypothesis of changes in nervous matter whether molecular or otherwise, but are to be explained by the varied states of the blood which causes the nervous system to functionate.

By a proper selection of functional poisons we can artificially induce some close imitations of functional neuroses and cause neuralgias, paralyses, delirium, convulsions and all intermittent symptoms of the kind and then note these symptoms disappear in about the time and order that the functional nervous attacks decline. Another correspondence between functional poisons and functional neuroses is, that in both, pathological anatomy affords no assistance in the explanation of the results. Other correspondences between functional poisons and functional neuroses were given.

Modern chemistry tells us that in the healthiest processes of our digestion a whole series of poisons are elaborated which are of the same nature with the functional poisons with which we have been long familiar as quite sufficient to cause every variety of functional nervous derangements and even to kill without the microscope or scalpel being able to tell why.

Against the perils of auto-infection the system is provided with a variety of safeguards. One of the most efficient seems to be the antiseptic properties of the digestive secretions which keep the putrefactive processes in the alimentary canal in check. The liver also subserves a preservative function against auto-infection. But the complex chemistry of these secretions is liable to numerous disturbing influences, notably nervous irritations. If nervous influences are capable of deranging the chemistry of the body, why may not such perturbances of nervous origin, occurring now and then, as nervous actions characteristically do, suffice to produce either increased amounts of alkaloidal poisons or else to diminish the effectiveness of the normal antidotal processes? These considerations seem to offer us a hint of the explanation of the intermittency in functional neuroses.

The bearing of this view of functional neuroses on treatment is as follows: First, instead of vaguely expecting help from structural anatomy to show us the pathology and then the treatment of this difficult class of diseases, and meanwhile choosing our remedies according to the old empirical methods, the physician should look for aid to advance in the knowledge of the chemistry of diet. Second, gastro-intestinal antisepsis should be studied as a particular branch of therapeutics. (The value of a certain class of purgatives, conjoined with the administration of antisepsics, has been particularly impressed upon the author's mind in the treatment of migraine, of hysteria and of melancholia with quickened pulse.) Lastly, the investigation of leucomaines, of which lithemic states are an example, is of equal importance in a great variety of morbid states, with functional disturbances.

Directed by these three principles, suggested by the progress of organic chemistry, I think that our treatment of functional diseases would be much more effective than if we continue to seek for mere drugs with specific properties or fruitlessly to wait the verdict of pathological anatomy.

A COLLECTIVE INVESTIGATION IN REGARD TO THE VALUE OF QUININE IN MALARIAL HEMATURIA OR MALARIAL HEMOGLOBINURIA,

by DR. H. A. HARE, Philadelphia.

This paper consisted of an analysis of about 150 reports from physicians through the South as to the frequency, danger, chief symptoms and treatment of malarial hematuria and hemoglobinuria, with particular reference to the value of quinine in this condition.

DR. I. E. ATKINSON: Undoubtedly the key-note has been struck when the production of hematuria and hemoglobinuria by quinine is attributed to idiosyncrasy. That quinine has any fixed tendency to produce these conditions I do not believe, but that idiosyncrasy will call forth these conditions I have no doubt. Some five or six years ago I had an opportunity of studying several cases of hematuria in patients residing in an extremely malarious district south of the James River in Virginia. They did not suffer from distinct paroxysms of malarial fever. Their hematuria would come on at irregular times, would last for weeks and months, than would stop only to recur again. They were very anæmic. It occurred to me that these cases were of parasitic origin. I looked for the Bilharzia haemotobia, but did not find it, nor did I find any parasite, but the suspicion still remains in my mind that these forms of haematuria

that are found in certain low portions of the country in which malaria prevails will be found to be due to some form of parasite not malarial. I have saturated these people with quinine, without good results. I have stopped the haematuria by other agents, notably turpentine.

DR. TYSON: I am satisfied that for the mild form of malarial haematuria which occurs in the Middle States, quinine is the remedy. In the severe cases, the blood has been reduced to a broken-down condition; the mischief has already been done and we must treat the condition which has resulted rather than prevent its occurrence. There doubtless occur all over the country even in the extreme South where these marked cases occur, certain of the milder cases such as we have in the Middle States. These milder cases are curable with quinine and I think they may account for the difference of opinion amongst Southern physicians in regard to the use of quinine. If I were living in the South and were confronted with these severe cases, it seems to me that I would prefer to run the risk of using quinine, rather than lose the chance of the good it might do.

I have had experience with the class of cases mentioned by Dr. Atkinson, but I was not led to the belief that they were due to a parasite. I never found a parasite, and it seems to me that they would not have improved had they been due to parasitic origin. I have saturated these cases with quinine and given them arsenic until they were edematous, without any effect whatever. I have had better success with astringent mineral waters, such, for example, as Rockbridge Alum Water.

DR. C. G. STOCKTON: Some years ago, at a meeting of the American Medical Association, I heard a paper upon hematuria, in which the use of large doses of alum were recommended. I have since had experience with this drug in this condition and I believe that many cases of hematuria that have resisted other remedies can be controlled by its use in large doses.

DR. HENRY: Before concluding that quinine is injurious in malarial haematuria, I think we would need to have more cases than those collected by Dr. Hare. I think it ought to be thoroughly established by microscopic examination that the cases in question are malarious and no conclusions should be drawn until such evidence is forthcoming. It may be interesting, from a historical point of view, to know that the first four cases of hematuria on record were cured by large doses of quinine.

DR. V. C. VAUGHAN: I do not believe that quinine has any marked tendency to cause hematuria. I have seen a great deal of quinine administered and have seen many idiosyncrasies, but I have yet to see a case of hematuria. I once took one hundred grains of quinine at a dose and never had any irritation of the kidneys and certainly no hematuria. In the malaria of the South there must be some other factor than in that of the North. The plasmodium is the same in Illinois as in Louisiana and still hematuria is very rare in Illinois and the North.

DR. STARLING LOVING: I have seen a good many people who have had idiosyncrasies in regard to quinine, but I have never seen blood coming from the kidneys in consequence of the influence of quinine. The cause is not the quinine but the structural change that has taken place in the kidney or elsewhere before the quinine has been administered.

DR. H. A. HARE: I did not mean to urge that quinine should or should not be given. The point that I wanted to bring out is that every case is a law unto itself; that certain cases can take quinine and in other cases it ought not to be given. As to the first cases reported having been cured with quinine; of course these cases have no more significance than any other like number of cases.

THIRD DAY, THURSDAY.—MORNING SESSION.

A paper on

PULSATATING PLEURAL EFFUSION,

by DR. JAMES C. WILSON, Philadelphia, and one on

TUBE CASTS AND THEIR DIAGNOSTIC VALUE,

by DR. I. N. DANFORTH, Chicago, were read by title.

MISCONCEPTIONS AND MISNOMERS REVEALED BY MODERN GASTRIC RESEARCH,

by DR. C. G. STOCKTON, Buffalo.

(1) The conditions usually called lithemia, chronic gout and oxaluria, in this country, are in reality almost always forms of toxemia of gastric origin.

(2) That the albuminoid diet so often advised in these conditions is frequently harmful and based on a misconception.

(3) That toxemia of gastric origin expresses itself in special symptoms which are sometimes misunderstood. That certain affections of the nervous system, the air-passages and the joints are, amongst others, the result of auto-intoxication.

From his case-book, Dr. Stockton reported a number of instances showing that neurastenia, vertigo, persistent headache, insomnia, muscular-spasm, and epileptiform convulsions, naso-pharyngeal catarrh, laryngitis, tracheo-bronchitis, asthma, Bouchard's nodules, some cases of so-called arthritis deformans and other joint troubles, depend upon gastro intestinal toxemia. These cases proved manageable by treatment directed to the digestion, as guided by a study of the gastric contents, although in most instances they had long resisted other lines of treatment.

DR. MUSSER: I quite agree as to the necessity for local treatment in such cases, but I want to emphasize the necessity of general treatment and general management also. In my care of such cases I have always been impressed with the efficacy and necessity of general treatment and management, the gastric condition being secondary. All such cases seem to arise from excessive wear and tear; and, whether by local treatment or general management, you must add to their nutrition.

DR. H. M. LYMAN: I wish to say a word as to the importance of considering the general condition of the patient. The etiology of these cases is generally connected with a history of scrofula or the arthritic diathesis, and it is important to recognize the connection of the local disease with the general substratum. Topical treatment is not, however, rendered any less necessary.

DR. C. G. STOCKTON: I do not advocate the treatment of these affections by any special plan of gastric medication or lavage, nor do I forget the importance of the general management of the cases. I wish to insist upon the utmost importance of guiding the general management of these cases upon the findings from the examination of the stomach. Just as our knowledge of certain diseases is improved by ex-

amination of the eye and urine, so our knowledge will be improved by examining the contents of the stomach. I think it is a mistake to regard these cases from the general stand-point as much as we have been in the habit of doing. While we should recognize that there is a failure in the nervous system, we should also realize that when the stomach fails, we have toxemias which give rise to a great variety of evils, and by relieving these toxemias we relieve our patient.

THE PRODUCTION OF TUBULAR BREATHING IN CONSOLIDATION AND OTHER CONDITIONS OF THE LUNGS,

by DR. CHARLES CAREY, Buffalo.

The commonly accepted physical principles involved in the production of the sound designated bronchial or tubular breathing were given. The views of Laennec, Scoda, Flint and others were given.

Metallic casts of the lungs of man, sheep, calves and dogs were exhibited. Some of them were purely tubular castings; others castings of the most minute tubules; and in some the air-cells were shown. Where the air-cells were injected by the metal, they hid the tubes which they surrounded. These castings showed a uniform bifurcation of the air-passages, the bifurcating tubes being of equal size, and the large number of tubes of sufficient size to produce a blowing sound if air passes over their mouths.

The sound of bronchial breathing is due to the laryngeal-tracheal sound, transmitted, and raised in pitch by the air blowing over the patent tubes leading to the lung, which does not receive air, or which receives it in diminished volume.

Diagrams were exhibited, showing how tubular breathing could be produced in pleurisy with effusion, where the lung is compressed up against the thoracic wall and adherent, and how, if fluid intervened between the compressed lung and the test wall, it would not be heard; how, in like manner, in a bronchial tube terminating in a cavity due to necrosis there is destruction of the vesicular expansion, and, as a result, a reverberation of the air in the cavity, as the air, rushing to other parts of the lung, blew over the mouth of the tube leading to this cavity.

DR. TYSON: Dr. Carey's paper has been of intense interest to me, and his demonstration seems to me a very reasonable one. It is certainly a great privilege to see his splendid preparations of lung castings.

DR. MASON: I have often been in doubt, in examining cases with pleural effusions, as to why in some cases we get bronchial breathing, and in others, with apparently a similar amount of fluid, we do not. I suppose from Dr. Carey's remarks and diagrams that it is due to the presence or absence of pleural adhesions.

DR. H. A. HARE: The openings of the bronchial tubes are not absolutely rigid, but to a great extent elastic, and the more elastic and yielding the tube the less the sound. In the act of respiration the air must flow with comparatively little force over the mouths of these tubes, and consequently the sound produced could not be great.

DR. J. P. C. GRIFFITH: What Dr. Mason has alluded to has often been puzzling to me, namely, the frequency with which bronchial breathing is heard in large pleural effusions. I once believed that I could diagnose between pneumonia and pleural effusion, but the older I grow the more I am coming to the conclusion that I can do nothing of the sort.

I should like to ask Dr. Carey, if, from his study of the anatomy of the lung, he has come to any conclusion as to why there is a difference in the auscultatory sounds, in the two sides of the chest, heard at the apices, in a normal condition.

DR. CHARLES CAREY: With reference to the point raised by Dr. Hare in regard to the elasticity of the bronchial tubes, while the bronchial tubes are not rigid yet they are provided with cartilaginous rings which will maintain them as a cavity in spite of the most continuous pressure of fluid from without or from inflammatory exudate.

Regarding the difference in auscultatory sounds at the right and left apices, I think the true explanation is to be found in the point of departure of the upper tube going to the right lung, which starts nearer the surface of the chest and much higher up than any of those that go to the left lung, as is shown in the metal castings.

THE DIFFERENT FORMS OF CARDIAC PAIN,

by DR. SAMUEL C. CHEW, Baltimore.

This kind of pain is found as a prominent symptom principally in three different forms of disease of the heart, and these are referred to from a clinical rather than a pathological point of view.

The first of these, and the one in which the pain exists in the most intense degree, is angina pectoris,—true angina, with increased arterial tension, occurring in paroxysms, and most frequently associated with aortic or coronary disease or with fatty degeneration of the heart. As the name of this affection implies, the pain is of the very essence of the disease itself. As recorded by Dr. Latham from his own observations, it is "a suffering as sharp as anything that can be conceived in the nature of pain, including something which is beyond the nature of pain — a sense of dying." The structural changes connected with true angina are in a very large proportion of cases those that produce cardiac ischemia, especially insufficiency or atherosomatous rigidity of the aorta, obstructions of the coronaries, or fatty degeneration of the heart. Any one of these changes may lessen the blood-supply to the heart muscle; but only the first two are diagnosticable with certainty by auscultation. On the other hand, post-mortem examinations not infrequently show great sclerosis of the coronaries and also fatty degeneration, in cases in which the symptoms of angina pectoris had not been present during life.

In view of the many cases of angina in which great and prompt relief has been given by the nitrite of amyl, I cannot but feel surprised at the opinion expressed by several recent writers that it is doubtful whether there are any remedial agents that have any power to arrest or greatly relieve paroxysms of the disease. I fully agree with Prof. F. C. Shattuck, that the value of the nitrites in angina is greater than Strümpell, the author upon whom he comments, would seem to admit.

A second form of cardiac pain, closely allied in character to the one already considered, and yet distinct from it in its pathological relations and generally less intense in type, is encountered as a complication of some cases of chronic nephritis, chiefly the contracted kidney of interstitial nephritis. In this class of cases the changes in the kidneys and sometimes in the heart are parts of a general arterio-sclerosis, and the pain in the heart is probably the expression of resistance to the blood-flow through the arterioles. In this form of

cardiac pain, the attacks may be frequent, but they are in general less severe than those of true angina connected with heart lesions. It is in cases of this kind that potassium iodide in large doses, as advised by Huchard, may sometimes prove beneficial by lessening the arterio-sclerosis. In the painful attacks, a certain degree of relief may be obtained from amyl nitrite, which though it cannot reach the organic cause of obstruction, may lessen an incidental increase of tension.

A third form of cardiac pain is found in dilatation of the heart, and is perhaps due to tension and stretching of the nerves in the heart-substance. Traube held that the pain of true angina is due to this cause. Whether it be so or not, the subjects of cardiac dilatation frequently experience pain about the heart, greater in degree, in general, in proportion to the rapidity with which the dilatation is induced. If dilatation be extreme and acutely developed, free venesection may be the best means not only for relieving pain, but also for saving life.

In all forms of cardiac pain, arsenic is a remedy of much value, from its action as an anti-neuritic, and from its power of promoting the nutrition of the heart. I hold with Anstie and Balfour, that there is no more important prophylactic tonic against cardiac neuralgia than arsenic.

It is quite possible that the chief factor in the production of pain common to all of these three forms of disease is pressure brought to bear upon the cardiac nerves or upon the cardiac ganglia themselves. The connection between these ganglia and the cervical and brachial plexuses gives a ready explanation of the extension of the pains to the arms that may occur in any form of cardiac pain. In the first, or strictly paroxysmal form, true angina, the pressure may be occasioned by the sudden tension of the arterioles; in the second form, by the general sclerotic state of the vessels; and in the third form, with dilatation of the heart, by the alteration of the heart walls.

DR. M. A. STARR: It does not seem to me that all the cases of cardiac pain can be classified under these three heads. It seems to me that a further class should be added, and that this may possibly be divided into several sub-classes. I am accustomed to see very intense pain in connection with paroxysmal tachycardia. Again, in cases of extreme neurasthenia, especially in what I term the vaso-motor type, I am accustomed to find patients complaining very much of pain about the heart. Here, it seems to me, we have two separate and distinct forms that cannot be included under Dr. Chew's headings.

DR. MUSSER: I think we would all be better off in practice if we considered all sorts of cardiac pain as angina. The doctor dropped a word about pain in the arms in association with cardiac pain. I have at present under my care a patient suffering severe pains in both arms without cardiac pain but always associated with high arterial tension and other phenomena of angina. I would like to lay stress upon the necessity of absolute rest in the treatment of all these cases and a regulation of diet based upon accurate knowledge of the actual functional disorder of the stomach that is present.

DR. A. MCPHEDRAN: In regard to the treatment of these cases, I have found nitro-glycerine even preferable to amyl nitrite, its effects lasting longer. I have at present a patient who has arterio-sclerosis and suf-

fers from cardiac angina. He is now taking forty to fifty minims of the one per cent. solution of nitro-glycerine daily with absolute relief.

DR. C. G. STOCKTON: It is satisfactory to see the relation existing between cardiac pain and the morbid anatomy in certain cases, and exceedingly disappointing in other cases to discover the same lesions without the history of pain. It is exceedingly common to find dilatation without a history of pain. The claim that dilatation of the heart muscle of the left ventricle is the chief cause of cardiac pain must be abandoned. That cardiac pain exists more frequently with morbid changes than without them is true, but further than this we can hardly go.

DR. SAMUEL G. CHEW: Referring to the remarks of Dr. Starr, I would simply state that I did not attempt to present a complete category of all the cases in which cardiac pain might occur. I merely meant to set forth the three most important conditions. Had I intended to go into a complete exposition of all kinds of cardiac conditions in which pain occurs, I might also have referred to cardiac aneurism.

I have used nitro-glycerine in a number of cases with a good deal of success, but it seems to me that its rôle is different from that of nitrite of amyl: amyl nitrite is efficacious in giving immediate relief, nitro-glycerine in lessening the disposition to these paroxysms. In the minute doses commonly given I have never seen it possess any power of checking a paroxysm when it has come on.

DR. C. G. STOCKTON: I have in mind an instance of a man in whom amyl nitrite excited but did not relieve pain, but who was completely relieved from his paroxysms by nitro-glycerine. He took half a grain of nitro-glycerine at a dose and the effect was almost instantaneous in the relief of pain. During twenty-four hours he has often taken five or six grains of nitro-glycerine.

AMERICAN MEDICAL ASSOCIATION. SECTION IN THE PRACTICE OF MEDICINE.

(Continued from No. 25, page 630.)

SECOND DAY, WEDNESDAY, JUNE 8TH.

POSITIVE AND NEGATIVE MEDICATION,

by DR. BEDFORD BROWN, of Alexandria, Va.

More or less deaths occurring in practice are due to the incompetency of physicians, the incurable nature of given disease, careless nursing, and the adulteration and substitution by dishonest pharmacy. A point of primary importance is to assure ourselves of the solubility in the stomach of the remedies we use. On this account pills and capsules are often objectionable. Not infrequently they pass through the system, and are found unchanged in the dejecta. Furthermore, in all fevers and in many other states, the solvent power of the secretions is greatly lessened. Dr. Brown uses only glycerine or honey as excipient for pills; and gums of all kinds are open to the same charge of insolubility as sugar and gelatine. Often we must use solutions; and if these are not well borne, resort to rectal medication. Here mucilage offers itself as a proper vehicle for quinine when the latter remedy is indicated. The cold bath in high temperatures may often further increase the absorptive power of the system. Moreover, one should see to it that when we

order infusions and decoctions, the latter are made out of pure materials. We should avoid cheap drugs, because that very cheapness is a confession of inferiority.

DR. H. D. DIDAMA, of New York, used tablets and wafers entirely to the exclusion of pills. It was evident that dispensing by the physician was growing in both professional and popular favor.

DR. WILSON, of Kansas City, and DR. HERRICK of Cleveland, also commended the practice alluded to.

THE RELATIVE INTER-DEPENDENCE OF ORGANS IN HEALTH AND DISEASE,

by DR. HERRICK, of Cleveland, O.

He divided the various organs into three groups. In the first were the osseous, connective, and cellular tissues. In the second the circulatory, muscular, nervous and reproductive organs; and in the third the organs of secretion, of digestion, absorption, assimilation and excretion. The first was entirely passive, the second was active in securing the alternate end of life, and the integrity of the third was necessary for the functions of the second to be performed in a proper manner. The third group had for its alternate end the transformation of food stuffs into blood.

A CASE OF ANEMIC DYSENTERY,¹

was reported by DR. E. P. GERRY, of Jamaica Plain, Mass.

RETAINED FECES,

by DR. W. D. CHRISTOPHER, of Chicago.

Bowels apparently normal, often contained scybalous masses which could be brought away only by intestinal irrigation. These masses may cause peritonitis, local or general, typhlitis, and appendicitis. They may give rise to certain catarrhal states, in which the bacterium coli communis, ordinarily harmless, becomes exceedingly virulent. Of the poisons engendered by fecal retention a small amount may be destroyed by the liver, but if this organ is impaired or the dose of the poison is large, we may have the "stercoemias," "stercoemic" of the French writers. In using rectal injections the water should be warm. Several trials may be necessary before much fecal matter comes away. Iron and belladonna are a useful combination to enable the bowel to retain its healthy state.

DR. N. S. DAVIS, JR., of Chicago, believed that fecal retention was common in those whose bowels moved daily; these evacuations were merely nature's overflow and were utterly insufficient to empty the gut.

The paper was also discussed by several of the other members present.

THE TRANSMISSION AND BEHAVIOR OF TYPHOID POISON AS OBSERVED IN COUNTRY PRACTICE,

by DR. LEWIS N. DAVIS, of Farmland, Ind.

It was generally believed that water is in the main, if not the only, channel by which the typhoid poison was conveyed, and that the germs in the stool were passive when they left the body of the patient; but in country practice there were many evidences to be had that the disease was contagious, and that it was conveyed by the air; also that the poison was virulent as it left the body. Several epidemics were quoted in support of this view.

The paper was discussed by DR. CHAPIN, of Michigan, who thought that the views of the writer were correct; and by DR. J. H. MUSSER, of Cincinnati,

who did not think the conclusions were sound. He himself believed in transmission of the poison through drinking-water.

CATARRHAL GASTRITIS,

by DR. HAROLD N. MAYER, of Chicago.

The term dyspepsia should be given up. It is a symptom and not a disease in itself. In chronic catarrhal gastritis we have too much mucus with a resulting impairment of digestive power. Out of 118 cases of gastric trouble, he had found 17 of uncomplicated gastritis (chronic) giving the usual symptoms in different combination and varying severity of epigastric pains, nausea and vomiting. Less common were fullness, coated tongue, eructations, anorexia, vomiting, constipation, etc. As to etiology, the trouble is more common in males and users of tobacco, alcohol, and excesses in iced drinks. The duration varies from months to years. The treatment is one of diet and but little medicine. Lavage had in his opinion but a limited value, because patients would not submit to it. He is in the habit of directing patients to drink from eight to sixteen ounces of very hot solution of bicarbonate of soda (ten grains to the pint) twenty minutes before eating. This removes the mucus and enables the food to come into direct contact with the mucous membrane of the stomach. Thereby normal peristalsis is set up. As to diet, trial meal of lean meat and buttered bread should be given. As the patient improves, oysters, eggs, etc., can be added. Pastry should be avoided. Bismuth, cerum, nux vomica, and tonics can only be adjuvants; papain is good where there is atrophy of the gastric tubules or organic structural changes; also in anæmic cases.

DR. STOCKTON, of Buffalo, N. Y., regarded lavage as especially good for diagnosis, if not for treatment. Many of these cases are due to excess of hydrochloric acid, and such a condition must, of course, largely determine the nature of the diet. The stomach contents are often too long retained in that organ, and imperfectly digested, even where no symptoms are complained of.

DR. LYON, of Philadelphia, had found an absence of hydrochloric acid in many of these cases.

DR. HARE, of Philadelphia, believed that the pepsin and soda mixture is often of service, because the acid to enable the latter to act overcame the alkaline effect of the soda and aided digestion. We make the mistake of prescribing too much pepsin and too little acid. Bitter tonics he believed, did more harm than good. Intestinal digestion was more powerful than gastric; hence we should give food rapidly passing into the bowels.

The paper was also discussed by DR. SCOLL, of Cleveland; PORTER, of Michigan; and DAVIS, JR., of Chicago.

THE VERTIGO OF ARTERIO-SCLEROSIS,²

by DR. ARCHIBALD CHURCH, of Chicago.

SOME NON-VALVULAR HEART MURMURS,

by DR. N. S. DAVIS, JR., of Chicago.

Non-valvular heart murmurs may give the same physical signs as valvular ones, the same changes also in the size and position of the heart. Not infrequently we have cough, dyspnea, vascular disturbance, œdema, urinary changes, etc. He related the

¹ Journal, vol. cxiv, p. 592.

² See page 650 of the Journal.

histories of several cases in which the autopsy showed the cause of the murmurs to be old and tenacious decolorized clots in the ventricles and entangled among the chordae tendinae. In one case there was an old calcified plate of connective tissue (the result of a former pericarditis) in pericardium. The murmur in this latter instance was probably due to irregular contraction in the ventricular walls, causing various eddies in the blood-current. Anemia also caused murmurs not distinguishable in their physical characteristics from those of valvular lesions.

THE IMPORTANCE OF POSITION IN EXAMINATION FOR DISEASE OF THE HEART,

a paper by DR. O. B. CAMPBELL, of Ovid, Mich.

The anatomical relations of the diaphragm are fixed, but the apex may be bagged down from change of size of the heart. If the patient bends forward the apex beat becomes more diffused transversely, but not vertically. He recommended recumbency in examining for cardiac disease, as he believed that the sounds became thereby more distinct. Out of 100 cases the murmur became more distinct in the recumbent position in 78; more distinct in the upright position in 6; not heard standing but developed on lying down, 4; unaffected by change of position, 12.

These papers were discussed by DRs. KENNEDY, of Michigan, and NEWCOMB, of New York.

THIRD DAY, THURSDAY, JUNE 9TH.

THE GENESIS OF PNEUMONIA,

by DR. W. W. PENNELL, of Fredericktown, O.

The great question is, as to whether pneumonia is a general fever or a local disease. Bacteria, the writer believes, plays only a secondary part in an exudative affection. The inflammation produced experimentally by pure cultures of this germ differs from that of the primary culture. There is not an exact analogy with so-called specific diseases, and our treatment is not such as to carry out this view. The infectious character of the disease is not observed in country districts.

As against this specific character are the following arguments: (1) more than one germ is found; (2) the patients are liable to subsequent attacks of the disease; (3) it is not contagious; (4) there are not prodromata; (5) there are no sequelæ as in typhoid fever; (6) there is a distinct crisis unless peri-infiltration or abscess result, and if the exudate can be kept in the vesicles (in quarantine as it were), it will lose its power to infect; (7) antiphlogistic treatment will often abort the disease.

The causes of the disease may be enumerated as follows: (1) cold, merely, is not a cause; (2) continued exposure with wide thermometric range; (3) dust-chill, often felt by farmers after thrashing grain; (4) as a sequela of lowered vitality due to vicious habits, especially alcohol and venery; (5) inhalation of dust and foreign bodies; (6) bad general hygiene, poor sanitation, enervating habits, etc.; (7) some persons and families appear to have a predisposition; (8) neither age nor sex gives exemption.

The three factors then, in pneumonia, appear to be, predisposition, loss or lack of normal tissue resistance, and exciting cause.

DR. BAILEY, of Kentucky, believed that the typical history points to a definite cause. The fever terminates irrespective or independently of the local condi-

tion. The physical signs show more blood infiltration the day after the crisis of the disease, than the day before.

THE CARDIAC INDICATIONS IN THE TREATMENT OF PNEUMONIA,

by DR. J. M. AMBERS, of Philadelphia.

The causes of this cardiac weakness may be threefold: (1) We may have absorption of cardiac ptomaines as a result of the disease process, with a weakening of the heart muscles. (2) There may be pulmonary obstruction produced by the presence of the exudate acting as a local barrier to the integrity of the circulation. (3) We may have the formation of cardiac thrombi which are found in the right ventricle. The latter becomes dilated and thus we have a failure of the heart power.

The signs of the muscular degeneration appear as feebleness, shortening of the first apex sound, and a similar condition of the aortic second sound. The pulmonary second sound may be accentuated, at least temporarily. Here, alcohol in moderate doses is indicated. It stimulates the cardiac ganglia, respiration and nerve-centres. It should be followed up by strichnine, which remedy has a well-known stimulating effect upon the cardio-pulmonary apparatus. Digitalis is to be used very cautiously, if at all; it may, in some cases, by lengthening the period of diastole, favor the nutrition of the heart muscles. For the local engorgement, cups, leeches and especially ice-bags are found to be very efficacious. The writer, however, distinctly deprecates the use of veratrum viride, antimony, aconite and similar cardiac sedatives. To control any cardiac over-action, morphine is the remedy *par excellence*. Venesection may be occasionally, but rarely, necessary. If there is much consolidation with difficult heart action, veratrum might be cautiously exhibited.

In regard to the temperature, where it runs high, it should be reduced without, at the same time, reducing the force of the heart's action. A fever of 104° F. needs no antipyretic measure. Beyond that point, however, we should employ cold sponging, and administer from sixteen to twenty grains of quinine daily. The coal-tar derivatives come under the ban, for they are all cardiac depressors to a greater or lesser degree, and cardiac depression is the one thing we wish to avoid.

In regard to the obstructed pulmonary circulation, we must remember, first, that consolidation of a single lobe does not greatly interfere with the breathing, but should the pulmonary second sound lose its sharp accentuation, and gradually become weaker, we have a double duty to perform; we must increase the power of the heart and deplete the lung. For this purpose we must not depend on any of the nitrites alone, as they will be useless, cups and venesection alone prove inadequate, and here we find the indication for the employment of digitalis combined with nitro-glycerine. The formation of cardiac thrombi is probably far more frequent than is generally believed, and is often associated with two factors. In this disease, the fibrin-forming elements are increased. The signs of this condition are not difficult to recognize. The impulse is irregular and the area of dulness runs beyond the sternum. There is a systolic bruit heard at the xiphoid cartilage, which is transmitted upwards and to the left.

Ammonium salts appear to be the only remedy at

our command with which to effect the fluidity of the blood, and they should be freely administered.

DR. BAILEY believed that phenacetine could be safely used as an antipyretic in pneumonia. It is as efficient as the external application of cold water, and no more depressing to the heart. He did not believe in blood-letting and had never seen a case of pneumonia where, in his opinion, venesection was indicated. He doubted the power of the ammonium compounds to dissolve clots already existing, but believed the latter might thereby be prevented from forming.

DR. TRUAX, of New York, favored venesection.

DR. HERRICK, of Cleveland, thought that the antecedents of pneumonia were to be found in the perverted action of the abdominal organs.

DR. DIDAMA, of Syracuse, thought that venesection was good for those cases in which there was extreme cyanosis with prune-juice expectoration.

DR. MUSSER, of Cincinnati, regarded the disease as specific and infectious, and the three remedies generally required are cold, venesection and rest. The indication for venesection are physical signs, the spreading of hepaticization to any areas of lung tissue and altered relations between pulse, respiration and temperature. Strychnine should be used hypodermatically. Digitalis was not of much service. Alcohol, in the form of champagne, held a very high place in his estimation. For rest and freedom from worry, nothing equalled morphine in value.

DARWINISM AND DISEASE,

by DR. HUTCHINSON, of Des Moines, Iowa.

The leading idea was that the majority if not all pathological processes are merely illustrations of various phases of evolutions and at times of benefit to animal cells and to the body at large. Reversion of type often takes place and is followed by corresponding disadvantages. Numerous illustrations are given showing practical applications of these views to the recognition of the apparent deformities in body structures and anomalies in disease.

Tissue group reversions may be either caseous, calcareous, fatty or fibroid. They might all be characterized as vital action gone wrong.

Reproductive reversions are tubercular, gumma, benign growths, malignant growths and hypertrophy.

If malignant reversion occur in connective tissue we have sarcoma with its round or spindle shaped cells. If in glandular or epithelial layers, carcinoma, which may be described as a parody on glandular tissue. From all this we must believe that there must be another factor in disease than the germ. Lowered vitality is concerned therein and our treatment should be to improve the nutrition and thus elevate vitality that the normal process of bodily evolution should go on undisturbed.

ON THE ANALOGY BETWEEN ACUTE IDIOPATHIC PLEURITIS AND ACUTE ARTICULAR RHEUMATISM,

by DR. E. L. SHURLY, of Detroit, Mich.

Pleural as well as synovial and other serous membranes, spring from some primordial layer and mesoblast and are ultimately developed into some endothelial lining; hence that would naturally be affected by any pathological process.

On the other hand, there is a correspondence between phenomena characteristics and general clinical history of the two diseases.

The presence of pleuritic effusion in rheumatism may be suspected when we have fugitive pains in the side, respiratory embarrassment or sudden exacerbation of temperature unattended by any increase in the joint disturbances. Often these appearances are regarded as due to pericarditis or endocarditis when they are really of pleuritic origin. Furthermore, the results of treatment are corroborative of the views expressed as to the identity of the two affections.

As to treatment, salicylate of soda appears to be the most efficient remedy for this condition of the pleura.

DR. STOCKTON, of Buffalo, spoke of the causes of pleurisy associated with and preceded by articular rheumatism. The former trouble might be worse than the joint disease.

DR. ATKINSON, of Baltimore, thought that while the relation between the two diseases might be true in theory, the revelations of the dead-house negatived the idea of there being any great amount of pleurisy in these rheumatic cases. Most of the cases of pleurisy could not be explained on the rheumatic theory.

In pericarditis we find pleuro-pericardial signs which may be mistaken for simple pleurisy.

DR. COLLINS, of London, Ontario, remarked that sodium salicylate will often cure inflammation in any serous membrane. The remedy can be regarded as a true germicide.

ADDITIONAL EVIDENCES OF THE VALUE OF FORCED RESPIRATION, FELL-METHOD, IN OPIUM NARCOSIS,

by DR. GEORGE E. FELL, of Cincinnati, O.

In addition to the nineteen cases previously reported the author gave five additional ones. He thought that this method of resuscitation would be applicable to drowning or asphyxia from any cause. His apparatus with its face-mask was exhibited and its method of use demonstrated.

Ten more papers were announced but not read.

AMERICAN MEDICAL ASSOCIATION. SECTION ON SURGERY AND ANATOMY.

FIRST DAY, TUESDAY, JUNE 7TH.

SURGERY OF THE GALL-BLADDER AND DUCTS.

DR. J. McFADDEN GASTON, of Atlanta, Ga., read a paper with the foregoing title, in which he referred to his experiments upon dogs and considered the literature of the subject down to the present time. Surgery of the gall-bladder is, as a rule, confined to the measures indicated in occlusion of the common duct. Where the duct is occluded by other cause than impacted stone, it is generally necessary to remove the gall bladder. The dissection of its upper portion from the lower is a rather difficult operation and attended with risk. He is accustomed to leave this portion of the bladder *in situ*. All stone obstructions should be removed, and an external opening only, should be regarded merely as a temporary expedient. The gall-bladder should be united with the intestine. While it is most desirable to establish the fistula with the duodenum, one with the jejunum would not prove less useful; but one with the colon gave an unsatisfactory result.

OBSTRUCTION OF THE CYSTIC DUCT,

by DR. W. H. MYERS, of Fort Wayne, Ind.

Stones might be present in the gall-bladder with-

out pain, and there might be pain without jaundice; but when the cystic duct was the seat of the impacted calculus the pain was very severe. The paroxysms usually come on within an hour or two after the ingestion of food, and are apparently due to the effort of the gall-bladder to empty itself by the contraction of its muscular coats. In the case which he reported several stones were removed, and the bladder and abdominal opening stitched together. Only a slight quantity of bile appeared on the dressings, but the fistula remained open. In all similar cases he would remove the viscera.

PERITONITIS FROM GALL-STONES.

DR. W. E. B. DAVIS, of Rome, Ga., claimed that the risk from the rupture of the gall-bladder or ducts, was from infection of the peritoneal cavity by septic material from the gall-bladder rather than from the bile itself. Bile is not a septic fluid, and only causes peritonitis by irritation, and then only when in large quantities. Escaping slowly, it sets up protective inflammations which cause adhesions which cuts it off from the general peritoneal cavity. Peritonitis from escaping gall-stones is rare, and even then is usually due to the septic quality of the fluid which accompanies them. In his experiments upon dogs the bile did not produce peritonitis when allowed to escape into the peritoneal cavity. Packing the wound with iodoform gauze, which was left in three days, prevented peritonitis. Of course, the danger of peritonitis is greater from the presence of a gall-stone than in experimental work where pure bile only was allowed to escape. The chief point he wished to make was the protection given by packing with iodoform gauze.

In the discussion which followed, DR. A. VANDER VEER, of Albany, N. Y., said he felt it unsafe to leave the anterior wall of the gall-bladder as advised by Dr. Gaston. He cited a case from which he removed sixty-four calculi. The external fistula remained open. Some time later the patient dying of tuberculosis, he found the duct was closed. He favored medicinal treatment for a time, but should the case grow worse, he would then operate. Jaundice is absent in the majority of the cases of the paroxysmal; pain is the principal symptom for which the surgeon must look. Perforation and a resultant septic peritonitis is the chief danger in delaying the operation. Be sure there is an opening into the intestine before closing the external opening.

DR. MARCY, of Boston, reported four unpublished cases, and urged early operation.

DR. J. F. W. ROSS, of Toronto, thought puncturing the intestine by the needle in suturing, with escape of the intestinal contents into the peritoneal cavity, was one of the greatest risks.

DR. FRIGER, of Chicago, spoke of inflammation of the gall-bladder without obstruction to the flow of bile, and thought that two operations a safer procedure than to attempt to relieve the condition all at a single sitting.

DR. ALLEN, of Cleveland, reported a case of a patient who had refused the operation and who died from the pain caused by the plugging of the cystic duct.

GUNSHOT WOUND OF THE LIVER AND STOMACH.

DR. JAMES T. JELKS, of Hot Springs, Ark., reported a case where a ball entered the left of the spinal column, just below the lower border of the ribs. The

patient when first seen had vomited much blood and was in a state of shock. An opening was made extending from the ensiform cartilage to two inches below the umbilicus. The patient again vomited blood and the stomach and ball was thrown out of the abdominal cavity into the hands of the operator. Careful examination revealed no stomach wound, but a bleeding wound was found on the posterior border of the liver. This was packed with iodoform gauze, the cavity washed out, the intestines returned, a glass drainage-tube inserted and the abdominal wound closed by sutures. Before union was perfect a fit of coughing caused the wound to break open and a knuckle of intestine protruded. This was replaced and a good recovery resulted in three weeks.

RUPTURE OF THE LIVER.

DR. FERGER reported a case of liver rupture resulting from a fall through an elevator shaft, where he found, a year later, that much hemorrhage had taken place without evil results.

DR. GREGORY, of St. Louis, thought that in Dr. Jelks' case, the patient would have recovered without any operation, unless the plugging of the liver wound had saved his life.

DR. THORN, of Toledo, reported a case of laceration of the liver left without treatment and which resulted in death from loss of blood.

DR. B. A. WATSON, of Jersey City, said shock was not always present, and if absent, what indications have we for operation if we are not to operate on all cases.

DR. WALKER, of Tennessee, cited a case in which there was shock when he was called to see the patient, who declined operation, but who died from hemorrhage some three hours later.

TREATMENT OF OESOPHAGEAL STRICTURE BY ELECTROLYSIS.

DR. D. S. CAMPBELL, of Detroit, reported seven new cases and one old case of esophageal stricture treated by electrolysis, all of which made good recoveries.

SECOND DAY, WEDNESDAY, JUNE 8TH.

THE LATE MANIFESTATIONS OF APPENDICITIS AND THEIR TREATMENT,

a paper by DR. DUDLEY P. ALLEN, of Cleveland, containing a report of six cases selected for illustration and discussion, showing the dangers and complications arising in cases which had escaped the primary attack of appendicitis. These cases included large collections of pus in the side, secondary abscess in the liver, lung, psoas muscle, thigh, and long existing circumscribed abscess opening repeatedly into the intestine.

The writer's personal experience fully convinced him of the dangerous character of appendicitis when left to follow its natural course, and he was also convinced of the soundness of the opinion of the American surgeons favoring operation in all suitable cases, as against that of a large number of English surgeons, who prefer leaving the disease to medical treatment. He had operated on several cases where the patients had supposed themselves suffering from repeated attacks of intestinal colic and the observation was well established that many cases of appendicitis resulting in operation or death had been preceded by other attacks of a less serious nature.

The use of salines as opposed to the opium treatment was discussed, more particularly in its reference to primary attacks of appendicitis than to those of a marked nature, and, while the dangers of salines were recognized, it was claimed, in certain cases, they relieved the extreme tympanites which, when present, rendered the operation difficult and apparently destroyed the patient after a successful operation had been performed, through paralysis of the intestine from extreme distension. The extra-peritoneal operation was favored, where feasible; but one great objection to this method was the undeniable fact that a certain proportion of small abscesses and foreign bodies might be overlooked, therefore, the transperitoneal operation was advocated where the surgeon considered it necessary to get at the seat of the disease. Many surgeons hesitated in undertaking so serious an operation when the disease was apparently quiescent, but where the difficulty was recurrent the operation should not be delayed too long, since the danger from recurrent attacks is considered much greater than the operation.

DESÉMOID TUMORS OF THE ABDOMINAL WALLS,

was the title of a paper to have been read by DR. NICHOLAS SENN, of Chicago, but which he had been unable to complete, and in lieu of which he made a few remarks. He cited a case where all the symptoms indicated a dilated stomach from cicatrical contraction and stenosis of the pylorus. On operating the stomach was found very much dilated, but cicatrical stenosis of the pylorus was absent. However, there were many adhesions, especially in the neighborhood of the gall-bladder, in which he found a gall-stone, which upon being removed and the adhesions separated, terminated in recovery with complete relief from the gastric symptoms. The patient had no symptoms indicating the presence of gall-stones. Another case presented the symptoms of acute intestinal obstruction of the lower part of the small intestine whereupon operation a gall-stone the size of a walnut was found about twenty inches above the ilio-caecal valve.

Dr. Senn, thought stones of this size always enter the intestine by perforation of the gall-bladder and local peritonitis, rather than through the normal biliary passage. He operated upon four cases of desmoid tumor of the abdominal wall during the past two years. These tumors originate from the mesoblast, arising from the sheath of some one of the abdominal muscles. In structure they resemble a fibroma, with some of the characteristics of a sarcoma. The four tumors were all in child-bearing women, and perhaps due to trauma of the sheath of one of the abdominal muscles. They grow more rapid than ordinary fibroma, are less distinctly separated at their margins from surrounding tissues, and are often attached internally to the peritoneum, necessitating an intra-peritoneal operation. The gap in the peritoneum is closed by making use of the omentum. The diagnosis between intra-mural and intra-abdominal tumors is often very difficult.

A specimen tumor with a drawing of its microscopic appearance was exhibited.

INTESTINAL LESIONS IN ABDOMINAL AND PELVIC SURGERY,

by DR. JOSEPH PRICE, of Philadelphia.

He said he would only present the leading features

of the part these lesions play in making the pathology of these complaints complex, and afterward consider the best way of dealing with them for the good of the patient and comfort of the surgeon. Aside from the conditions brought about by purely pathological processes, past operative complications, due principally to hasty, ill-advised work, or unfinished operations, are at the bottom of many surgical complications that would not otherwise exist. These operations are the worst surgery has to deal with, because they involve both old and new inflammations and the obliteration of anatomical landmarks previously existing.

We may also place in the same category complications due to failure to drain and the use of irritating solutions. Meddlesome interference with natural drainage, by the introduction of quantities of gauze into the pelvis, must necessarily produce adhesions. The less the peritoneum is meddled with after completing an operation, the less liable are we to have damaging adhesions. Finger-tips and not the knife should be used in separating parts and organs joined by adhesions. The complication arising by separating adhesions is hemorrhage. This should be controlled by packing and flushing the bleeding cavities with very hot water. Ligatures should be used only in exceptional cases. In all suppurative and inflammatory abdominal and pelvic disease the line of treatment should be as follows: Remove the diseased organs, carefully flush the parts free from débris, and lastly drain carefully.

THE COMPARATIVE MERITS OF INGUINAL AND LUMBAR COLOTOMY.

DR. J. MATTHEWS claimed that few if any surgeons of this country now performed lumbar colotomy, holding that the lumbar operation was practically obsolete. He, however, did not consider the inguinal operation any easier or safer, since the inguinal operation is intra-peritoneal, while the lumbar is extra-peritoneal.

THE SIGNIFICANCE OF A HERNIAL SAC.

DR. E. H. GREGORY, of St. Louis, claimed it to be of the greatest importance to diognosticate a hernia before a sac is formed. When a sac is formed the patient is liable to all of the calamities, such as incarceration or strangulation. Palliative treatment consists in the permanent evacuation of the sac; the radical cure consists of obliteration of the sac. The early diagnosis of hernia, and prevention of the sac formation, is apparently the only hope of a perfect result.

THE TREATMENT OF INJURIES OF THE ABDOMEN NOT REQUIRING SURGICAL OPERATION,

was the title of a paper read by DR. J. SCHNECK, of Mt. Carmel, Ill.

Injuries received above the umbilicus are much more serious than those below that point. This fact is apparently because the organs above the umbilicus are of more vital importance than those situated below it. The restoration of innervation is one of the most important effects to be accomplished in the way of treatment, and this is best done by the application of heat both internally and externally. The administration of stimulants has but little if any value, while hot water is always of use, even if vomited. The injection of hot water is always of value.

BASSINI'S METHOD FOR THE CURE OF INGUINAL HERNIA APPLIED TO A CASE COMPLICATED BY UNDESCENDED TESTICLE.

A report was furnished by DR. SAMUEL E. MILLIKEN, of New York, of a patient, aged eighteen, who had been under observation for a year or more, with the hope of straining the hernia, at the same time allowing the testis to descend. The truss was worn day and night with but little improvement, when it was decided to perform the radical operation after the method of Bassini, and at the same time attempt to anchor the testicle in the scrotum. The case illustrated that although the testis and hernia had escaped into the internal rings when the patient was etherized, the sac had not been reduced. After the slitting of the tendon of the external oblique muscle after Bassini's method the testis was readily reproduced by making traction on the vas deferens, a loop of which remained in the canal firmly adherent to the tunica vaginalis. The sac, being congenital, was cut off an inch above the testis and the tunica vaginalis reformed. Three catgut sutures were passed through this newly formed tunica and the bottom of the scrotum, simultaneously for fixation. The inguinal canal having been reconstructed, the wound was dressed as a single herniotomy.

HERNIA, OPERABLE AND INOPERABLE.

DR. THOMAS H. MANLY, of New York, reviewed the literature of the subject and epitomized it and considered the question of the treatment of hernia in a general way. He said :

(1) No operative scheme yet being devised which effectually removes the causes of every species of hernia, permanent cure is out of the question in certain cases.

(2) The radical cure of hernia may be regarded as one of the most satisfactory operations of surgery. That the disease sometimes relapses is not valid objection against surgical intervention, for relapses are common in the majority of operations performed on the human body.

(3) Unless there are pressing reasons, no radical operation should be encouraged for a non-strangulated hernia which gave no serious inconvenience.

(4) Hernial operations should not be performed in the extremes of age.

(5) Inguinal hernia in women should always be treated by a radical open operation, unless there are especially contra-indicating factors in the case.

(6) All operations, as a rule, on reducible unincarcerated hernia are radically curative, though there are many relapses.

(7) All operations for strangulated hernia should always include such additional steps as will effect thereafter a complete obliteration of the inguinal canal.

(8) Except in case of strangulation, very large old hernia in any of the abdominal regions, are not operable.

A FEW POINTS ON THE MANAGEMENT OF STRANGULATED HERNIA,

by DR. W. B. DEGARMO, of New York.

The death-rate from strangulated hernia is far in excess of what it should be on account of reliance placed in certain internal remedies, and to the exaggerated ideas as to the difficulties attending operative measures. A physician who tests the merits of non-

surgical methods is not only wasting valuable time, but he is assuming a grave responsibility, and probably sacrificing the patient's life. He warns them regarding cases where local pain is absent or where all symptoms have been masked by the use of the hypodermic syringe. He believes many lives have been sacrificed as a result of its use. Shock or collapse is a symptom of the gravest importance and demands very prompt surgical relief. He believes medical treatment, on the whole, is not only unreliable, but in many cases injurious, and as a means of reducing hernia, no reliance should be placed in it. The causative action of muscular spasm is not believed in. Among all external applications, but one is commended, and that is, pour a small amount of sulphuric ether over the tumor every few minutes, exposing the parts to the atmosphere to favor rapid evaporation. This, however, should be done only in the early stages and before the vitality of the parts has been impaired. Taxis, as ordinarily performed, is condemned, and a method of traction and compression described, having for its object the lengthening out the neck of the tumor, relieving by compression the engorged vessels and imprisoned fluids and gases. Anesthetics for the purpose of reducing hernia are not commended, although careful manipulation under their effect, should always precede an operation; aspiration should not be used except in some very rare cases.

He believes the Emly operation to be one of the most simple in surgery, and should always be done early. Waiting for fecal vomiting is a relic of the (surgical) dark ages. It is always safer to open and examine the contents of the sac. In amputating masses of omentum, numerous aseptic silk ligatures should be used, instead of tying off with one ligature of catgut. Should the bowel be of a dark chocolate color, but not necrotic, hot compresses should be applied after cutting the constriction. Where the gut is gangrenous, a temporary artificial anus is believed to be the safer method for the patient. The use of methods for favoring permanent cure to follow operations for relief are strongly commended. The author has used silk exclusively for four years in all hernial operations, and since he has himself sterilized and prepared it, has had no trouble about its coming out of the deep muscular tissues.

THE MANAGEMENT OF GANGRENOUS HERNIA.

DR. JOSEPH RANSOHOFF, of Cincinnati, read a paper and cited the statistics of strangulated hernia during the past twenty years. Of these but fourteen per cent. were found gangrenous. Four cases were reported in detail. In two, the suspicious area was returned to the abdomen; they both died. In the other two the constricting band was divided, the gangrenous portion excised, and the healthy part returned to the peritoneal cavity; both these latter cases recovered. The author discussed at length the steps of the operation and the logic by which this treatment might be expected to give satisfactory results.

DISCUSSION OF HERNIA.

DR. MARCY, of Boston, after discussing the subject in full, enumerated as essentials for the operation:

- (1) Asepsia.
- (2) Resection of the sac.
- (3) Restoration of the obliquity of the canal in inguinal hernia in the male.

(4) Closure of the wounds by means of buried tendon sutures.

(5) Coaptation of the skin by a blind buried suture, and sealing with iodoform collodion, re-enforced by a few fibres of cotton without drainage.

DISCUSSION ON ABDOMINAL SURGERY.

DR. B. A. WATSON, of Jersey City, said the essential in all abdominal surgery was asepsis. Had we any means of knowing the condition of the peritoneal cavity as to asepsis, we would know when to operate and when operation should be avoided or postponed. In the absence of this knowledge he was inclined to wait a short time and be guided by the symptoms presenting, watching with the utmost care and prepared to operate at any hour. He strongly disapproved of Dr. Link's idea that the family physician and the country doctor should operate in all cases at once and not wait for the arrival of a surgeon, claiming that no one unfamiliar with the details of antiseptic work should attempt an abdominal operation, or, indeed, any operation whatever.

Recent Literature.

Diseases of the Skin. A manual for practitioners and students. By W. ALLAN JAMIESON, M.D., F.R.C.P. (Ed.). Third edition. Philadelphia : Lea Bros. & Co.

A third edition of Dr. Jamieson's work on diseases of the skin has appeared, enlarged and enriched by the additions of increased space to several subjects that have of late come into prominence, as dermatitis herpetiformis, pityriasis rubra pilaris, lymphangioma circumscriptum, etc. The author's plan of interpolating a description of cases, of which 118 are scattered through the volume, makes the book an interesting one for the expert, but diminishes its value considerably for the student and general practitioner, as many of these cases are cited on account of some obscure deviation from the ordinary type, or leave some doubt as to their nature. Exception will be taken by almost all modern histologists to the author's view (the old one) of the anatomical nature of molluscum contagiosum. Whether or not the view that the contents of these tumors are in part composed of causative gregarines be accepted, it is quite generally conceded that the growths are not connected with the glands or hair follicles. It is also a disappointment not to see lupus classified distinctly under the heading of tuberculosis, in an edition bearing the date of the current year.

In the matter of treatment the book is to be commended as affording much that is interesting and suggestive, as an account of the management of almost every specified case is included. Whether the modifications of previously existing methods that have been proposed by Unna, of whom the author is an ardent disciple, have in every case constituted an important advance in treatment, may be as yet regarded as a matter of individual opinion.

Dr. Jamieson's large experience ensures for the book a wide reading, especially among those particularly interested in dermatology. The book is original, and on the whole strong : and the writer impresses us, even when we differ from him, with a sense of his honesty and straightforwardness. The nine colored illustrations may be characterized as fair.

A Practical Manual of Diseases of the Skin. By GEORGE H. ROHÉ, M.D., assisted by J. WILLIAMS LORD, A.B., M.D. No. 13, in the Physicians and Students' Ready Reference Series. Philadelphia and London : The F. A. Davis Co.

As this book is intended only to serve as a handbook for the general practitioner, and does not claim to be anything more than a brief *résumé* of the more important established facts, criticism is, of course, limited to the care with which the matter has been compiled. Unfortunately, the book does not bear the mark of great painstaking. The space is most peculiarly apportioned, nearly one-third of the whole book being devoted to the cutaneous manifestations of syphilis, while almost as much space is given to exfoliative dermatitis as to psoriasis. The statements made do not always coincide with those of a majority of modern specialists. At the end of the book are numerous formulae, but it is noticed that many of their numbers do not tally with those in the text that refer to them. In a word, the book cannot be regarded as a valuable addition to the "Ready Reference Series."

Higher Medical Culture : Medical Science Based on the Four Vital Properties and Laws of Organic Force. By W. R. DUNHAM, M.D. Cambridge : Printed for the author. 1892.

The four vital properties of our author are named sensibility, sensation, instinct, and contractility. There seems to be "three departments for the exhibition of applied law of organic force."

Those who desire to acquaint themselves with the results which the author reaches after propounding these propositions had better procure his little book from him and read it. We have no desire to prejudice a possible reader one way or the other, as we are sure we do not understand what is presented in these pages.

On the Simulation of Hysteria by Organic Disease of the Nervous System. By THOMAS BUZZARD, M.D., F.R.C.P.L., etc. 16mo, pp. iv, 113. London : J. & A. Churchill. 1891.

This little volume is the reprint of a presidential address delivered before the Neurological Society of London. The author first speaks of cases of weakness of the legs often thought to be functional, but due probably to progressive muscular atrophy beginning in the ilio-psoas muscle, and characterized by inability to flex the thigh strongly on the pelvis, or to go up stairs. He next dwells upon the value of absence of knee-jerk as a distinctive feature of organic disease, and of the absence or diminution of the plantar reflex as an indication of hysteria, provided there be no distinctive symptoms, such as loss of knee-jerk, atrophy, degenerative reaction or spasticity. More than half the book is devoted to cases of atypical multiple sclerosis, which is very often mistaken for hysteria. Most hysterical symptoms may be due to multiple sclerosis, and temporary paralyses, shifting from one limb to another, are more probably due to sclerosis than to hysteria. In sclerosis, the plantar reflex is apt to be retained, the knee-jerks may be exaggerated, squint or optic atrophy may occur, and if intention tremor develop the diagnosis may become clear. "The figure of Hysteria shrinks in proportion as the various forms of organic disease acquire greater solidity and sharper definition." The author's style is clear and agreeable, the mechanical execution admirable, and no one can regret the half-hour spent in its perusal.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JUNE 30, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS.

THE PLACE OF DYSPEPSIA IN GENERAL
 NOSOLOGY.

ONE of the essayists at the recent meeting of the American Medical Association thinks that "the time has now come for discarding the term dyspepsia altogether as a pathological entity, and of relegating it to the limbo of broad symptom-groups occupied by such terms as heart-disease, paralysis and deafness."¹

What to do with dyspepsia has long been the puzzle with writers on both special and general pathology, and we see the subject disposed of variously, according to prevalent doctrines. To some authorities, the term is only an expression of material lesions of the stomach, to others, it is from first to last a neurosis. From Broussais down to the present time, multitudes have regarded dyspepsia as a manifestation of chronic or catarrhal gastritis. Thus Leube, for the most part, treats it in Ziemssen's Cyclopedias, and in the article on "Disorders of the Stomach," in Wood's Reference Handbook, the term is not used. Fox, in his "Diseases of the Stomach" has only one form of dyspepsia, the "atonic" (that is, nervous). In 1878, Leube demonstrated the fact that many cases which had previously been grouped under the term gastric catarrh were clearly free from catarrh. The stomachs were to all appearances organically sound. He found derangements of the gastric juice associated with many of the troubles of digestion; the use of the stomach-tube now gave an immense impetus to the study of gastric disorders. Some enthusiastic workers in this line outstripped Leube himself, and came to regard dyspepsia as simply a plus or minus of hydrochloric acid. Germain Sée's work on the dyspepsias (1879-1882) is written from this point of view, and the still more recent and masterly treatise of Hayen and Winter treats of dyspepsia as, in the main, a morbid chemical phenomena. "To constitute a dyspepsia," says Germain Sée, "a chemical disorder is the condition *sine qua non*." The terms *hyperchlorhydria*, *hypochlorhydria*, *anachlorhydria* express Sée's principal divisions; these terms almost correspond to the *hyperpepsias* and *hypopepsias* of Hayen and Winter. According to these writers, the chemical alteration is the primordial lesion, the nervous trouble and the digestive derangements which follow are only secondary effects.

There is already vigorous reaction against this too exclusive way of regarding the subject; neurasthenia is coming to the front as the primordial lesion, the chemical and functional derangements being effects, and this is especially the standpoint of the French school of medicine under the leadership of Charcot, Debove, Bouchard and others. It is agreed that the term dyspepsia stands for a definite clinical syndrome that demands separate and independent consideration in treatises on medicine; and the authors of the new *Traité de Médecine* seem, in handling this subject, to have attained the proper mean, assigning to the nervous and constitutional element the primordial rôle, while making due account both of morbid states of the mucous and muscular coats and of chemical derangements of the gastric juice. Recognizing the fact that the same causes may give rise to all the different forms of dyspepsia, and that in the present state of science the classification that commands itself must be pathological and clinical rather than etiological, they divide the dyspepsias as follows, into:

(1) Simple neuro-motor dyspepsia without hyperacidity, organic or hydrochloric.

(2) Hyperchlorhydria.

(3) Hypochlorhydria with stagnation of the contents of the stomach and often hyperacidity.

Dilatation of the stomach, concerning which so much has been written of late years, and which has been the subject of a very ingenious theory by Glenard, is reserved for separate consideration. It is a common resultant of a number of etiologic factors; stenosis of the pylorus from any cause, fatty degeneration or atrophy of the muscular coats, etc. Under the name of dilatation of the stomach, Bouchard has described a morbid state in which the gastrectasis is the primordial fact, and in which the sensory and dyspeptic phenomena are more or less pronounced. He attributes to toxæmia from absorption of poisons (toxines) produced in the stomach the principal rôle in the genesis of the accidents observed in connection with gastrectasis. Just here, it is proper to say that modern pathologists are assigning more and more importance to the part which these toxines of gastric origin play in the symptomatology, direct and remote, of all the dyspepsias, and what a few years ago was ascribed to lithæmia more properly comes under the head of toxæmia, as is well shown by Dr. C. G. Stockton in his address last month before the Association of American Physicians, at Washington.

(1) Dyspepsia with neuro-motor predominance includes nearly one-half of the cases of dyspepsia. Persons belonging to this category are affected with *nervöse dyspepsia* (nervous dyspepsia), as Leube understood it. The symptoms are those of discomfort and pain, with

¹ Dr. Harold N. Meyer: On Catarrhal Gastritis.

weight in the epigastrum after eating. The stomach and abdomen are flatulently distended, and there are eructations. Among the toxicemic symptoms are headache, disinclination for study or exercise, malaise, vertigo, insomnia. Constipation and haemorrhoids are seldom absent; the dyspepsia is both intestinal and gastric. The appetite may remain good, and there may be no emaciation. In a word, these patients present to a greater or less extent the symptoms peculiar to neurasthenia. A neuropathic temperament is the foundation of their ailments.

Repeated examination by the Debove tube reveal neither organic hyperacidity nor hyperchlorhydria. There may even be hydrochloric deficiency, but this is of little importance if the muscular mechanism of the stomach is all right—if there is no stagnation and resulting-exaggerated acid fermentation. The work of the stomach may be a minimum quantity, almost nil, without the general condition suffering much in consequence, as has been shown by many experimental and clinical facts. "Robust healthy persons, not at all dyspeptical may present a marked degree of hyperchlorhydria." Dogs have had their stomachs extirpated, and have got well and remained in health, with their oesophagus opening into the duodenum; and Van Noorden, by his experiments in the "dosage" of urea of the ingesta and egesta, has found that albuminoid substances are as well utilized in dyspeptics with insufficient gastric digestion as in healthy individuals.² Facts of this kind are not lacking to show that neither an excess nor a deficiency of HCl in the gastric juice is of sufficient importance to characterize a clinical form of dyspepsia.

(2) The second division of the dyspepsias, "hyperchlorhydria," indicates a constant relation between the dyspeptic manifestations and an excess of HCl. "The vice of secretion—the acid hypersecretion—seems to be often the expression of a state of general neurosis with predominant gastric determination." In other words, the hyperchlorhydria and the troubles of secretory and motor innervation all take their rise in the same neuropathic state.

Hyperchlorhydria presents itself under numerous clinical types, all of which are characterized by pain which is often most marked when the stomach is empty. The crises of pain resemble those of migraine or tabes, and often suggest the possibility of a real material alteration in the cerebro-spinal axis. Generally the pain comes on near the close of a meal, is in the pit of the stomach and takes on an increasing intensity.

This pain is relieved by the ingestion of a little liquid, sometimes of food, and especially of an alkaline liquid. In some patients it comes on regularly at one or two o'clock in the morning. Sensation of burning or rending, radiating to the back, are complained of. These pains when very intense are followed by vomiting. The dilution of the gastric juice, its saturation by alkalies, its mechanical expulsion, are conditions which suppress the cause of the pain by suppressing

the action on the mucous membrane of a gastric juice charged with HCl (Mathieu).

These dyspeptics endure fasting poorly, eat much, and do better on a diet largely animalized. They are nervous, irritable, easily fatigued, and are tormented by insomnia. A multitude of hypochondriacs belong to this class. They, too, have abdominal distension, eructations, and constipation. When the gastric juice, siphoned from the stomach, is examined, it is found to be inordinately acid from HCl (two to three per thousand), and the chyme shows albuminoids to be much better digested than starches. With the filtered gastric juice, artificial digestions rich in peptones can be rapidly obtained.

Hyperchlorhydria was described for the first time by Reichmann in 1882 and 1884.

(3) The third type of dyspepsia is "hypochlorhydria, with organic hyperacidity and stasis." Here, hydrochloric acid secretion is deficient, but there is excess of organic acids from abnormal fermentations taking place in the stomach. There is more or less dilatation from atony and relaxation of the muscular walls; foods and liquids stagnate in the stomach and ferment, giving rise to acid eructations, pyrosis and pain. Vomiting is also a frequent symptom. Undigested food long remains in the stomach. If the contents of that organ be siphoned off in the morning after fasting, quite a quantity of sour rancid liquid will be obtained; there will be from a pint to three pints with débris of the last meal. Gastritis is apt to supervene sooner or later in these cases.

The writers of the new *Traité de Médecine*, it will be seen, consider all the dyspepsias, except such as clearly follow gastritis, cancer, round ulcer, or are secondary to heart disease, liver disease, etc., as nervous in their origin. They refer to the fact that we often find simple neuro-motor dyspepsia with or without excess or deficiency of HCl in persons of neuropathic or arthritic family (arthritic may be regarded as almost the equivalent of neuropathic). In these patients, we see the neuropathic manifestations precede the dyspeptic. Moreover, the general symptoms: Headache, vertigo, dizziness, erratic pains, etc., are such as belong to the neurasthenic series. A similar dyspeptic tendency is noticed in candidates for gout, diabetes, in the migrainous, in exophthalmic goitre and in hysteria. Nervous dyspepsia has often been known to arise in predisposed persons under the influence of strong emotions, disappointments, reverses. Lastly these patients are habitually relieved by a treatment addressed especially to the neuropathic state, as rest, hydropathy, and change of climate.

The principal cause of dyspepsia being as above stated,—as occasional or exciting causes, may be mentioned, mental emotions, excesses in eating or drinking, the abuse of highly seasoned meats, indigestible foods generally, and of alcoholic liquors. In some cases, nervous dyspepsia has been known to follow influenza, and in not a few it has succeeded an attack of typhoid fever.

MEDICAL NOTES.

THE LATE DR. D. HAYES AGNEW left an estate of about \$250,000. He bequeaths to the University of Pennsylvania, \$50,000, his work on surgery, his library and anatomical collections.

CHOLERA has spread from Persia to the provinces on the south shore of the Caspian Sea, and from these provinces to Russian ports on the west shore. The appearance of the disease at Baku, the centre of the petroleum trade, threatens those southern provinces of Russia, in which the inhabitants are already weakened by famine.

ROTUNDA HOSPITAL, DUBLIN.—The governors of the Rotunda Hospital in Dublin, have decided to build an additional hospital building, and have already raised a large part of the necessary funds for the purpose.

EXPERIMENTS IN SNAKE POISONS.—There has recently been erected, in connection with the Calcutta Zoological Garden, a building for the study of the poisoning of snakes. Specimens of the principal poisonous snakes will be kept.

A MICROBE OF BERI-BERI.—The *Review Scientifique* of May 28th states that Dr. Leopold, of Montevideo, in cultivations of the blood of animals suffering from beri-beri, has discovered a micrococcus which, after culture and injection into the blood of healthy animals, seem to reproduce the two chief forms of the disease, generalized œdema due to dilatation of the heart, and paralysis.

SUCCI THE FASTER.—Succi, the Italian who has made himself prominent both in this country and in Europe, by his fasting, has become insane and has been sent to an asylum in Paris. Two years ago he completed a period of forty days fast in London, and later in New York a fast of forty-five days. He recently attempted another one in London, but broke down before it was accomplished and went to Paris, where he was soon afterwards found to be insane.

BOSTON AND NEW ENGLAND.

THE ALUMNI ASSOCIATION OF THE HARVARD MEDICAL SCHOOL held its second annual meeting and dinner on Tuesday, June 28th. About 260 members sat down to dinner, at which Dr. J. R. Chadwick presided. Speeches were made by the presiding officers, President Eliot of the University, Dr. Wm. Pepper, Provost of the University of Pennsylvania, Prof. Wm. H. Welch, of the Johns Hopkins University, and Dr. James C. White, President of the Massachusetts Medical Society. An able and interesting report was presented by the committee appointed to visit the medical school. The occasion was very successful from every point, and will be more fully reported in a future number.

DRAINAGE INTO THE BACK BAY.—On account of the odors from the Back Bay in Boston at low tide, the Board of Health have taken measures to prevent the houses on the water side of Beacon Street from

discharging their house sewers into the bay, as is at present done.

SMALL-POX IN QUINCY.—A case of small-pox is reported from Quincy, the patient being a girl sixteen years old, who has recently arrived from Sweden. She was promptly isolated, as were also the other inmates of the house. Every one who was suspected of having been exposed to the disease was vaccinated.

A RHODE ISLAND LAW FOR THE PREVENTION OF BLINDNESS.—A law has recently been passed in Rhode Island similar to those in New York and Maine, part of which is as follows: "Should any midwife or nurse, or person acting as nurse, having charge of an infant in this State, notice that one or both eyes of such infant are inflamed or reddened at any time within two weeks after its birth, it shall be the duty of such midwife or nurse, or person acting as nurse, so having charge of such infant, to report the fact in writing within six hours to the health officer, or some qualified practitioner of medicine, of the city or town in which the parents of the infant reside."

Miscellan.

THE THERAPEUTIC VALUE OF SUPPURATION.

VOCHIER having observed improvement in cases of puerperal septicemia, taking place coincidently with the appearance of a focus of suppuration in some part of the body, suggested that in certain cases the establishment of suppuration by the subcutaneous injection of turpentine might be of therapeutic value. Later a case of pneumonia was reported by Lepine, in which this method appeared to have been of great benefit. A case has recently been reported by Gingeot.¹ A man twenty-nine years of age, of alcoholic history, suffering from acute pneumonia, received on the ninth day subcutaneous injections of turpentine into the four limbs. At the time his condition was very critical. The injections were very painful and were followed by extensive edematous patches, and later by suppuration. Within two hours of the first injection the temperature fell two degrees, and this was followed by subsequent improvement. The patient ultimately recovered. A similar case is reported by Raoul in which a patient, apparently moribund on the sixth day, was apparently cured by similar treatment. The explanation of the improvement given by Gingeot is that the production of artificial abscesses, by setting up leucocytosis, brings up reinforcements of phagocytes, as it were, to the assistance of the original defenders.

THE LEGAL REQUIREMENT OF PROFESSIONAL SECRECY.

The Supreme Court of Michigan has confirmed a decision bearing upon the conduct of physician who introduced an unprofessional, unmarried man as his assistant in a case of confinement, the patient naturally supposing that the assistant was a physician.² The

¹ Sem. med., May 18.

² International Medical Magazine, June.

defence of the doctor was that he was sick and very much fatigued, and therefore asked this friend to accompany him. No objection was made by the patient or her husband, and it is agreed that he behaved himself in a perfectly proper and becoming manner. The plaintiff having found out later, not only that he was not a medical man but that he was young and unmarried, brought a suit to recover damages sustained from shame and mortification upon discovering the true character of the defendant. The court held that the plaintiff and her husband had a right to presume that a practising physician would not, upon an occasion of that character, take with him and introduce into the house a young man in no way, either by education or otherwise, connected with the medical profession. This person could hear, if not see, all that was said and done. The fact that at the time the plaintiff consented to his presence supposing him to be a physician does not preclude her from maintaining an action and recovering substantial damages upon afterwards ascertaining his true character.

EFFECTS OF AN OVERDOSE OF CODEINE.

METTENHEIMER reports a case showing the effects of an overdose of codeine.¹ An elderly lady consulted him for a slight catarrhal, non-febrile affection which, however, gave rise to a troublesome, spasmodic form of cough. For this he prescribed 0.03 grammie (about half a grain) of phosphate of codeine, in the form of a pill, to be taken every three hours. The patient, however, swallowed four of these pills, or about a grain and a half of the codeine salt, at once. Shortly afterwards she vomited twice and suffered from abdominal pain. There was, too, suppression of urine, and she felt very ill, being sleepy, but unable to go to sleep. The next day she was still drowsy and had no appetite, but there was no return of the sickness. She was then seen by Dr. Mettenheimer, who found the pupils contracted, the pulse hard and quick, and the respiration accelerated. The cough had entirely disappeared. The contracted state of the pupils, the loss of appetite, and the abdominal pain persisted for several days. No urine was passed until thirty-six hours after the pills were taken. On the third day the drowsiness had passed away. The cough did not return for a week, and when it did it was comparatively slight. This case seems to show that codeine in large doses has a very similar effect to opium, and that it may prove a most efficient remedy for some kinds of cough. As the tongue remained clean it would appear that the vomiting was due to cerebral, rather than to gastric, irritation.

PREPARATION FOR THE STUDY OF MEDICINE.

DR. E. L. HOLMES,² in his doctorate address at the Rush Medical College, takes up the question of the study of Latin and Greek in connection with the study of medicine. The address was intended for those who cannot pursue a collegiate course preparatory to their medical studies, and who consequently may enter a medical school with absolutely no knowledge of either Latin or Greek. So many medical technical terms

are directly taken from one or the other of these languages that a certain amount of knowledge of them is almost necessary. Without having studied either language when he receives his degree of Doctor of Medicine, a student has learned a large number of Greek and Latin words with their English technical meanings. The English language contains so many words from one or the other of these languages that the study of English alone involves the unconscious study of a certain amount of Greek and Latin. The author proposes by the use of very simple grammars to take advantage of this for teaching as much as is required for medical reading. A rudimentary Latin and also a Greek grammar should be constructed for the primary object of teaching English, secondary of teaching Latin and Greek. In connection with these there should be a reader containing extracts from classical prose or poetry, almost every word of which should be a good English word. By learning the meaning of the roots and prefixes and suffixes of those words which are used both in literary English and in medicine, he would be able to appreciate and to find out for himself the derivation of most of the compound words which he meets. After this study of English, Latin and Greek, the student can understand without difficulty the technical terms of every science in every modern language. He has a systematic knowledge of sufficient Latin and Greek to enable him to continue along his readings of classics, if he has the time and taste so to do. The author considers there is great need of such elementary text-books for the use of professional students.

THE CURE OF INFECTIVE DISEASES.

G. AND F. KLEMPERER, in the *Berliner Klinische Wochenschrift*, May 2d, treat of this subject in regard to immunity induced subsequently to infection.³ The value of the immunity depends upon its degree and the rapidity with which it can be established. The most rapid method is by blood serum, as discovered by Behring and Kitasato. In animals the cure of several diseases has already been thus effected.

Every well-marked and acquired immunity is transferable to other animals. The serum treatment is a specific one. The authors have been able to establish immunity in the same rabbit against two separate infections, namely, that of the pneumococcus and that of mouse septæmia. The difficulty of obtaining the serum must constitute an obstacle to hematherapy, and hence a simpler method of establishing immunity is sought for. This consists in the introduction of an attenuated culture into the veins. By this process the protective substances have still to develop, whereas they are already present in the serum. Thus the immunity conferred by the former method occurs only after a few days, but that by the latter in a few hours. Previous failure by the first method has been due to the feebleness of the immunity induced. The degree of the immunity depends on the amount of the culture introduced. The difficulty lies in concentrating the latter. The authors have effected by means of the air-pump down to one-tenth of its former volume, and without the application of too great heat. Against the pneumococcus infection some degree of the immunity is present on the following day. In a

¹ Lancet, June 18th.

² Journal American Medical Association, June 4th.

³ British Medical Journal, May 29th.

very virulent pneumococcus infection in rabbits this method does not succeed, but a less virulent infection can be easily cured. Thus, in addition to the serum treatment, a slowly-developing infection in animals can be cured by an immunity subsequently induced by the introduction of an attenuated culture into the veins.

The advantage of this method consists in the readiness with which the remedy may be prepared, the disadvantage in its uselessness against sudden and rapidly fatal infection. In man the majority of the infective diseases develop slowly, so that they may permit of this method of treatment.

THERAPEUTIC NOTES.

RESORCIN IN GASTRIC ULCERS. — Pope¹ uses resorcin in a dose of five grains three times a day in cases of gastric ulcer. It is both antiseptic, analgesic and haemostatic. Its analgesic property being the most valuable, enabling the stomach to tolerate food. He has also given it with advantage in gastric cancer.

TREATMENT OF POISONING BY COCAINE. — Eloy² gives the following directions for the treatment of acute poisoning by cocaine. The patient is placed in a horizontal position in order to prevent syncope, and his face bathed with cold water. If convulsions come on cold should be applied. If asphyxia is present flagellation, massage and artificial respiration are resorted to, and if the respiration depends upon the tetanic contraction of the respiratory muscles inhalations of chloroform are employed. For the intense pallor it is well to give inhalations of nitrite of amyl. Should these means prove insufficient, it may be well to administer strong coffee or caffeine, or if swallowing is impossible, hypodermic injections of ether. The entire object of the treatment is to moderate the reflex excitability of the nervous system, to sustain the heart, and to re-establish the equilibrium of the circulation.

PERMANGANATE OF POTASSIUM IN THE TREATMENT OF DIPHTHERIA. — Bowman³ reports several cases of diphtheria in which most excellent results were obtained by the use of a solution of permanganate of potash of the strength of three grains to the ounce. Three or four applications an hour were made directly to the membrane with a large camel's-hair brush for eight or twelve hours. After this once every two to six hours is sufficient. In some cases a spray is a better method of application.

METHYL-VIOLET IN MALIGNANT TUMORS. — Nanu has obtained very good results⁴ in ten out of twenty-five cases of malignant tumors by injecting methyl-violet according to the system of Von Moorhof. The diagnoses were confirmed by microscopic examination. On the other hand, Torrie after a trial of this method in several cases comes to the conclusion that it is never of any benefit and may be harmful.

CHLORIDE OF ZINC INJECTIONS IN UNUNITED FRACTURES. — Menard⁵ reports a case in which an oblique compound fracture of both bones of the leg had failed to unite at the end of five months. Remembering Lannelongue's experiment on the formation of

bone in rabbits as the result of injections of chloride of zinc into the periosteum, Menard then injected 1.25 g. of a one in ten solution of chloride of zinc into the outer and posterior surfaces of the tibia and into the space between the fragments. The injection caused a good deal of pain, but after immobilization of the limb for a fortnight the swelling of the soft parts had completely disappeared, and the seat of the fracture was surrounded with firm callus. A month after the injection consolidation was complete and the patient was able to walk.

A NEW TREPHINE. — Tauber⁶ describes a new form of trephine, by means of which a disc of bone in the shape of a truncated cone can be removed from the skull. The advantage claimed for this shaped button is that on replacing it the level of the skull is preserved, that is, the button does not tend to fall in, also its margin is in close contact with the hole from which it was removed. The author believes that with this instrument, a surgeon may safely remove a series of discs and thus expose a large extent of the surface of the brain. The openings which are not united may be immediately filled up with every confidence of complete closure by speedy osseous reunion.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 18, 1892, TO JUNE 24, 1892.

Leave of absence for one month to take effect on or about July 1, 1892, is granted CAPTAIN WILLIAM BANISTER, assistant surgeon, U. S. A.

MAJOR JOHN S. BILLINGS, surgeon, U. S. A., granted leave of absence for one month and fourteen days, with permission to go beyond sea.

RECENT DEATHS.

RICHARD SPRAGUE, M.D., M.M.S.S., died at the Massachusetts General Hospital, June 28th, aged thirty-two years. On Friday last he was thrown from an open electric car while attempting to get on, and received a fracture of the base of the skull. Dr. Sprague graduated from Harvard College in the class of 1881, and from the Medical School in 1887. He was surgical house-officer in the Massachusetts General Hospital, 1887-88.

SIR WILLIAM ATKINSON, professor of pathology in the Army Medical School at Wetley, died in London, June 27. He was the author of several works, and was prominent in the introduction of the clinical thermometer.
